15,206. W. Hood. Improvements in evaporating and distilling apparatus. August 9.

15,249. C. J. Bagley, L. Roberts, and the Moor Steel and Iron Co., Ltd. Improved arrangements and apparatus for the utilisation of the waste heat of furnaces of the open-hearth type. August 10.

**COMPLETE SPECIFICATIONS ACCEPTED.\***

1893.

15,209. K. E. Libert and J. A. Wentzel. Improvements in machines for compressing gases and the like. August 15.

23,595. J. Y. Johnson.—From C. Gouelle. Improvements in and connected with oil and other like presses. July 25.

1894.

9958. T. Craney. Improvements in evaporating apparatus. August 8.

9959. T. Craney. Improvements in evaporating apparatus. August 8.

**Monthly Patent List.**

\* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

**I.—GENERAL PLANT, APPARATUS, AND  
MACHINERY.**

**APPLICATIONS.**

13,857. G. Fletcher. Improvements in multiple-effect and other vessels for evaporating liquids. July 18.

14,014. E. J. Barbier. Improvements in or relating to condensing towers. July 20.

14,184. F. Kleemann. Improvements in the process of and apparatus for heating and concentrating liquids. Complete Specification. July 24.

14,192. W. P. Thompson. Improvements in separating mixed gases or liquids of different specific gravities and in apparatus therefor. July 24.

14,431. W. W. Pilkington. Improvements in gas generators or producers and furnaces and appliances for smelting glass, for melting and heating metals, alkalis, and other substances, and for heating steam-generators and for like purposes. July 27.

14,553. N. Teissier and G. L. A. Negre. Improvements in the manufacture of retorts of refractory material. July 28.

14,554. A. Lawrence, and Bennett, Sons, and Shears, Limited. Improvements in apparatus for heating and cooling liquids. July 28.

14,766. H. L. Doulton and L. E. Sanceau. Improvements in condensers used for the condensation of acid fumes. August 1.

14,767. H. L. Doulton and L. E. Sanceau. Improvements in the filling of towers used in the purification of acid and for such like purposes. August 1.

15,150. B. Dawson. Improvements in gas producers. August 8.

15,200. G. Bell and G. W. Bell. Improvements in the utilisation of the waste products of gas and the like engines. August 9.

**II.—FUEL, GAS, AND LIGHT.**

**APPLICATIONS.**

13,758. F. Mayer. Improvements in apparatus for manufacturing gas. Complete Specification. July 17.

13,841. A. Scott and P. McLean. Improvements in and relating to fire-clay and metal retorts for the manufacture of gas from coal, oil, tar, or other material. July 18.

14,196. A. D. Shrewsbury. Improvements in coke ovens. July 24.

14,761. C. T. Cayley. An improved furnace for the manufacture of oxygen. August 1.

14,772. J. Lyle. Improvements in block agglomerated and briquette fuels. August 1.

14,885. W. A. Fourness. Improvements in apparatus for generating and carburetting water-gas. August 3.

14,995. P. Dvorkovitz. Improvements in apparatus for obtaining gas and by-products from liquid hydrocarbons. August 4.

15,066. J. David. Manufacture of variegated candles and apparatus therefor. August 7.

15,290. S. B. Boulton, T. B. Haywood, H. E. Boulton, and H. Fergusson. See Class III.

15,323. J. Schrader. An improved process for purifying petroleum. August 11.

**COMPLETE SPECIFICATIONS ACCEPTED.**

1893.

16,220. R. Nobel. Improvements in the method of burning and controlling the combustion of solid fuel, and in hearths or furnaces therefor. August 1.

17,811. E. Manfield. Improvements relating to the manufacture of gas. August 1.

1894.

12,761. W. P. Thompson.—From E. Scott. A new or improved combustible material and process of manufacturing the same. August 8.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

#### APPLICATIONS.

13,847. J. Imray.—From La Société Anonyme des Matières Colorantes et Produits Chimiques de St. Denis and A. Haller, France. Process for purifying benzene by removing the thiophene which it contains. July 18.

15,290. S. B. Boulton, T. B. Haywood, H. E. Boulton, and H. Fergusson. Process for the purification or washing of coal-tar, naphtha, naphthalene, mineral burning oils, and the like. August 10.

### IV.—COLOURING MATTERS AND DYES.

#### APPLICATIONS.

13,695. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning, Germany. Manufacture of nitro-amidoanthraquinone. July 16.

14,056. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning, Germany. Manufacture of azo-colouring matters, derivatives of the 1,4- $\alpha$ -naphtholsulphonic acid from corresponding azo-colouring matters of naphthionic acid. July 21.

14,134. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning, Germany. Manufacture of the 1,4,6 and 1,4,7- $\alpha$ -naphtholdisulphonic acids. July 23.

14,135. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning, Germany. Manufacture of  $\alpha$ -naphtholmonosulphonic acid 1,4 from  $\alpha$ -naphtholcarbonate. July 23.

14,137. J. C. L. Durand, D. E. Huguenin, and A. J. J. d'Andiran. Manufacture of blue galloeyamin colouring matters. July 23.

14,461. G. W. Johnson.—From Kalle and Co. Improvements in and connected with the manufacture and production of chemical products suitable for use as or for dyes. July 27.

14,600. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning, Germany. Production of methylglyoxalidine CHN. July 30.

14,601. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning, Germany. A process for the production of fast azo-colours upon the fibre. July 30.

14,745. J. C. L. Durand, D. E. Huguenin, and A. J. J. d'Andiran. Manufacture of new bases and colouring matters derived therefrom. August 1.

14,983. J. C. L. Durand, D. E. Huguenin, and A. J. J. d'Andiran. Manufacture of new colouring matters derived from muscarine. Filed August 4. Date applied for, January 16, 1894, being date of application in France.

15,064. J. C. L. Durand, D. E. Huguenin, and A. J. J. d'Andiran. Manufacture of new condensation products and colouring matters for dyeing and printing. Complete Specification. August 7.

15,067. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning, Germany. Manufacture of  $\alpha$ -naphthylamine sulphonic acid. August 7.

15,205. T. R. Shillito.—From J. R. Geigy and Co., Switzerland. Production of green and blue dyes or colouring matters. August 9.

15,305. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik, Germany. The production of yellow colour in or upon silk by the aid of diazo-compounds or nitrosamines. August 10.

### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

14,089. H. Goebel. See Class XI.

17,542. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Improvements in the production of oxyanthraquinone. July 25.

17,543. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of a novel colouring matter. July 25.

17,544. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Improvements in dyeing wool with sulphonic acids of anthraquinone colouring matters. July 25.

18,317. B. Willecox.—From The Badische Anilin und Soda Fabrik. The manufacture and production of new disazo dyes. July 25.

18,374. B. Willecox.—From The Badische Anilin und Soda Fabrik. The manufacture and production of new dyes of the phenanthrene series. August 1.

18,925. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik. Improvements in the manufacture of alphabetadimethyleurhodines. August 8.

1894.

12,214. O. Imray.—From The Society of Chemical Industry, Basle. Manufacture of polyoxythionine colouring matters dyeing on mordants. August 1.

### V.—TEXTILES, COTTON, WOOL, SILK, Etc.

#### APPLICATIONS.

13,672. E. Richard-Lagerie. Improvements in apparatus for extracting suint from wool and other substances. Complete Specification. July 16.

13,677. E. Richard-Lagerie. See Class XII.

14,036. T. Seddon and C. Long. An improved preparation for use in the manufacture of wool, woollen textiles, and the like. July 21.

14,299. W. Pickstone and A. Greenhalgh. An improved thick, soft, absorbent cloth. Complete Specification. July 25.

14,363. H. S. Close and W. O. Roff. Improvements in or in connection with retting flax, jute, or other similar fibrous materials, and eliminating the gummy or other matter therefrom, and utilising the resultant residuals. July 26.

14,788. J. S. Lenton and R. B. Caldieott. Improvements in the manufacture of textile fabrics, and in apparatus therefor. August 2.

14,903. T. Burrows. Improved means or apparatus for de-gumming or otherwise treating the fibres extracted from the plants, stems, or straws of flax, hemp, ramie, or the like. August 3.

15,140. A. Gruschwitz. An improved process for retting, cleansing, and deoxidising textile fibres. Complete Specification. August 8.

### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

19,095. H. Jacob. New or improved process and machinery for imparting a silky appearance to cotton and other yarns. August 15.

19,177. T. Pickles. Improvement in the treatment of cotton or linen warps or warp yarns for weaving purposes. August 15.

1894.

11,754. W. E. Heys.—From G. Mahard. Improvements in the process of and apparatus for scouring and de-greasing wool. July 25.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

### APPLICATIONS.

14,092. F. Barraclough. Improvements in apparatus for dyeing and otherwise treating yarns. July 23.

14,136. W. Mather. Improvements in apparatus for printing on paper or fabrics. July 23.

14,193. E. B. Manby. An improved thickening and fixing medium for colours in calico printing and dyeing and padding, also applicable to finishing purposes. July 24.

14,223. H. H. Lake.—From M. E. Waldstein, A. H. Peter, and E. Spott. United States. Improvements relating to the dyeing of fibre. Complete Specification. July 24.

14,275. J. Rhodes, jun. Improvements in apparatus for scouring and dyeing slubbing or slivers of fibrous material. July 25.

14,334. M. Cockroft and S. J. Pegg. Improvements in or appertaining to dyeing machines. July 26.

14,374. B. Walsh. Improvements in kiers or vessels for bleaching textile fabrics. July 26.

14,565. J. Booth and L. Thornley. Improvements in apparatus for dyeing, veneering, and washing hat bodies. July 30.

15,017. T. Illingworth. Improvements in apparatus for steaming textile fabrics. August 7.

15,305. J. Y. Johnson.—From The Badische Anilin and Soda Fabrik, Germany. See Class IV.

### COMPLETE SPECIFICATIONS ACCEPTED.

1894.

13,210. H. W. Sanderson. Improvements in and relating to the printing of textile fabrics. August 15.

## VII.—ACIDS, ALKALIS, AND SALTS.

### APPLICATIONS.

13,697. L. Lederer. A new process for manufacturing sodium persulphate, and for disinfection and preservation by means or persulphates. July 16.

14,054. W. Schulte and F. A. Sapp. Improvements in the manufacture of cyanide of potassium and in furnaces for producing cyanide of ammonia. July 21.

14,154. G. S. Albright and J. J. Hood. Improvements in the manufacture of sulphocyanides. July 23.

14,215. J. W. Scott. Improved process of rectifying sulphuric acid and means or apparatus therefor. July 24.

14,228. E. W. Enequist. Improvements in the process of manufacturing carbonic acid and in the production of by-products, such as sodium sulphate and magnesium sulphate. Complete Specification. July 24.

14,503. G. T. Beilby. A process for the recovery of hydro-cyanic acid from mixtures. July 28.

14,520. W. B. Maxfield.—From W. Dieterle and L. Rohmann, Germany. Producing nitric acid free of halogen and nitroso by blowing air into the mixture of nitric and sulphuric acid. Complete Specification. July 28.

14,856. A. Buisine. Improvements in extracting sulphur from raw pyrites or from its residuum, and recovering the by-products. August 2.

14,894. C. P. Peak, J. Peak, H. Peak, and A. G. Haddock. Improvements in the manufacture of soda crystals or washing soda. August 3.

14,905. E. Dresel and J. Lenhoff. Process for the manufacture of neutral sodium carbonate, neutral sodium sulphite, and sodium borates from sodium chloride. Complete Specification. August 3.

14,954. J. S. MacArthur. Improvements in apparatus for obtaining cyanides. August 4.

14,985. W. L. Wise.—From Solvay and Co., Belgium. Improvements in or relating to the manufacture or treatment of bicarbonate of soda. August 4.

14,986. W. L. Wise.—From E. Solvay, Belgium. Improvements in or relating to the manufacture of bleaching powder and other hypochlorites. August 4.

14,987. W. L. Wise. From Solvay and Co., Belgium. Improvements in or relating to the separation of caustic alkalis from the liquors obtained by the electrolysis of alkaline salts. August 4.

### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

16,760. A. Gordon and J. Gordon. Improved process and apparatus for the manufacture of cyanides. August 8.

18,831. W. Wolters. Improvements in the process of concentrating sulphuric acid in lead vessels. July 25.

1894.

12,881. H. H. Lake.—From L. Sternberg. Improvements in apparatus for obtaining anamonia and ammonia-salts from nitrogenous organic matters. August 8.

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

### APPLICATIONS.

13,797. J. Slaytor. Improvements in or relating to moulds for casting balls of glass or the like material. July 17.

14,006. G. Bamberg. Improvements in apparatus particularly adapted for the direct manufacture of alkaline silicates and glass, but also applicable to other purposes. July 20.

14,018. J. F. Russell. An improved imitation stained glass. July 21.

14,875. J. C. Bailey. Improved methods of preparing "transfers" for use in decorating pottery ware. August 3.

14,938. W. Grüne, sen. Improvements relating to the ornamentation of porcelain, glass, and the like. Complete Specification. August 3.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

13,888. C. Copeland. Improved seggars for use in enamelling, hardening on lustre, and majolica kilns. August 8.

1894.

13,017. P. Shelly. Process of decorating pottery, glass, or similar goods. August 15.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

## APPLICATIONS.

13,926. J. B. Filloh, E. Hebrard, and L. Loustalot. Improvements relating to the treatment of wood for preserving and other purposes. July 19.

14,081. F. A. P. Stolte. Improvements in fireproof ceilings and floors. July 21.

14,145. J. E. Golding. Improvements in the construction of floors and ceilings. July 23.

14,210. W. W. Hughes. Improvements in or relating to drying cement and other materials. July 24.

14,308. A. E. Carey. Construction in combinations of plastic building materials and metal. July 25.

14,342. F. H. Brooke. Improvements in bricks for paving and the like. July 26.

14,494. W. Thomlinson. Improvements in the treatment of slag for the manufacture of cement. July 28.

14,599. E. Groebe. Improvements in the preservation of wood. Complete Specification. July 30.

14,699. W. Whittaker. Improvements in fireproof and waterproof ceilings and flues. July 31.

14,846. L. Mack. Improvements relating to the manufacture of cement from schist and bituminous marl. Complete Specification. August 2.

14,934. A. Muirhead and G. Hackford. Improvements relating to the manufacture of artificial stone and the like. August 3.

15,156. J. Roy. Improvements in or relating to the construction of fireproof floors or the like. August 8.

15,231. C. Howard. Improved method of vulcanising and drying wood. Complete Specification. August 9.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

16,470. T. C. Kitto. The asphalt and lead cement paving. August 15.

1894.

8,475. J. L. Kerr. Artificial plaster of Paris, made from the lime residue resulting from the reduction of sulphate of ammonia. July 25.

## X.—METALLURGY, MINING, Etc.

## APPLICATIONS.

13,683. J. P. V. Ploeg. Improvements in or relating to the chemical extraction of copper, silver, gold, and other metals accompanying them, from ores and materials containing them, with or without recovery of non-metals combined with them, and recovery of the chemicals used in the process. July 16.

13,851. W. T. Gibbs. Process for the treatment of nickeliferous iron ores. July 18.

13,868. H. C. Barker and R. Pearson. Improvements in the method of extracting gold from gold ores, quartz, and auriferous alluvials, and collecting and retaining float gold. July 18.

13,920. J. A. Mays. Process of and apparatus for comminuting molten substances. July 19.

14,155. J. J. Hood. Improvements in extracting metals. July 23.

14,306. Davies Bros. and Co., Lim., E. A. Davies, and S. T. Thomas. A novel or improved method of preparing metal sheets for the purpose of galvanising them or otherwise coating them with metal or metallic alloy, and apparatus for use therein. July 25.

14,327. A. F. B. Gomess. Improvements in the manufacture of aluminium and aluminium alloys, and the electro-deposition of the same. July 25.

14,481. A. Mieg. Improvements relating to the manufacture of tungsten articles and to apparatus therefor. July 27.

14,496. C. J. Sandahl. Improvements in the manufacture of iron. July 28.

14,502. J. W. Dixon and W. Skinner. An improved metallic alloy. Complete Specification. July 28.

14,547. E. L. Mayer. Improvement in the treatment of gold and silver ores, and of auriferous and argentiferous products derived from such ores. July 28.

14,568. J. H. Roberts and J. Cooper, jun. Improvements in the method of and apparatus for hardening and tempering steel wire. July 30.

14,649. E. Tarin. Improved process for the manufacture of aluminium. July 31.

14,706. W. W. Fyfe. Improvements in means for treating crushed complex or refractory ores in process of amalgamation. July 31.

15,225. S. Hufty and J. K. Caldwell. Certain improvements in processes of converting cast iron into malleable iron or steel. August 9.

15,339. J. Maetear. Improvements in the obtainment of precious metals. August 11.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

9045. H. W. G. Fairfax. Improved method of and apparatus for hardening and moulding or shaping steel plates and other articles. August 8.

15,507. S. O. Cowper-Coles. Improved method of and apparatus for pickling metal articles. August 1.

19,235. R. Brown. Improvements in apparatus for treating ores of precious metals with chemical agents. August 15.

19,375. W. F. Berner. Improvements in the manufacture or production of metals from their ores, and in plant or apparatus therefor. August 8.

1894.

9536. A. G. Fell. Improvements in methods of treating lead ores. July 25.

10,439. A. H. Moore and G. Whitlock. Improvements in and relating to the manufacture of combined iron and steel ingots. July 25.

11,797. E. D. Kendall. Improvement in the method or process of treating gold and silver ores, and a composition of matter for the same purpose. July 25.

## XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

### APPLICATIONS.

13,756. C. N. Waite. Improvements in or connected with electrolytic cells, and diaphragms therefor. Complete Specification. July 17.

13,795. W. P. Thompson.—From C. M. Barber, United States. Improvements in the process of electro-plating, and apparatus therefor. July 17.

13,836. C. J. Yarnold. Improvements in apparatus employed in the evolution and collection of hydrogen and oxygen gases by electrolysis. July 18.

14,327. A. F. B. Gomess. See Class X.

14,536. C. F. Parkinson and W. Gatwood. Improvements in apparatus for heating and welding by electricity. July 28.

14,634. C. E. Buell. Galvanic battery. Complete Specification. July 31.

14,642. V. I. Feeny.—From F. Duhero and P. Mohrdieck, United States. Electrical battery. Complete Specification. July 31.

14,689. F. Tallack, F. W. Tallack, and L. Hendle. Improvements in secondary batteries. July 31.

14,769. R. W. Hill. Improvements in or relating to apparatus for the production of sulphuric acid by the aid of an electric current. August 1.

14,770. R. W. Hill. New or improved automatic apparatus for use in and in connection with the production of sulphuric and other acids. August 1.

14,858. J. Y. Johnson.—From E. Javaux, C. F. Gallois, and F. Dupont, France. Improvements in the purification of saccharine juices by electrolysis. August 2.

15,276. M. Kiliani, W. Rathenau, C. Suter, and the Elektrochemische Werke Gesellschaft mit Beschränkter Haftung. Improvements in or connected with diaphragms for electrolytic purposes. Complete Specification. August 10.

### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

14,089. H. Goebel. Improvements relating to the manufacture of Paris blue or Berlin blue, and of Berlin green, by electrolysis. July 25.

14,130. J. Hargreaves and T. Bird. Improvements in the electrolysis of iodides, bromides, nitrates, and other salts. July 25.

14,131. J. Hargreaves and T. Bird. Improvements in the electrolysis of chlorides, iodides, bromides, nitrates, and other salts, and in apparatus therefor. July 25.

15,264. P. Marino. Improvements in plating metallic surfaces and also prepared surfaces of non-conducting substances by electro-chemical deposition. August 15.

17,866. L. W. Schöffer and G. E. W. Schöffer. An improved manufacture of electric accumulators. July 25.

1894.

11,664. T. Drake. An improved method, means, or process of producing caustic soda and chlorine gas, or caustic potash and chlorine gas, by the electrolysis of common salt in solution, or chloride of potassium in solution. August 1.

## XII.—FATS, OILS, AND SOAP MANUFACTURE.

### APPLICATIONS.

13,672. F. Richard-Lagerie. Improvements in apparatus for extracting suet from wool and other substances. Complete Specification. July 16.

13,677. F. Richard-Lagerie. Improvements in machines for extracting potash from the grease contained in sheep's wool. Complete Specification. July 16.

13,853. A. Gross, S. Seidenberger, and S. Leitersdorfer. Improvements in or relating to cleansing or washing agents. Complete Specification. July 18.

14,821. W. O. Robbins. A new or improved apparatus for treating substances containing fats and oils. Complete Specification. August 2.

14,946. S. Rosenblum and F. L. Battet. Improvements in soap, oils, greases, petroleum, mineral, vegetable, fish, and animal fats and oils. August 4.

15,086. B. J. B. Mills.—From J. H. Campbell and C. H. Campbell, United States. Improvements in the process of refining and improving butter, lard, oils, and other fatty matters. August 7.

15,228. J. O. Klimsch. Improvements relating to the manufacture of soaps. Complete Specification. August 9.

### COMPLETE SPECIFICATIONS ACCEPTED.

1894.

11,885. H. Perl. Improvements in and connected with soap pieces. July 25.

12,367. J. van Ruymbeke and W. F. Jobbins. Process of and apparatus for obtaining glycerine and other products from soapmakers' spent lyes. August 1.

13,104. F. Heilbron. Improvements in or applicable to soap in tablets, cakes, or bars. August 15.

## XIII.—PAINTS, PIGMENTS, VARNISHES, RESINS, INDIA-RUBBER, ETC

### APPLICATIONS.

13,873. W. M. Williams. Improvements in copying ink. July 19.

14,375. I. Frankenburg. Improvements in stoves for vulcanising and deodorising india-rubber waterproof garments. July 26.

14,407. D. Marcus. Improvements in varnishes. July 27.

14,598. R. J. Mostyn and F. Strickland. Improvements relating to chalk for manual use. July 30.

14,758. G. C. Dymond. From L. Auerbach and Co., Germany. Improvements in the manufacture of water-colour paints. August 1.

15,251. W. B. Priest. Improvements in the manufacture of white lead. August 10.

15,266. E. van den Hoff. An improved process for the manufacture of white lead. August 10.

15,317. W. B. Priest. Improvements in the manufacture of lead pigments. August 10.

### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

11,972. A. Macdonald. An improvement in the manufacture of sulphate of lead pigment. July 25.

17,477. J. Anderson, jun. Improvements in treating rubber waste for the separation of foreign substances therefrom: also applicable to other purposes. August 8.

17,581. J. E. Bedford, and C. S. Bedford. Improvements in the manufacture of a drying medium for paints and of oil varnish. July 25.

1894.

7465. A. Angell. Improvements in the manufacture of oil paints and compositions from carbonised or calcined ironstone or iron ore. July 25.

13,004. J. Clasen. A new or improved binding medium for size colours and method of manufacturing the same. August 8.

#### XIV.—TANNING, LEATHER, GLUE, AND SIZE.

##### APPLICATIONS.

14,012. J. Y. Johnson.—From F. Kornacher and Diesel, Weise, and Co., Germany. Improvements in tanning leather. July .

14,162. J. Hibbert and E. Roberts. Improvements in apparatus for boiling starch and size. July 25.

14,165. J. Hibbert and E. Roberts. Improvements in apparatus for boiling starch and size. July 23.

14,697. F. Hartmann. A new or improved process for the production from skins or hides of a substitute for whalebone, horn, or the like. Complete Specification. July 31.

14,820. Brooke, Simpson, and Spiller, Limited, and R. J. Friswell. A new substance suitable for tanning, dyeing, and other purposes, and the processes for its production. August 2.

18,949. J. T. Hardy. An improved method or process of fastening the colours upon and within coloured leathers. August 8.

##### COMPLETE SPECIFICATION ACCEPTED.

1894.

13,414. A. Hermann. An improved process for colouring tanned hides by means of smoke. August 15.

#### XV.—AGRICULTURE AND MANURES, ETC.

##### APPLICATION.

14,195. W. Davidson. Improvements in apparatus for sowing artificial manure. July 24.

#### XVI.—SUGARS, STARCHES, GUMS, ETC.

##### APPLICATIONS.

14,606. R. H. Hunstock. An improved method of and apparatus for making syrups. July 30.

14,842. H. H. Leigh.—From G. Cambray, France. Improved process for the treatment of the juice of sugar-canes. Complete Specification. August 2.

14,858. J. Y. Johnson.—From E. Javaux, C. F. Gallois, and F. Dupont, France. See Class XI.

15,031. H. Walker. See Class XXI.

17,632. C. Steffen. Process for purifying and decolourising saccharine juices and sugar solutions generally. August 15.

##### COMPLETE SPECIFICATION ACCEPTED.

1894.

9054. H. H. Lake.—From A. L. Tédesco. Improvements relating to the manufacture of sugar, syrups, alcohol, and beer. August 8.

#### XVII.—BREWING, WINES, SPIRITS, ETC.

##### APPLICATIONS.

14,011. E. Weymar. Improvements in the method of and means for obtaining infusions of hops. July 20.

14,741. H. A. Leverett and A. Martin. A new method for maturing wines, spirits, oils, tobacco, or any other vegetable production. August 1.

14,918. L. Prochazka. An improved process and apparatus for rendering soluble the proteine in mash and wort. August 3.

14,919. L. Prochazka. An improved process and appliances for mashing and brewing in breweries. August 3.

17,912. A. W. Billings. Improvements in apparatus for the manufacture of beer. August 1.

##### COMPLETE SPECIFICATION ACCEPTED.

1893.

9054. H. H. Lake.—From A. L. Tédesco. See Class XVI.

#### XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

##### APPLICATIONS.

##### A.—Chemistry of Foods.

13,667. C. Greenhalgh. Improvements in the manufacture of candied lemon, orange, or citron peel. July 16.

13,712. R. G. Nash. Improvements in or relating to the sterilisation and preservation of milk. July 16.

14,015. H. J. N. Berge. Treatment of potable waters by alkalisation and subsequent neutralisation with a view to their sterilisation and purification. July 20.

14,179. G. Weddell. A new and improved baking powder. July 24.

14,332. E. Howarth. A new and improved process or means of preserving vegetables, cereals, and farinaceous foods in a cooked or partially cooked state or condition. July 26.

14,433. P. A. Noll. Process for manufacturing a compote from jelly. July 27.

14,675. B. F. McIntyre. Improvements in process of and apparatus for condensing and preserving milk. Complete Specification. July 31.

15,166. J. Swan. An improved method of treating eggs. August 8.

15,168. B. Biggs. Improvements in preserving extracts from lemons and the like. August 8.

*B.—Sanitary Chemistry.*

13,777. W. J. Pughley. Improved means of purifying the effluent waste waters of tin-plate works and the like. Complete Specification. July 17.

14,760. H. L. Sulman. Improvements in the treatment of sewage. August 1.

14,927. C. Jones. Improvements in the method or process of treating and utilising town refuse. August 3.

15,265. S. Brown. The purification of sewage or sewage matter, or the effluent from sewage or sewage matter. August 10.

*C.—Disinfectants.*

14,067. E. J. B. P. Jodelay and M. J. E. Laurans. Improvements in apparatus for mixing liquids designed for disinfecting and other purposes. July 21.

15,361. J. Y. Johnson.—From F. von Heyden, Germany. Improvements in the manufacture of antiseptic agents. August 11.

COMPLETE SPECIFICATIONS ACCEPTED.

*A.—Chemistry of Foods.*

1893.

15,762. J. Fordred. Improvements in the treatment of eggs. August 1.

17,732. E. Maris. Improvements in and in apparatus for the treatment of alimentary substances. July 25.

1894.

13,031. H. L. C. Paulsen. Improvements in and relating to the preservation of food. August 15.

*B.—Sanitary Chemistry.*

1893.

18,416. L. Archbutt and R. M. Decey. Improvements in the purification of sewage. August 8.

19,069. H. Lockwood. Improvements in the construction of tanks for the subsidence of the precipitate or sludge resulting from the chemical treatment of sewage or other foul waters. August 15.

1894.

12,903. Count Heinrich von Puckler. Improved means for purifying and disinfecting air, and for consuming deleterious gases and vapours. August 8.

*C.—Disinfectants.*

1893.

10,465. P. Hakansson. Improved antiseptic and preserving agents. August 1.

XIX.—PAPER, PASTEBOARD, Etc.

APPLICATIONS.

14,384. H. O. Band. Improvements in the manufacture of parchment. Complete Specification. July 26.

14,923. A. Gray. Improvements in the manufacture of articles impregnated with celluloid and the like, applicable also in the recovery of spirit and other solvents from celluloid and like solutions, and from varnishes. August 3.

COMPLETE SPECIFICATIONS ACCEPTED.

1893.

15,332. W. H. Coldwell. Improvements in apparatus used in the manufacture of paper-pulp. August 15.

1894.

14,440. E. Partington. Improvements in the treatment of "sulphite pulp" used in the manufacture of paper and the like from wood. August 15.

13,139. S. Hahn. A process of manufacture of films imitating mother-of-pearl. August 15.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

APPLICATIONS.

14,138. L. R. Seammell. An improved process for the extraction and estimation of eucalyptol. Complete Specification. July 23.

14,249. A. M. A. F. E. van Dyck. Improvements in or relating to camphor. July 24.

15,171. P. P. Monnet. A process for the manufacture of a scent essence. Complete Specification. August 8.

15,348. H. E. Newton.—From The Farnefabriken vormals F. Bayer & Co., Germany. The manufacture or production of chemical compounds. August 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1893.

17,539. J. C. W. F. Tiemann. Production of substances suitable for manufacture of perfumery and aromatics. August 8.

17,703. A. Baur. Production of artificial musk from hydrogenated aromatic hydrocarbons. July 25.

17,781. A. Baur. A process for the production of artificial musk. July 25.

19,628. A. Muller and H. Dubois. An improved method of producing carbon tetrachloride. August 15.

20,245. L. O. Helmers. Improvements in the process of obtaining aqueous solutions of phenols and other substances. August 8.

1894.

12,796. F. W. Fletcher. Improvements in cinchona preparations. August 8.

XXI.—PHOTOGRAPHIC PROCESSES AND MATERIALS.

APPLICATIONS.

14,161. J. Joly. Improvements in or relating to photographing in colours. Complete Specification. July 23.

15,031. H. Walker. A solution for use in mounting photographic prints. August 7.

## XIII—EXPLOSIVES, MATCHES, ETC.

## APPLICATIONS.

No. 1. J. J. J. J. J. Improvements in or relating to  
the use of blast charges in mines. Complete Specification.  
July 16.

14,064. T. Malson, W. A. Malson, S. R. Malson, and F. Smith. Improved fuse head for use in blasting. July 21.

11,665. W. A. Malson, T. Malson, S. R. Malson, and E. Smith. Improved electric fuse head for use in blasting. July 21.

14,068. R. Odeyn. A new or improved combustible composition. Complete Specification. July 21.

15,307. L. G. Searson. Improvements in the manufacture of gunpowder. August 11.

PATENT UNCLASSIFIABLE.

### APPLICATION.

13,838. G. Hagemann. Improvements in the manufacture of artificial cork. Complete Specification. July 18.

# THE JOURNAL

OF THE

# Society of Chemical Industry:

## A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 9.—Vol. XIII.]

SEPTEMBER 29, 1894.

[Non-Members 30 - per annum; Members  
21 - per Set of extra or back numbers;  
Single Copies (Members only) 2 6.]

## The Society of Chemical Industry.

### Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S. ....	1881—1882.
Sir Frederick Abel, Bart., D.C.L., F.R.S. ....	1882—1883.
Walter Weldon, F.R.S. ....	1883—1884.
W. H. Perkin, Ph.D., F.R.S. ....	1884—1885.
E. K. Muspratt ....	1885—1886.
David Howard ....	1886—1887.
Prof. James Dewar, F.R.S. ....	1887—1888.
Ludwig Mond, F.R.S. ....	1888—1889.
Sir Lowthian Bell, Bart., F.R.S. ....	1889—1890.
E. Rider Cook ....	1890—1891.
Prof. J. Emerson Reynolds, M.D., D.Sc., F.R.S. ....	1891—1892.
Sir John Evans, K.C.B., F.R.S. ....	1892—1893.
E. C. C. Stanford ....	1893—1894.

## COUNCIL FOR YEAR ENDING JULY, 1895

**President:** Prof. T. E. Thorpe, F.R.S.

### Vice-Presidents:

Sir F. A. Abel, Bart., F.R.S.	Sir John Evans, K.C.B., F.R.S.
Horace T. Brown, F.R.S.	E. K. Muspratt.
H. Brunner.	Dr. W. H. Perkin, F.R.S.
John Calderwood.	John Spiller.
Chas. Dreyfus.	E. C. C. Stanford.
Dr. A. Dupré, F.R.S.	Prof. W. A. Fildes, F.R.S.

### Ordinary Members of Council:

R. Forbes Carpenter.	Prof. A. K. Huntington.
Frank Clowes, D.Sc.	Manning Prentice.
Thos. Fairley.	G. N. Stoker.
C. A. Fawcitt.	Wm. Thorp, B.Sc.
Prof. G. G. Henderson, D.Sc.	T. Tyrer.
David Howard.	Frank Wilson.

With the Chairmen and Secretaries of Sections.

### Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

### Honorary Foreign Secretary:

Ludwig Mond, F.R.S.

### General Secretary:

Charles G. Cresswell.

Offices: Palace Chambers, 9, Bridge Street, Westminster, S.W.

### Editor:

Watson Smith, 34, Upper Park Road, Haverstock Hall, N.W.

### Assisted by the following Staff of Abstractors:

H. Aner..... VII.	F. Machenhauer III., IV., VI.
D. Bendix..... III.	W. G. McMillan { X., XI., XIV., XXII.
E. Bentz..... IV., V., VI.	W. Macnab..... XXII.
Jos. Bernays, M.I.C.E. I.	N. H. J. Miller, Ph.D. XV.
Bertram Blount. { IX., XI., XII., XIII.	Herbert Morris. { III., IV., VII., XII.
Arthur G. Bloxam XIV., XV.	H. S. Pattinson, Ph.D. VII., X.

## THE JOURNAL.

### Publication Committee:

The President.

A. H. Allen.	Prof. A. K. Huntington.
L. Archbutt.	F. Hurter, Ph.D.
G. H. Bailey, D.Sc., Ph.D.	C. Clarke Hutchinson.
Joseph Bernays, M.I.C.E.	Wm. Kellner, Ph.D.
H. Brunner.	Ludwig Mond, F.R.S.
E. Rider Cook.	B. E. R. Newlands.
W. Y. Dent.	John Pattinson.
Chas. Dreyfus, Ph.D.	W. H. Perkin, Ph.D., F.R.S.
Sir John Evans, K.C.B., F.R.S.	H. R. Procter.
Percy Gilchrist, F.R.S.	Boverton Redwood.
John Heron.	John Spiller.
D. B. Hewitt, M.D.	Wm. Thorp.
David Howard.	Thomas Tyrer.
Prof. J. J. Hummel.	

## NOTICES.

Notice is hereby given that, in accordance with the alterations in Rule 27 sanctioned at the Annual General Meeting in Edinburgh, all new members elected after January 1st next, and also those elected after the date of this notice who do not pay subscription for 1894, will be required to pay an entrance fee of one guinea. In accordance with the same rule the Life Composition Fee will be 20*l.*, instead of 15*l.*, as heretofore after the 1st January next.

## BANKERS' ORDERS.

For the convenience of Members, the Treasurer has arranged with the Bankers of the Society that they shall collect subscriptions from Bankers in town and country; and Members, who have not already done so, are invited to fill up and sign the Banker's Order enclosed with the December number of the Journal, which should then be sent to the Honorary Treasurer, Mr. E. Rider Cook, East London Soap Works, Bow, E.

Authors of communications read before the Society, or any of its Local Sections, are requested to take notice that under Rule 41 of the bye-laws, the Society has the right of priority of publication for three months of all such papers. Infringement of this bye-law renders papers liable to be rejected by the Publication Committee, or ordered to be abstracted for the Journal, in which case no reprints can be furnished to the author.

Notice is hereby given, for the information of members and advertisers, that the advertisement columns of this Journal have been contracted for by Messrs. EYRE and SPOTTISWOODE, the Society's printers and publishers, to whom all communications respecting them should be addressed.

Notice is hereby given that the next List of Members will contain the professions or business occupations of the Members of the Society. Any Member who desires to confirm or alter his description as given before election should communicate with the General Secretary.

## CHANGES OF ADDRESS.

Auerbach, Dr. G., 1/o Mannheim; c/o Gluck and Co., Hünningen, Elsass, Germany.

Brown, Horace T., F.R.S., 1/o Cromwell Crescent; 52, Neven Square, Kensington, S.W.

Buchan, Alex., 1/o 93; 56, Malmesbury Road, Canning Town, E.

Carswell, T. R., 1/o Newcastle; 5, Borough Road, London, S.E.

Chadwick, L. N., 1/o Ponders End; 24, Elsham Road, Kensington, W.

Cooke, A. W., 1/o Wakefield; Retain Journals until further notice.

Douglas, Wm., 1/o Stamford Hill; Diamond, Demerara.

Dunn, Dr. J. T., 1/o Gateshead; Technical Schools, Plymouth.

Frankland, Prof. P., F.R.S., 1/o Dundee; Chemical Department, Mason College, Birmingham.

Hopkins, Gerald V.; address for subscriptions: Nicholson House, Penmaen, near Swansea.

Innes, Murray, 1/o San Francisco; P.O. Box 106, Morenci, Arizona, U.S.A.

## I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

*The Pneumatic Pyrometer.* H. Morton. Engineering, 1894, 251—252.

A PERFECT pyrometer should possess the following characteristics:—

1. Applicable to all temperatures between the softening point of platinum and the freezing point of liquid air.
2. Giving constant indications by mere inspection, without any manipulation or calculation.
3. Allowing its indications to be observed at once in a number of locations at a considerable distance.
4. Operating automatically in every respect, and requiring no skill or special intelligence in its use.

The author having direct knowledge of an instrument proved to possess this remarkable combination of good qualities, draws the attention of others to the subject. An instrument which is said to fulfil the above conditions is the pneumatic pyrometer invented in the first instance by Mr. E. A. Uehling, M.E., and finally developed by him in combination with Dr. Alfred Steinbart. Its operation depends upon the action described as "effusion" by Graham in 1846 (*Phil. Trans.* 1846, 274), namely, the passing of a gas through a minute aperture in a thin plate. Suppose that we have a closed space or vessel through which a current of gas is forced or drawn by a constant pressure, and that the entrance and exit openings are minute apertures of the same size. In this case the differences of pressure causing the flow through the two apertures will be, roughly speaking, equal; or, in other words, the available force will divide itself between the two. Thus, suppose a certain pressure is available to force the gas through the apparatus, this will at first be all available to drive the air into the vessel, but the pressure within will at once begin to rise, because the air will come

in faster than it goes out, until the difference of pressure between the air in the interior of the vessel and the space into which it is delivered is equal to the difference between the pressure inside and outside the vessel. When this condition is established, the gas will pass out of the vessel as fast as it enters, and thus the pressure within the vessel will be constant. If arrangements are made by which the air forced in is heated at the instant of entrance, but cooled within to its original temperature at exit, experience shows that the density of the heated air and the mass introduced in a given time will be less, and (the outflow temperature being kept constant) more air will go out than comes in, until the interior pressure is reduced sufficiently to compensate for the diminished supply. We thus see that a rise in temperature of the entering air will cause a fall of pressure or tension in the air within the vessel, and this change in tension can be directly observed by a manometer connected with the vessel. Though calculation, as well as experiment, shows that the variations in density grow less in proportion with the rise in temperature, yet even at 1,200° F. to 1,500° F., with an available air pressure equal to 28 in. of water column, there will be a change of tension equal to 1 in. of water for each 100° F.

The first practical application of a pyrometer embodying the above principle has been to the hot blast of an iron-smelting furnace.

The pneumatic pyrometer, as illustrated, is shown as attached to the hot blast main of a blast furnace (Fig. 2), and is especially designed for that purpose. It consists of a platinum tube  $B^3$   $\frac{1}{2}$  in. in diameter and of sufficient length to extend very nearly through the lining of the hot blast main, to the shell of which it is secured by the coupling  $a$ , and the gland  $b$ , which is secured to the flange  $c$  bolted to the shell. Concentric within the tube  $B^3$ , is placed a smaller platinum tube  $c^1$   $\frac{3}{8}$  in. in diameter (Fig. 3), which extends very close to the end of the tube  $B^3$ , and is held in position by the coupling  $f$ . The connection between  $a$  and  $f$  is provided with a branch  $h$ , to which is connected a filter  $B^1$ . The latter consists of a chamber about 2 in. in diameter and 10 in. long, loosely filled with cotton-wool. The inner pipe  $c^1$  continues by the pipe  $i$  to the vessel  $C$  (Fig. 1), and within this by the pipe  $j$  and worm  $k$  to the coupling  $C^1$ , which is shown in detail (Figs. 4 and 5). The first small aperture is located at the end  $d^1$  of the inner tube  $c^1$ , and the second aperture is located in the coupling  $C^1$ , as shown in Fig. 4 at  $l$ . From  $C^1$  the tube continues by  $m$  to the top of the chamber  $A$ , which is connected with an aspirator (not shown) by the pipe  $n$ , and with the manometer  $q$  by the bent tube  $o$ ; it is further provided with a stopcock  $p$  and with a tube  $r$ , which is open to the atmosphere at the upper end, and reaches to within 3 in. of the bottom of the chamber  $A$ . The upper end of  $r$  passes through a stuffing-box, and is provided with a rack and pinion and wheel  $s$ , by which it may be raised or lowered. The pipe  $i$  communicates through the capillary tube  $t$  with the manometer  $u$ , and may be prolonged by means of a T-piece  $v$  and tube  $w$  to the office or any other place or places where it may be necessary or desirable to indicate the temperatures to be measured. The manometer tubes  $q$  and  $u$  have their lower ends immersed in coloured water contained in the reservoir  $R$ . The vessels  $A$  and  $C$ , which are made of brass tubes 7 in. in diameter, are respectively 4 ft. 8 in. and 1 ft. 6 in. long, and are connected with the water-supply pipe by the pipe connection  $E$   $F$   $T$  and  $E$   $S$   $N$ . A temperature regulator is shown at  $G$ , and with the valve  $K$  closed, and  $L$  and  $I$  open, is kept filled with water to the level of the overflow  $H$ . The pipe and worm  $x$   $y$   $z$ , which is connected with the steam or hot-air main, continually keeps the water boiling, and because  $C$  is open to the atmosphere through  $D$ , a constant temperature of 212° F. is maintained.  $A$  is the suction regulator. By opening the stopcock  $p$  and the valve  $M$  it is filled with water to the proper level. The tube  $r$  must be immersed into the water in  $A$  exactly 4 ft., which can be readily done by the wheel  $s$ . By these means the essentials for exact determination of temperatures are supplied. The aspirator, with a somewhat greater capacity than is required by the apertures, is turned on, the excess of exhaustion being

\* Any of these specifications may be obtained by post by remitting 8d.—the price now fixed for all specifications, postage included—to Sir Henry Reader Lusk, Comptroller of the Patent Office, Southampton Buildings Chancery Lane, London, W.C.

corrected through the tube *rr* against a constant head of 4 ft. of water, the suction at *C*<sup>1</sup>, the second aperture, cannot vary appreciably above or below that point. By the manometer *qq* the suction may be at any moment observed, and will be found standing steadily at the point 4 so long as the tube *rr* dips into the water to the proper depth.

The water in *A* very gradually evaporates, and as this occurs to an appreciable amount, *rr* is lowered; when it has reached the bottom it is again raised, and the waste is supplied through the valve *M*. This, in continual use, is found necessary about once a month.

The suction being applied, the air from the atmosphere enters through the filter *B*<sup>1</sup>, where it is freed from dust,

flows through *h* into the platinum tube *B*<sup>3</sup>, where it assumes the temperature of the hot blast in the main *B*, at which temperature it enters the first aperture at the end of *e e*<sup>1</sup>, by which it returns and passes through *i i* into *j*, and the worm *k k* located in the boiling water maintained in *C*. (Melting ice or any other constant temperature would answer as well.) In its passage through the worm it assumes the constant normal temperature at which it flows through the

second aperture located in *C*<sup>1</sup>, as shown in the detailed section (Fig. 4), thence through *m m* into the regulator *A*, and from it by the pipe *n n* to the aspirator.

As already explained, the tension in the chamber or tube between the two apertures is a correct indication of the difference of temperature at which the air flows through each of them respectively, therefore the manometer *u u* supplied with a proper index and connected to the tube *i i*

by the capillary tube *t t t*, will continuously and accurately indicate the temperature in B. The temperature manifesting itself as tension of a continuous current of air through *i i*, *j j*, *k k*, the length of the capillary tube *t t t* does not affect the accuracy of the indications, neither does the number of manometers connected, so long as the connections are perfectly air-tight. It is, therefore, quite feasible to indicate the temperature in as many places as may be desirable. It is also immaterial, so far as the accuracy of the indications is concerned, at what distance the tension and temperature regulators A and C are located from the place at which the temperature exists which is to be measured, so long as the area of the tube between the two apertures is sufficiently in excess of the area of the apertures. The latter being only  $\frac{1}{8}$  in. (and it can be made even less),  $\frac{3}{8}$ -in. pipe is ample for distances below 500 ft.

The pneumatic pyrometer can, therefore, readily be made semi-portable. By making the tube *i i* of sufficient length and flexibility, it would be quite feasible to change it from the smoke-box to the furnace, or into any portion of a flue of a boiler which may be undergoing a test.

Changes of temperature of the air in the conduit between the apertures affect the accuracy of the indications only momentarily. By virtue of the continuous flow of the air through the tube equilibrium is very soon established, and then the difference of temperature at which the air flows through the respective apertures determines the tension irrespective of its temperature while flowing from one aperture to the other. This property renders the pneumatic pyrometer available for measuring the temperature of very small areas as well as large ones. For instance, it is just as feasible to measure with it the temperature of the contents of a 10-grm. crucible as of 40 tons of molten steel contained in a huge ladle; and it can be made to indicate the temperature of the flame of a Bansen burner as accurately as heat of the flame issuing from a converter.

To call the above-described instrument a pyrometer is really a misnomer, for while it is capable of measuring temperatures up to where platinum ceases to be a solid, its range for low temperatures terminates only where air ceases to be a perfect gas. Its telemetric properties would seem to render it particularly applicable in cold-storage plants and all other industries where it is important to know the temperature of a place without going into it. The most important effect of the telemetric feature of this instrument will manifest itself in the moral force which it exerts on those who have to be relied upon to maintain the necessary or desirable temperatures. It is one thing to give instructions that certain temperatures shall be maintained, and another to know that the orders are carried out. If you have the means of knowing whether your orders have been faithfully carried out, they generally will be carried out, and *vice versa*.

*Notes on the Manufacture of Sulphuric Acid in America.* (Siphon.) G. Lunge. Zeits. angew. Chem. 1894, 133—137.

See under VII., page 884.

## PATENTS.

*Improvements in Centrifugal Separators.* O. Linden, Stockholm, Sweden. Eng. Pat. 9533, May 15, 1893.

WITHIN a rotating cylindrical drum is placed an annulus containing a number of radial channels, connecting the central space with a series of zig-zag vertical channels, running from the enclosed space at the bottom of the drum to the discharge outlet at the top. The liquid to be treated is led into the lower part of the drum by a central pipe, from whence it flows into the zig-zag channels, the heavier portion being retained there, but the lighter is caused to flow to the central annular space through the radial channels by the centrifugal action, and is there discharged at the top by suitable orifices into a collecting cistern. The heavy liquid also mounts up until it reaches the top of the apparatus and is discharged through a similar

set of orifices. To prevent the channels from being filled up with dirt or slime, a number of pockets are arranged outside the channels, communicating with these latter by orifices situated at the points of the zig-zag channels farthest from the centre.—E. G. C.

*An Improved Furnace.* R. Dempster, Des Moines, Iowa, U.S.A. Eng. Pat. 11,412, June 10, 1893.

THE improvements are means for supplying heated air to the products of combustion in furnaces, more especially in boiler furnaces, consisting of hollow fire-bridges, a series of flues in the side walls, and a heating coil.—R. B. P.

*Improvements in Hot Air Evaporating and Drying Machine.* O. T. Newton, Egremont, Cheshire, Eng. Pat. 14,924, August 1, 1893.

THE machine consists of a closed casing, divided into chambers by horizontal division plates, for evaporating, drying, and cooling respectively. The material to be treated is fed from a reservoir into a pivoted tray, the outer end of which overhangs and rests upon one of the buckets of an endless chain stretched over polygonal drums at each end. As each bucket passes under the tray it receives a charge of liquid material, and the hot air forced into the chamber through perforated pipes causes this liquid to rapidly evaporate, leaving a pasty mass, which is delivered at the other end of the chamber, and scraped out of the buckets by fixed knives. The pasty mass is then passed through a pair of rollers and delivered on to an endless band, where it is further dried by hot air and delivered to another travelling band to be cooled by currents of cold air, until it finally attains the temperature of the atmosphere, when it is delivered into receivers. The supply of material is regulated by a governor, actuating a weighted quadrant, and arranged to cut off the supply when the machine is not in motion.—E. G. C.

*Improvements relating to Rotary Drying, Pulverising, and Evaporating Machinery.* A. von Podewils, Munich, Germany. Eng. Pat. 15,772, August 19, 1893.

THE apparatus is intended to treat faecal matters, meat, bone, slaughter-house, fish, and vegetable refuse, and other matters requiring high temperatures for being dried and pulverised. It consists of a rotating drum, with end covers adapted for being heated, and formed of two conical or spherical discs arranged base to base; the axle of the drum is riveted to one of the two inner discs and connected by a stuffing box with the other; a pipe is led through one of the hollow trunnions (forming the axle) to serve as an outlet for either vapour or liquid. To pulverise the material in the drum, prism-shaped scrubbers are provided, with edges so arranged as to be kept sharpened by their rotating motion within the cylinder. The drum is heated externally by the hot gases from a furnace, and to prevent overheating when the drum stops, a governor rotated from the trunnions by a train of wheels controls the plate-valve of the flue, which conveys the hot air and gases to the casing round the drum. Modified constructions are described and illustrated.—E. G. C.

*Improvements in Apparatus for Separating Foreign Substances from Waste Rubber, Bark, Guai, and other Materials.* J. Anderson, junr., Manchester. Eng. Pat. 17,477, September 16, 1893.

AN oblong sheet of wire or gauze is surrounded by a wood framing to form a shallow tray, which latter is supported by rollers upon inclined guides, so that it is capable of rapidly oscillating to and fro under the influence of a crank and connecting-rod arrangement: a number of transverse undercut strips of wood are also arranged upon the upper surface of the gauze. The rubber or other substance to be treated is fed on to the upper end of the tray in a pulverised condition, and the heavier particles, such as nails, eyelets, and

the like, by the jiggling action set up, are arrested by the under cut wood stops, and pass out by means of inclined channels, to bags placed at the side, while the lighter and purer material passes over the strips, and is finally discharged at the lower end of the tray into a suitable box or receptacle.—E. G. C.

*Improvements relating to the Manufacture of Filters.* H. H. Lake, London. From Bittel and Co., Worms-on-the-Rhine. Eng. Pat. 19,873, October 21, 1893.

THE filters hitherto made by cementing together pulverised materials have been unsuitable for use with active solvents, such as acids or alkalis. The material prepared according to this process resists all the ordinary chemical solvents, except hydrofluoric acid.

Quartz, preferably as quartzose sand, and powdered glass are mixed together, and the mixture having been placed in boxes or moulds, is heated above the melting point of the glass, and is maintained at this high temperature for a considerable time. A chemical action takes place under these conditions, an acid silicate, or hard glass, being formed by the combination of the glass and quartz. The burning and annealing is carried out in horizontal moulds for the purpose of obtaining plates of uniform density. The structure into which the plates of the filtering material are formed consists of two plates connected by bolts without the employment of external frames, such plates being kept at the required distance apart by strips of packing material inserted between them at their peripheries.—V. C.

*Improvements in Evaporating Apparatus.* Y. Craney, Bay City, Michigan, U.S.A. Eng. Pat. 9958, May 22, 1894.

THE invention described is the combination of one or more furnace evaporating pans with two or more steam evaporating pans, whereby the steam generated in the furnace pans may be used for double or triple expansion in the steam pans. The furnace pan is a cylindrical casing, having an internal furnace provided with feed doors, and the combustion products therefrom circulate through a number of horizontal tubes and an external casing, thereby heating and evaporating the liquid, the vapour of which is led out by a goose neck to a condenser, or, if it is to be used for double or triple expansion, into the steam pans. The steam evaporating pans are formed of a sheet-metal casing having within a steam chamber connected with an outer steam ring and evaporating chamber. From the top of the evaporating chamber extends a goose neck having a condenser in the discharge leg. The steam evaporating pans are placed in a line, with a furnace pan at each end, and are connected by piping provided with valves, so that any combination of pans can be at work at one time. The settling chambers are below the pans, to which they are connected by a discharge leg connected to a trunk provided with a suitable elevator for carrying off the salt crystals as they form. With this arrangement any pan may be repaired while the others are in full work.—E. G. C.

*Improvements in Evaporating Apparatus.* T. Craney, Bay City, Michigan, U.S.A. Eng. Pat. 9959, May 22, 1894.

THE invention described is the combination of a series of steam evaporating chambers, of the type described in the Eng. Pat. 9958, May 22, 1894 (see preceding abstract), each provided with a discharge pipe for vapour and a settling leg or chamber, whereby each evaporator may be operated independently or in a series. To effect this the discharge pipes are connected to a common trunk having feed pipes to the various pans controlled by valves, whereby connection can be made with any of the pans.—E. G. C.

## II.—FUEL, GAS, AND LIGHT.

*American and Russian Petroleum.* Becker. Zeits. angew. Chem. 1894, 216—221.

AFTER dealing at some length with the characteristics of American and Russian mineral oils, and the influence of competition, &c. on the quality of the commercial article, the author gives in detail the results of a series of comparative tests applied to two petroleum, the one being American the other Russian (Nobel). The points to be elucidated were:—1. Physical properties. 2. Illuminating power (during a nine hours' continuous trial). 3. Consumption of oil. 4. Odour of the products of combustion. 5. Consumption of wick. The results are given in considerable detail. The palm was awarded to the Russian oil on account of:—(1.) Its distinctly higher flashing point, greater purity, and comparative freedom from products of low boiling point. (2.) Its constant illuminating power as compared with the American oil, which fluctuated between wide limits. (3.) Its distinctly higher efficiency as expressed in grms. of oil consumed per normal candle-hour.—H. T. P.

*The Manufacture of Water-gas in New York.* G. Lunge. Zeits. angew. Chem. 1894, 137—142.

ILLUMINATION by means of water-gas is rapidly gaining favour in America. In the first instance this is due to the fact that anthracite is plentiful in the States and gas coals scarce. The illuminating power of carburetted water-gas is greatly in excess of that of the best coal-gas; and whilst it is true that carburetted water-gas contains three times the quantity of carbon monoxide present in coal-gas, yet the danger arising from the prevalence of this poisonous gas is greatly minimised by the penetrating odour which it acquires in the process of carburetting. As regards costs of labour and superintendence, the comparison is said to be likewise in favour of water-gas.

At the Municipal Gas Works Tessié du Motay's process is in operation. The plant consists of five sets of twin generators, 2.5 × 2.5 metres in section, 3.5 metres high, and charged with anthracite and coke. Air is introduced below the bars for 10 minutes, and the gases so produced are allowed to escape. Steam of 200 lb. pressure is then passed in, and the resulting water-gas is led into a chamber, where it impinges against heated plates down which a current of naphtha is flowing. In the gases thus saturated with naphtha vapours, the latter are fixed by passing through a retort raised to white heat by means of liquid fuel. The product is then cooled, scrubbed, and finally purified with lime.

Ten generators and 18 sets of carburetting retorts produce in the winter season seven million cb. ft. of gas, containing 70 per cent. of water-gas proper and 30 per cent. of illuminating gases derived from naphtha. 440 lb. of anthracite and coke, and 260 lb. naphtha of 0.706 sp. gr., yield 10,000 cb. ft. of gas of 28 candle-power. Deposition of naphthalene in the pipes may be prevented by passing kerosene of 0.810 sp. gr. into the white-hot retorts.

Lowe's process is much superior, in which air and steam are passed alternately for a period of 10 minutes through the generator charge. When blowing with air the resulting gases are used for heating the carburetors, of which there are two in series; these are fed with a cheap crude mineral oil from Ohio. One of Lowe's cylinders measures 4 metres in diameter and 6 m. high, and supplies 1½ million cb. ft. of gas in 24 hours. The gas leaves the generator at 15 candle-power and the superheater at 28—30 candle-power.

Humphreys' apparatus is equally praised. It consists of two generators, two carburetors, and two superheaters. The generators are connected by means of a flue, and each of them is also in connection with a carburettor and a generator. When starting, air is blown into both generators; steam is introduced into the superheater to the right, and after passing downward in this and upward in the carburettor, it enters the generator to the right in a superheated condition; it then passes down this and upward in the left generator, and the gas so produced entering the left

carburettor, meets here four streams of oil. The gas mixture is "fixed" in the left superheater, and the operation is subsequently reversed.

Oxide of iron does not seem to find favour for purifying gas, and is almost entirely replaced with lime prepared from oyster shells. Attempts are now being made to revivify the spent lime.—H. A.

*The Action of Heat upon Ethylene.* V. B. Lewes.  
Proc. Royal Soc. 55, 90—107.

AFTER reviewing the work which has been carried out on the effect of heat on ethylene, and has led to the text-book equations, i.  $C_2H_4 = C_2 + 2H_2$  (as representing the reaction at very high temperatures), and ii.  $C_2H_4 = C + CH_4$  at lower temperatures, the author describes a long series of experiments of his own on this subject. In these he has passed ethylene, both alone and with hydrogen, and at various rates through 140 mm. of platinum tube 2 mm. in diameter, heated to various temperatures, the temperatures being determined by a Le Chatelier platinum-rhodium pyrometer inserted in the tube. Experiments made to test the point showed that platinum had no especial action on the hot gases, and could therefore be safely used. Experiments were also made on the effect of similar heating, on methane, ethane, and benzene, probable products of the reactions.

Below  $800^\circ C$ . practically no action takes place; at that temperature, traces of acetylene are formed. Between  $800^\circ$ — $900^\circ C$ . the acetylene increases in quantity, and large quantities of methane are generated, accompanied by liquid products. This action increases until just below  $1,200^\circ C$ . when hydrogen begins to appear amongst the products of decomposition, whilst at the same moment deposition of carbon commences, and the formation of oil begins to decrease, until at  $1,500^\circ$  the decomposition of the ethylene is practically complete and the products are mainly hydrogen and carbon, with a little undecomposed methane. The quantity of acetylene found is never large, but this is probably due to the nascent acetylene polymerising so readily between  $900^\circ$  and  $1,300^\circ C$ . and thus producing the oils found, and to the decomposition of the acetylene at high temperatures. Methane was found to be very stable at  $1,000^\circ C$ . slowly decomposed between that and  $1,300^\circ C$ . and rapidly at  $1,500^\circ$ . Benzene began to decompose rapidly above  $1,000^\circ$ . Ethane decomposes even below  $900^\circ C$ . with liberation of hydrogen and formation of ethylene and acetylene. This latter fact shows that ethane cannot be a primary decomposition product of ethylene, or hydrogen would have been formed below  $1,200^\circ C$ . when that gas was heated.

As the result of his experiments the author concludes that the primary action of heat on ethylene is expressed by the equation  $3C_2H_4 = 2C_2H_2 + 2CH_4$ , whilst the final decomposition is  $C_2H_4 = C_2 + 2H_2$ , and that between these two extremes there occur a large number of reactions due to the polymerisation of the acetylene formed from the ethylene, and also, at higher temperatures, from the methane, according to the equation  $2CH_4 = C_2H_2 + 3H_2$ .

—L. T. T.

*The Carburetting of Coal-Gas with Benzene.* H. Ries.  
J. Gasbeleucht. 37, 1894, 1.

ABOUT one-third of gas from Bohemian coal was carburetted with benzene and mixed in a gasometer of 1,800 cub. m. capacity, with uncarburetted gas. In order to fully increase the lighting power of 1 cb. m. of gas 4 grms. of benzene are necessary, which result agrees with the former researches of Bunte on the small scale. Benzene is so readily taken up by coal-gas that the most primitive apparatus suffices for the treatment, which is not difficult.

—T. A. G.

*Improvements in the Paraffin and Mineral Oil Industries.*  
F. W. Mann. Chem. Zeit. 18, 1894, 863.

See under III., page 875.

PATENTS.

*Improvements in and relating to the Manufacture of Fuel.*  
W. B. Hartridge, London. Eng. Pat. 12,389, June 23, 1893.

CARBONACEOUS material, such as granulated coal or coke, or vegetable waste, is incorporated with an agglutinating material, such as crude dextrin. The pasty mixture is moulded into the form of a casing or shell, with a loose cover. The shell is then filled with granulated coal, &c., the cover fixed on, and the whole dried. The shell, being porous, acts as a retort; the gas generated within it escaping through the pores and burning freely over its surface.—R. R. P.

*Improvements in Coking Processes and Apparatus, and in the Recovery of the Products of Distillation.*  
J. Bowing, Tilbury, Essex. Eng. Pat. 12,903, July 1, 1893.

THIS invention relates to improvements in the retort apparatus described in a former specification (Eng. Pat. 16,622, 1892; this Journal, 1893, 255). The improved retort consists of a vertical cylinder with an upper and a lower cover plate, through each of which there is a central hole. The top plate has, in addition, an outlet for the products of distillation, and a charging hole. When charging the retort a mandril is passed through the central holes in the cover plates to form a core. The material to be coked is then charged in, being packed closely round the mandril, and if necessary moistened with water, or tar, to make it cohere. The mandril is then carefully withdrawn, leaving a central due cored out through the mass to be coked. Heat is then applied by burning a suitable fuel, such as gas, in this central due, only just sufficient air being admitted for the combustion of the fuel.—R. B. P.

*Improvements in the Production of Illuminating Gas.*  
J. Smith, Sunbury-on-Thames. Eng. Pat. 14,545, July 28, 1893.

THE object of this invention is the production of oil-gas for enriching coal gas, especially that obtained from inferior coal. The inventor claims a cast-iron retort somewhat similar to the usual coal-gas type, but provided with one or more longitudinal partitions extending from the front end to within a short distance of the back end, where the chambers thus formed communicate with each other. The retort is set either alone or in the stack over the coal retorts, and so heated by the same furnace. The oil is injected as a spray by superheated steam at the front end of the retort, and the vapour formed passes backwards and forwards through the several chambers, and finally leaves through the front end of the retort by the ascension pipe, and enters the hydraulic main, which is constructed somewhat larger than usual. The gas carries with it a quantity of tarry matter, the condensation of which is facilitated by a stream of cold water entering the dip-pipe, and passing with the gas into the hydraulic main. The gas, water, and tar leave the hydraulic main in the usual way. The oil is supplied from a suitable reservoir through a graduated cock to a funnel, where air may also be admitted, the quantity being regulated by the second cock on the pipe leading from the funnel to the injector. Cocks are fitted to the front end of the retort and upon the outlet from the hydraulic main, to ascertain the condition of the gas, according to which the supply of oil is regulated.

Detailed drawings of this retort and a modification of the same accompany the specification.—S. P. E.

*Improved Apparatus for Vaporising Oil.* R. H. Laird and W. H. Laird, New Jersey, U.S.A. Eng. Pat. 15,432, August 14, 1893.

IN vaporising "crude oils," the best results are said to be obtained when the oil is distributed in thin sheets over large generating surfaces or trays, and the heat applied by a coil

of steam-pipes placed between the trays. At 212° F. the so-called "alcoholic series of vapours" is driven off. The heat is gradually increased to 300° F., when the lightest of the "oleic vapours" are given off; and so on at 450° and 650° F. respectively, when still heavier oils are expelled. The trays are arranged in a closed receptacle, made of boiler-plates. One or more standards or pillars are erected inside. Suitable perforated metal trays, sloping from the centre to a point near their peripheries, are passed over each standard, and rest upon radial arms affixed to the standard. The trays have a depending flange upon their edges, which rest upon the radial arms and enclose a space between the arms and trays, which are arranged in tiers to the top of each standard. A perforated coil of pipe is placed between the trays, and emits steam or hot water into the space between the trays. The oil runs from a feed-pipe on to the highest tray, falling over its edge on the next one, and so on till it reaches the bottom.—J. J. K.

*Improvements in Furnaces for Burning Refuse Material, such as Town's Refuse.* J. B. Allott and J. McC. C. Paton, Nottingham. Eng. Pat. 15,717, August 18, 1893.

See under XVIII. B., page 898.

*Improvements in the Method of Burning and Controlling the Combustion of Solid Fuel, and in Hearths or Furnaces therefor.* R. Nobel, Geta Aby, Sweden. Eng. Pat. 16,220, August 28, 1893.

This invention relates to specially constructed furnaces by means of which the author claims to be able to regulate the consumption of solid fuel without preventing the complete combustion of the same. Each of the several types of furnaces illustrated and referred to in the specification consists essentially of a closed fuel-chamber provided with one or more openings, through which a regulated supply of air enters. The bottom of this chamber is constructed of brickwork, through which one or more openings are left for the escape of the gases generated, or fire-bars may be employed. As the gases leave the fuel-chamber, where incomplete combustion only takes place, they meet with a further supply of air to complete the combustion, and then pass on to the flue surrounding the boiler or apparatus to be heated. The air supply to the gases is preferably heated by passing through tunnels in the brickwork or through hollow fire-bars. The ash-pit, like the fuel-chamber, is closed, and provided with a suitable door for removing the ashes. Accompanying the specification are a number of sectional drawings, illustrating several modifications of this type of furnace for special purposes.—S. P. E.

*Improvements relating to the Manufacture of Gas.* E. Mansfield, Manchester. Eng. Pat. 17,811, September 22, 1893.

This invention relates to plant for the manufacture of gas for heating and lighting purposes from sawdust, shavings, straw, leaves, cones, and similar vegetable products. The retorts are set in suitable brickwork, either vertically, horizontally, or the upper portion vertically and the lower portion inclined. Upon the upper or mouth end of the retort, outside the brickwork, and occupying the usual position of the hydraulic main in coal-gas works, is fixed a hopper, at the bottom of which a slide door allows the woody material to drop into the retort. The gas produced by the dry distillation of the vegetable matter is conveyed away in the ordinary manner to the hydraulic main, and purified as desired on its way to the gas-holder. The retorts are also provided with doors at the lower end, through which the ashes and carbon may be removed. Under the retorts there is a suitable furnace for burning coal or coke, the gases from which meet a second supply of air in the combustion-chamber, and thence pass to flues surrounding the retorts. Accompanying the specification are a series of drawings showing the setting of the retorts and furnaces, and giving other details.—S. P. E.

*Improvements in Saturators and Jets for producing Oxy-hydrogen or Lime Light.* A. Suiter, London, Eng. Pat. 18,224, September 28, 1893.

According to the inventor, when saturators are employed for producing hydrogen for oxy-hydrogen or lime light, the flame is apt to pass back and fire in the mixing chamber of the jet—an objection which this invention claims to remedy. The apparatus is said to be less in weight and bulk than the ordinary form, and requires less time to get into working order. The mixing chamber or burner of the jet is used as a saturator or vaporiser by stuffing it with a porous material that dips into a cistern also stuffed with a porous material containing beezoline or a similar volatile compound. By this means the saturator is rapidly heated, being in actual contact with the flame. The saturator is fitted with an adjustable sheath with projecting arms to conduct more or less heat, as the volatile nature of the beezoline or similar compound may require, and thus enable an excess of vapour to be produced and prevent the flame from passing back.—S. P. E.

*A New or Improved Combustible Material and process of manufacturing the same.* E. Scott, Chattanooga, U.S.A. Eng. Pat. 12,761, July 2, 1894.

This is a cheap fuel which is said to readily ignite, burn vigorously with perfect combustion, and to be adapted for kindling less combustible materials, also serving to diffuse around aromatic and other compounds. Logs of wood are generally employed, preferably of a resinous character; they are cut into lengths of about one foot, which are split down into slabs of one inch thick. These slabs are carried by an endless conveyor through a closed vessel, in which they are subjected to steam or hot water until they are sufficiently soft to yield to the pressure of the rolling-machine. This latter apparatus, consisting of two ridged or corrugated rollers, mounted in a strong frame and gear-driven, somewhat opens or separates the fibres without actually disintegrating the slabs, and produces a flexible fibrous woody material, which, being very porous, allows the air to penetrate. This mat-like material may be saturated with any aromatic compounds, and is easily rolled into compact bundles for transport.—S. P. E.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*Spontaneous Ignition of Dried Petroleum Sludge.* R. Kissling. Zeits. angew. Chem. 1894, 197—199.

The occurrence in question was observed in a mineral-oil refinery. On opening the man-hole of a retort at the finish of a distillation, showers of sparks were seen to fall from the upper narrowed portion of the dome; and on removal of the latter, the phenomenon was found to be due to the spontaneous ignition of the sludge which had collected in a thick layer on a projecting portion of the dome. When freed from petroleum-oil, the sludge, formed a fine, black, flocculent powder having the following percentage composition:—Carbon, 67; iron, 24; sulphur, 9; obviously a mixture very liable to spontaneous ignition. A rough experiment showed that the dry powder when heated in the open air ignited at about 250° C. When saturated with paraffin oil, however, it did not fire even at 400° C.

It is probable, therefore, that towards the end of the distillation, the temperature in the retort must have been sufficiently high to expel the bulk of the oil from the sludge, the latter being subsequently ignited by the influx of air when the retort was drawn.—H. P. P.

*The Petroleum Industry in Baku in 1893.* Chem. Zeit. 18, 1894, 1130.

THE production of petroleum is becoming concentrated in the three districts of Balachani-Sabuntsehi, Bibi-Eibat, and the Romany Plain. The output of oil in 1893 was 337,051,834 poods, of which 324,763,197 poods (about 5,235,000 tons), or an increase of 13.6 per cent. over the previous year, was further worked in the refineries, the remainder being employed as fuel, or wasted. The increase is mainly due to the greater yield from fountains, where no pumping is needed, about one third of the total production being from this source. These fountains have lowered the price of crude petroleum, which varied between 2.75 kopeks (about  $\frac{1}{4}$ d.) per pood (36 lb.) in winter and 0.75 kopek ( $\frac{1}{4}$ d.) in summer. In 1893 there were about 38 fountains, and 458 wells where pumping was necessary, the average yield per pumping well being about 470,000 poods (about 7,577 tons) per annum. In 1893 there were 249.5 versts (about 165 miles) of pipe-lines, varying from 3 to 6 ins. in diameter, connecting the wells and factories, &c., and estimated to be capable of manufacturing about 1,440,000 poods (about 23,000 tons) of oil per day. In 1893 there were only 85 refineries, of which many were not working to their full capacity. This change is due to the growth of the large establishments at the cost of the small ones. The products of these refineries are about as follows:—Refined petroleum, 85,633,971 poods (about 1,380,000 tons); oils, 6,232,740 poods (109,000 tons); benzine, 252,193 poods (4,000 tons); goudron, asphalt, gasolin, &c., 437,620 poods (7,000 tons); and petroleum residuals, 143,538,890 poods (about 2,310,000 tons). These numbers are the exported amounts, and therefore exclusive of those used on the spot. The best works distil exclusively, or at least mainly, by driving superheated steam into the oil, and employ dephlegmators, though some works employ only fire heating. The vessels for acid and alkali treatment are usually fitted with air-agitators, but settling tanks are very commonly wanting, and in consequence the agitators or collecting tanks are used for this purpose with unsatisfactory results. From scarcity of fresh water, washing is often neglected or inefficiently carried out. Similarly, on economical grounds, insufficient quantities of acid and alkali are often used in purification, and in some cases a part of the soda has been replaced by the cheaper quicklime with doubtful results. Formerly the distillation was carried as far as possible, an average of 36.5 per cent. of the crude petroleum having been obtained as distillate. Now that the value of the residuals has risen and is generally higher than that of the oil, the distillation is usually not carried so far, only about 29.5 per cent. of the crude oil being distilled over. In addition to this crude oil, even asphalt, gasolin, &c., are sometimes added to the residuals.

The sulphuric acid and caustic soda used in the purification are now all made in the district, the first sulphuric acid chamber having been erected in 1880. In 1893 there were four factories making together about 9,000 tons of acid of 65°–66° Baumé, whilst in three regenerative factories about 2,700 tons of black acid were recovered. In 1893 there was one factory in work making soda from Glauber salt, and one Leblanc works in course of construction.—L. T. T.

*Improvements in the Paraffin and Mineral-Oil Industries.* F. W. Maun. Chem. Zeit. 18, 1894, 863–864.

A PAPER by Kern on this subject sets forth an account of some of the author's experiences during 12 years in America.

*Oil-gas.*—The economy of the so-called water-gas manufacture has caused water-gas almost completely to supplant retort coal-gas, since the manufacturer can produce a gas of 20–22 c.p. at a cost of 15 instead of 60 cents per 1,000 cub. ft., whilst the consumer obtains a gas of twice the luminosity at half the cost. The materials used embrace crude oils and by-products and residues from them, in

addition to coke or anthracite, the greater yield of gas from oils of low specific gravity being balanced by the higher luminosity of that from heavy oils, which permits the use of a larger proportion of water-gas. Any sulphur is removed by passing the gas through moistened sawdust, and then through slaked lime, sometimes mixed with ferrous sulphate. The author has retorted heavy mineral oils without steam, in order to obtain aromatic hydrocarbons, but the utility of the latter for the manufacture of dyestuffs was diminished through contamination by a small proportion of paraffins; a gas of great luminosity was obtained as a by-product. Some of the heavy mineral oils may be made to yield an excellent material for printers' ink.

The remainder of the paper contains brief reports on the subjects of the "*Influence of Temperature on the Gasification of Oils*," "*The Estimation of Paraffin*," "*On refining*," and "*On the use of petroleum as a boiler anti-incrustation medium*." On this latter subject it is stated that the action in the boilers is purely mechanical, saturating the deposit and preventing adhesion, but is perfect and characteristic of mineral oil. Light oils would be useless by reason of their volatility. (This Journal, 1893, 739; and 1894, 135.)—W. G. M.

#### IV.—COLOURING MATTERS AND DYES.

*Some Sulphonations of Naphthalene Derivatives.* O. Dressel and R. Kothe. Ber. 27, 1193–1210.

THE naphthol and naphthylamine sulphonic acids, the importance of which in the manufacture of dyes has long been recognised, have only in recent years been submitted to scientific investigation. The establishment of the laws governing the substitutions in the naphthalene nucleus is due chiefly to the researches of Clève, and of Armstrong and Wynne.

The authors have studied the sulphonic acids derived from  $\beta$ -naphthylamine-7-sulphonic acid,  $\beta$ -naphthylamine-3, 7-disulphonic acid, and  $\beta$ -naphthol-7-sulphonic acid, and have come to the conclusion that Armstrong and Wynne's theory does not entirely hold good. They find that at high temperatures migrations of the sulphonic groups are possible in the naphthalene nucleus, even in the presence of sulphuric anhydride. Further, that by the influence of the 2-amido group sulphonation may under certain conditions take place in the 4-position, and that all  $\beta$ -naphthol and  $\beta$ -naphthylamine sulphonic acids containing a sulphonic group in the  $\alpha$ -ortho-position to the hydroxyl- or amido-group are distinguished by the splitting off of this sulphonic group on heating with dilute mineral acids, this reaction occurring in the main more easily in the case of the naphthol- than of the naphthylamine-sulphonic acids. Interesting and important details are given leading to these conclusions.—F. M.

*8-Anthraquinone.* K. Lagodzinski. Ber. 27, 1438—39.

By heating 8-anthrol with the calculated quantity of sodium nitrite and zinc chloride in alcoholic solution, and digesting the zinc compound formed with caustic soda, the sodium compound of nitroso-anthrol is obtained. The free nitroso-anthrol, separated from this by the addition of an acid, is by reduction with stannous chloride converted into amido-anthrol, which, by oxidation in a sulphuric acid solution with chromic acid, yields a new anthraquinone. The process of formation is analogous to that of 1,2-naphthoquinone from 8-naphthol. The new anthraquinone produces with ease the azine reaction with phenylene diamine, and is therefore an ortho-derivative, containing the two oxygen atoms probably in the position 1,2.—F. M.

*The Reduction of Nitro Compounds.* A. Wohl. Ber. 27, 1432—1437.

By the action of zinc-dust and water upon nitrobenzene *β*-phenylhydroxylamine is produced, according to the equation—

$$\text{C}_6\text{H}_5\text{NO}_2 + 2\text{Zn} + 3\text{H}_2\text{O} = \text{C}_6\text{H}_5\text{NH(OH)} + 2\text{Zn(OH)}_2$$

The instability of this compound in aqueous solution at elevated temperatures leads to the formation of azoxybenzene, which, by the reducing action of the zinc-dust, is converted into azobenzene. Aniline is formed at the same time by the direct reduction of the hydroxylamine. The consequent difficulties in the way of obtaining a satisfactory yield of phenylhydroxylamine were found to be obviated by the employment, in the place of pure water, of solutions of salts capable of forming insoluble basic double salts with zinc hydroxide, such as calcium, magnesium, and zinc chlorides. The addition of alcohol to the mixture is advantageous. By gradually adding 75 grms. of zinc-dust to a hot solution of 60 grms. of nitrobenzene and 6 grms. of anhydrous calcium chloride in 250 cc. of 60 per cent. alcohol, from 70 to 75 per cent. of the theoretical yield of hydroxylamine is obtained. Its separation from the mixture is effected by filtration and quick distilling off of the alcohol from the filtrate. The oily liquid which settles out solidifies on cooling to a cake, which after washing with water and drying is recrystallised from benzene.

Phenylhydroxylamine melts at 81—82°. It is readily soluble in alcohol, ether, carbon bisulphide, chloroform, and hot benzene; very slightly in petroleum spirit. Hot water dissolves 10 per cent., cold water 2 per cent. Phenylhydroxylamine is by the action of hot dilute mineral acids converted into amidophenol, and possesses the property of combining readily with aldehydes and phenyl-mustard oil, and of forming a benzoyl compound, ethyl derivatives, &c. In concentrated sulphuric acid it dissolves with a deep blue colour.

By substituting finely pulverised iron for the zinc-dust employed in the above reduction process, aniline alone is obtained. This observation furnishes the explanation of the fact that in the manufacture of aniline on the large scale only a very small portion ( $\frac{1}{30}$ th) of the acid required by the equation—

is actually used. The mechanism of the reaction is in reality the following:—First of all the iron combines with the hydrochloric acid, forming ferrous chloride, the nascent hydrogen reducing a corresponding quantity of nitrobenzene. The acid being used up, the iron now acts upon the nitrobenzene direct, according to the equation—

The ferrous chloride formed in the first stage of the process combines with the ferric hydroxide, forming a basic salt, thus playing the part of an acid and increasing the energy of the reaction. The correctness of this explanation of its action is proved by the fact of its being replaceable by calcium chloride and other salts which cannot act otherwise.

The presence of free acid or alkali and of nascent hydrogen have hitherto been considered essentials in the reduction processes practised in the laboratory, but the

preparation of phenylhydroxylamine and the analogous production of aniline on a manufacturing scale are examples of the possibility of effecting reductions in neutral solution by the direct conversion of finely-divided metal into hydroxide or highly basic salt.—F. M.

*The Behaviour of Triphenylmethane Colouring Matters to Nascent Bromine.* W. Vaubel. Chem. Zeit. 18, 1894, 1093.

The colouring matters of the triphenylmethane series, which contain amido and hydroxyl groups, possess the property of taking up bromine, a reaction which is more or less sharply defined. The test is carried out in the manner already described (Chem. Zeit. 1893, 1263, 1897; this Journal, 1894, 518), and acetic acid is used as a solvent for those colouring matters insoluble or sparingly soluble in water. *Tetramethyl-diamido-triphenylmethane* takes up 2 atoms of bromine, a further quantity acting as an oxidising agent. The sulphate of *Malachite Green S* takes up 2 atoms, the end reaction being well defined. *Paraleucaniline* takes up 6, whereas *Leucaniline* only takes up 5, and *Pararosaniline* and *Rosaniline* take up 5 and 4 atoms of bromine respectively, the end point in all these cases being well marked. *Hexamethyl-p-leucaniline* takes up 3 atoms, whilst *Crystal Violet* takes up 1 atom quickly and two very slowly. *Methyl Green* takes up 2 atoms with a sharp end reaction, whilst *Iodine Green* does not react readily with nascent bromine. *Aurin*, *Phenolphthalein*, and *Auramine* all take up 4 atoms of bromine. The phenylated rosanilines react similarly, and certain of the sulphonic acids are being investigated as to their behaviour towards nascent bromine. It is not proposed that the method should replace dyeing tests, but it is suggested that there are cases in which it might be employed technically.

—T. A. L.

## PATENTS.

*Improvements relating to the Manufacture of Paris Blue or Berlin Blue, and of Berlin Green, by Electrolysis.* H. Goebel, Garzweiler, Germany. Eng. Pat. 14,089, July 20, 1893.

THESE improvements relate to a process of manufacturing Paris blue or Berlin blue (Prussian blue), and Berlin green, by ozone produced by electrolysis; the process consisting in the precipitating of a solution of yellow prussiate of potash by means of a ferrous salt, such as green vitriol, suspending this precipitate in water, and subjecting it to electrolysis.

It is stated that a Paris blue or Prussian blue of an extremely vivid violet reflex and coppery lustre is obtained. Sulphuric, hydrochloric, nitric, or phosphoric acids may be added to the electrolyte so that it may contain from 1—20 per cent. of acid. The precipitate is only introduced next the anode, the contents of which compartment are kept stirred, as well as those of the cathode, if a precipitate is produced there. The hydrogen may be taken up by manganese peroxide or organic nitro derivatives. When the electrolytic action is continued too long the blue becomes more and more faint, and ultimately changes to dark Berlin green, which, when moist or in moist air, reverts to blue. A sample of the anode liquor is filtered and the operation stopped as soon as the filtered sample shows a reddish-violet tint.—J. C. R.

*Manufacture of 2,7-Amidonaphtholdisulpho Acid and of Colouring Matters derived therefrom.* C. D. Abel, London. From "The Actien Gesellschaft für Anilin Fabrikation," Berlin, Germany. Eng. Pat. 16,199, August 28, 1893.

By sulphonating 2,2'-dihydroxynaphthalene under suitable conditions it is converted into a disulphonic acid which is easily soluble in water and is not precipitated by hydrochloric acid. The acid sodium salt is less soluble in water than the free acid, and is nearly insoluble in acid brine and insoluble in alcohol. When heated with ammonia under

pressure it yields an amido-naphthol disulphonic acid:—25 kilos. of dihydroxynaphthalene disulphonic acid are heated with 75 kilos. of liquor ammonia containing 23 per cent. of ammonia for 14 hours to 180°–220° C. The melt is dissolved in water and the new acid is precipitated with hydrochloric acid. It is sparingly soluble in water, whilst the sodium salt is easily soluble, and the solution shows a bluish-green fluorescence. Mineral acids precipitate the acid from a solution of its sodium salt, but acetic acid does not. The 2,2'-amido-naphthol disulphonic acid is to be employed for the production of colouring matters, and for this purpose may itself be diazotised and combined with amines and phenols and their derivatives; or the acid itself will combine with diazo- or tetrazo-compounds, the combination taking place in an alkaline or a slightly acid solution. The colouring matters thus obtained contain a diazotisable amido group, which may be diazotised and combined on the fibre, the colours produced varying from brown to greyish-black.—T. A. L.

*The Manufacture or Production of Sulpho Acids derived from β-Naphthol-β-Monosulpho Acid.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 17,141, September 12, 1893.

It has hitherto been supposed that the only acid produced by sulphonating β-naphthol sulphonic acid F (2,2'-naphthol sulphonic acid) is 2,3,2'-naphthol disulphonic acid, but the present specification describes processes for the production of a tri- and a tetra-sulphonic acid from the F acid. These two acids on hydrolysis lose one sulphonic acid group, and are converted into new naphthol di- and tri-sulphonic acids. All these naphthol sulphonic acids when heated with ammonia, produce the corresponding naphthylamine sulphonic acids, and one of the β-naphthylamine tri-sulphonic acids so formed when fused with caustic soda gives rise to a new amido-naphthol disulphonic acid. The following new acids are described:—β-naphthol trisulphonic acid, 2,1,3,2'.C<sub>10</sub>H<sub>4</sub>.OH(SO<sub>3</sub>H)<sub>3</sub>. One kilo. of sodium 2,2'-naphthol sulphonate is mixed with 3 kilos. of fuming sulphuric acid containing 25 per cent. of anhydride, and allowed to cool. The melt is then heated to 80°–90° C. until a sample no longer combines with diazo compounds, when the whole is poured on the ice, neutralised at a low temperature with slaked lime, the calcium salt converted into the sodium salt, and the solution of this evaporated down. On hydrolysing this acid by boiling it with 10 times its weight of 10 per cent. hydrochloric acid it is converted into so-called β-naphthol-β-disulphonic acid of Ger. Pat. 44,079, the sulphonic acid group of the trisulphonic acid ortho to the hydroxyl having been removed on hydrolysis. β-naphthol tetrasulphonic acid—

20 kilos. of sodium 2,2'-naphthol sulphonate are gradually added to 80 kilos. of fuming sulphuric acid containing 40 per cent. anhydride and heated to 120°–130° C. for 8–10 hours. The melt generally goes solid, and sulphonation is complete when a test no longer gives a colour with diazo-compounds, and gives a white sandy barium salt sparingly soluble even in boiling water. The melt is then added to ice, neutralised with lime, precipitated with sodium carbonate, and the solution of the β-naphthol sodium tetrasulphonate is evaporated to dryness. The constitution of the acid was determined by converting it first into a trisulphonic acid by heating with dilute acid, and then into the corresponding naphthylamine trisulphonic acid from which the amido group was removed. The naphthalene trisulphonic acid so obtained was identical with the 2,3,3'-naphthalene trisulphonic acid of Eng. Pat. 11,865 of 1892 (this Journal, 1893, 595). As already mentioned, when boiled with dilute acids the tetrasulphonic acid is converted into a trisulphonic acid, having the constitution—

the sulphonic acid group ortho to the hydroxyl having been split off as in the case of the trisulphonic acid mentioned above. This new trisulphonic acid differs from the former one in combining with diazo-compounds, and it is to

be used for the preparation of azo colouring matters. All the naphthol sulphonic acids described can, on heating with ammonia, be converted into the corresponding naphthylamine sulphonic acids; thus 2,1,3,2'-naphthol trisulphonic acid gives 2,1,3,2'-naphthylamine trisulphonic acid, which, on heating with dilute mineral acids, yields 2,3,2'-naphthylamine disulphonic acid. In a similar manner—

gives 2,1,3,2'.C<sub>10</sub>H<sub>4</sub>.NH<sub>2</sub>(SO<sub>3</sub>H)<sub>4</sub>, which on hydrolysis yields 2,3,2'.C<sub>10</sub>H<sub>4</sub>.NH<sub>2</sub>(SO<sub>3</sub>H)<sub>3</sub>, or this last acid may be obtained directly by the action of ammonia on 2,3,2'.C<sub>10</sub>H<sub>4</sub>.OH(SO<sub>3</sub>H)<sub>3</sub>. This last-named acid, when fused with caustic soda at 180°–240° C., gives a new amido-naphthol disulphonic acid, having probably the following constitution, 2,2',3,3'.C<sub>10</sub>H<sub>4</sub>.NH<sub>2</sub>.OH(SO<sub>3</sub>H)<sub>2</sub>. This acid yields a diazo compound which can be salted out in yellow flakes. It also combines with diazo and tetrazo compounds, yielding valuable dyestuffs.—F. A. L.

*The Manufacture or Production of Sulpho Acids derived from β-Naphthylamine-β,β'-Disulpho Acid.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 17,141A, September 12, 1893.

By sulphonating 2,3,2'-naphthylaminedisulphonic acid with fuming sulphuric acid the first product of the reaction is 2,1,3,2'-naphthylaminetrisulphonic acid, which, on further heating with fuming sulphuric acid, is converted into a mixture of two isomers, the sulphonic acid group in the position 1 "wandering" into the 3' and 4'-position forming the (2,3,2',1') and (2,3,2',3') naphthylaminetrisulphonic acids. When the latter of these two acids is further acted on by fuming sulphuric acid it is converted into 2,1,3,2',3'-naphthylaminetetrasulphonic acid. For the preparation of the 2,1,3,2'-naphthylamine trisulphonic acid, 1 kilo. of β-naphthylamine-β-disulphonic acid—

is mixed with 3–4 kilos. of fuming sulphuric acid containing 40 per cent. of anhydride and heated for several hours to 80°–90° C., until a sample, when diazotised and combined with R-salt, gives an easily soluble brownish orange-red colouring matter. The melt is then poured on to ice, and the acid converted at a low temperature into its calcium salt, from which the sodium salt is obtained. By continuing the action of the sulphuric acid for about 20–30 hours, and raising the temperature of the melt to 130° C., the acid first produced is converted into two isomeric trisulphonic acids. The melt also contains a β-naphthylamine tetrasulphonic acid, which, on hydrolysis, is converted into one of the isomeric trisulphonic acids simultaneously produced. The melt therefore as obtained above is poured on to ice, diluted with water, and boiled. The solution then contains two trisulphonic acids, which can be separated by the difference in solubility of their sodium salts. Taking the quantities given above, the solution of the sodium salt is evaporated to 5 litres and then acidulated with hydrochloric acid, when the acid sodium salt of 2,3,2',3'-naphthylamine-trisulphonic acid separates in long needles and can be filtered off. The solution is saturated with salt, when the acid sodium salt of 2,3,2',4'-naphthylaminetrisulphonic acid crystallises out in nodules. In order to prepare the tetrasulphonic acid, 1 kilo. of 2,3,2',3'-naphthylaminetrisulphonic acid, or of its acid sodium salt, is mixed with 3–4 kilos. of fuming sulphuric acid containing 40 per cent. of anhydride and heated at 120°–140° C. until a sample carefully poured on to ice, diazotised and combined with R-salt, yields an easily-soluble brown colouring matter. The colouring matter from diazotised 2,3,2',3'-naphthylamine trisulphonic acid and R-salt is only partially soluble. The melt is then poured on to ice and neutralised at a low temperature with slaked lime. The sodium salt is prepared from the solution of the calcium salt, and after evaporation the tetrasulphonic acid is precipitated by adding hydrochloric acid to the cold solution. All the β-naphthylamine sulphonic acids herein described are to be employed for the production of dyestuffs.—T. A. L.

*The Manufacture or Production of  $\alpha$ -Naphthylamine  $\beta$ - $\alpha$ - $\beta$ -Trisulpho Acid and of other Sulpho Acids derived therefrom.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 17,141n, September 12, 1893.

THE new  $\alpha$ -naphthylamine trisulphonic acid referred to has the constitution  $1.2.2'.1'.4'.11_1.NH_2.(SO_3H)_3$ , and can be obtained by the action of sulphonating agents on  $1.4'.2$ -naphthylamine disulphonic acid of Ger. Pat. 69,555,  $1.2.4'$ -naphthylamine disulphonic acid of Ger. Pat. 56,563,  $1.2$ -naphthylamine sulphonic acid, or  $1.4'$ -acetamidonaphthalene sulphonic acid. In order to obtain it from one of the disulphonic acids the acid sodium salt is mixed with three times its weight of fuming sulphuric acid, containing 40 per cent. of anhydride, and heated for about 10 hours to  $120-130^\circ C$ . The melt usually becomes solid, and after stirring into ice-water the liquor is saturated with lime, converted into the sodium salt, and after evaporation acidulated, when the acid sodium salt crystallises out on cooling. The salt so obtained forms nodular aggregates of fine white needles readily soluble in water, the solution showing a green fluorescence. The diazo compound crystallises in yellow needles readily soluble in water. On heating this acid under pressure with an equal weight of caustic potash and of water to  $180-200^\circ C$ , a new amido-naphthol disulphonic acid is obtained, which precipitates when the melt is acidulated. The new acid, which probably has the constitution  $1.4'.2.2'.C_{10}H_4.NH_2.OH.(SO_3H)_2$ , gives a sparingly soluble acid, but an easily soluble neutral sodium salt, the solutions showing a blue fluorescence. The diazo-compound can be salted out as a mass of orange-red crystals, and when added to alkalis produces an unstable blue colour which rapidly changes to orange. Ferric chloride added to a solution of the acid sodium salt produces a claret-red, whilst chloride of lime gives a yellow colour. The amido-naphthol disulphonic acid and the naphthylamine trisulphonic acid are to be used for the production of colouring matters, and the latter is also to be employed for obtaining other new sulphonic acids of the naphthalene series.—T. A. L.

*The Manufacture or Production of Sulpho Acids derived from Naphthalene  $\alpha$ - $\beta$ - $\alpha$ - (or  $\alpha$ - $\beta$ - $\alpha$ -) Trisulpho Acid, or analogous Sulpho Acids.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 17,141c, September 12, 1893.

By the action of nitric acid on  $1.3.4'$ -naphthalene trisulphonic acid, the nitro-group enters the molecule in the  $1'$ -position yielding  $1.4.1'.3'.C_{10}H_4.NO_2.(SO_3H)_3$ . This constitution was proved as follows:—The nitro-acid, on reduction, yields  $\alpha$ -naphthylamine trisulphonic acid, which, on diazotisation and boiling with dilute sulphuric acid, gives a naphthosultone disulphonic acid. This, on fusing with alkalis, gives an  $\alpha$ -naphthol trisulphonic acid different from the  $\alpha$ -naphthol trisulphonic acid S of Eng. Pat. 3397 of 1890 (this Journal, 1892, 999), which has the constitution  $1.2.4.1'.C_{10}H_4.OH.(SO_3H)_3$ . Starting from  $1.4'$ -naphthalene sodium disulphonate, which on sulphonation at  $130^\circ C$  is converted into the  $1.3.4'$ -naphthalene trisulphonic acid, the specification describes the preparation of the various derivatives mentioned above. If, instead of diazotising the  $1.4.1'.3'$ -naphthylamine trisulphonic acid, it is fused with alkalis, a new amido naphthol disulphonic acid, of the formula  $1.1'.4.3'.C_{10}H_4.NH_2.OH.(SO_3H)_2$ , is produced. The  $\alpha$ -naphthol trisulphonic acid obtained from the  $1.4.1'.3'$ -naphthylamine trisulphonic acid, when fused with alkalis, gives a new dihydroxy-naphthalene disulphonic acid having the constitution—

By carrying the fusion with alkalis to a higher temperature, another sulphonic acid group is replaced, and there results  $1.1'.3.3'$ -tri-hydroxy-naphthalene sulphonic acid, which, like the other derivatives mentioned, can also be used for the production of colouring matters.—T. A. L.

*Improvements in the Production of Oxy-Anthraquinone.* O. Imray, London. From "The Farbwerke vormals Meister, Lucius, and Brüning," Hoechst-on-the-Maine, Germany. Eng. Pat. 17,542, September 18, 1893.

CONTRARY to what has been previously stated, it is found that nitro-anthraquinone, when boiled with caustic alkalis, is converted into *o*-hydroxy-anthraquinone. Nitro-anthraquinone, obtained by nitrating anthraquinone in sulphuric acid, is heated in a vessel provided with a reflux condenser with an equal weight of caustic soda and 10–20 times its weight of ethyl or methyl alcohol. The boiling is continued for about two days, when the liquor is poured into cold water, and the sparingly-soluble sodium salt separates out. The *o*-hydroxy-anthraquinone is purified by precipitation from its dilute alkaline solution.—T. A. L.

*Manufacture of a Novel Colouring Matter.* O. Imray, London. From "The Farbenfabriken vormals Meister, Lucius, and Brüning," Hoechst-on-the-Maine, Germany. Eng. Pat. 17,543, September 18, 1893.

THE colouring matter described is obtained by the action of alkalis on the product formed by the acid reduction of dinitro-anthrachryson disulphonic acid. By reducing dinitro-anthrachryson disulphonic acid in an acid solution a colouring matter is obtained which dyes wool violet from an acid bath and chromed wool blue. By boiling the product obtained with a somewhat dilute sodium carbonate solution for about two hours, a red crystalline compound gradually separates. The solution is made slightly acid and the colouring matter is precipitated with salt from the hot solution. It forms a red crystalline powder dissolving in water with a red and in dilute alkalis with a blue colour, whilst an excess of alkali precipitates the alkali salt of the sulphonic acid, which is sparingly soluble. In concentrated sulphuric acid the dyestuff dissolves with a fluorescent bluish-red coloration. The free sulphonic acid is only slightly soluble in hot alcohol and acetone. The colouring matter dyes wool red from an acid bath and blue on a chrome mordant. The shades produced are said to be fast to light and fulling.—T. A. L.

*Improvements in the Manufacture of Beta-methyl-eurhodine.* B. Willeox, London. From "The Badische Anilin and Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 17,572, September 18, 1893.

THIS is an extension of Eng. Pats. 10,138 and 10,138A of 1892 (this Journal, 1893, 593 and 594), giving an alternative method for the production of  $\beta$ -methyl-eurhodine, which originally was prepared by heating the azo dyestuff from diazo sulphanilic acid and methyl-*p*-toluidine, together with  $\alpha$ -naphthylamine hydrochloride in presence of a suitable diluent. According to the present specification the same product is obtained by the interaction of  $\beta$ -hydroxy-naphthoquinone imide and methyl-*o*-tolylene diamine. The following is the method employed—About 173 kilos. of  $\beta$ -hydroxy-naphthoquinone imide, 136 kilos. of methyl-*o*-tolylene diamine, and 1,000 kilos. of glacial acetic acid, are heated on the water-bath. When the reaction is complete, which is ascertained by working up a test from time to time until no increase in the amount of colouring matter formed takes place, the melt is repeatedly extracted by boiling with very dilute hydrochloric acid. The extracts are filtered, and when cold are precipitated with caustic soda. The brown precipitate obtained is filtered, washed with water, and dissolved in dilute hydrochloric acid, from which, after filtering, the  $\beta$ -methyl-eurhodine is precipitated by adding salt. It may be further purified by dissolving in a slight excess of ammonia, and, after filtering, reprecipitating with salt. The  $\beta$ -methyl-eurhodine hydrochloride so obtained is a red crystalline powder, which dissolves easily in water to a red solution.—T. A. L.

*The Manufacture and Production of New Diazo Dyes.* B. Willcox, London. From "The Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 18,317, September 29, 1893.

THE colouring matters obtainable according to this invention are produced by the action of diazo compounds on 1,4-naphthylene diamine, the combination taking place first in an acid and afterwards in an alkaline solution. Dyestuffs from diazo compounds and naphthylene diamine appear to have been obtained according to Eng. Pat. 17,466 of 1887 (this Journal, 1888, 839), but these compounds on treatment with nitrous acid are diazotised, whereas the products obtained according to the present invention are destroyed by nitrous acid. About 23 kilos. of 1,4'-naphthylene diamine are dissolved in 600 litres of water, cooled, and the diazo-sulphanilic acid from 19.5 kilos. of sodium sulphanilate, 50 kilos. of 27 per cent. hydrochloric acid, 400 litres of water, and 7 kilos. of sodium nitrate, is run in. The formation of the colouring matter is not complete for about 12 to 24 hours, during which the mixture is stirred. When a sample on boiling no longer evolves nitrogen, a solution of 120 kilos. of caustic soda in 1,000 litres of water is added. A second quantity of the diazo compound from 21.5 kilos. of sodium naphthionate, 50 kilos. of hydrochloric acid, 1,000 litres of water, and 7 kilos. of sodium nitrite in 10 per cent. solution, is then run in and the mixture is stirred for 24 hours. As the diazo dyestuff forms, the red solution of the azo dyestuff turns blue; and when a sample, after acidifying, on boiling no longer gives off nitrogen, the colouring matter is precipitated with salt, filter-pressed, and dried. The dyestuff thus obtained forms a bluish-black powder, which dissolves to a blue solution in water.—T. A. L.

*Improvements in the Manufacture of Alpha-beta-dimethyl-eurhodines.* J. Y. Johnson, London. From "The Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 18,925, October 9, 1893.

ACCORDING to Eng. Pats 10,138 and 10,138A of 1892 (this Journal, 1893, 593 and 594), of which this an extension,  $\alpha$ -methyl-homo-eurhodine is prepared by the interaction of an amido-azo compound of *p*-toluidine and methyl- $\alpha$ -naphthylamine, and is subsequently converted into the dimethyl-eurhodine by alkylation. It has now been discovered that both alkyl groups may be directly introduced into the non-alkylated eurhodines by the prolonged action of an alkyl iodide. Thus homo-eurhodine,  $C_{17}H_{15}N_3$ , when treated with methyl iodide, yields a mixture of the hydriodides of  $\alpha$ -methyl-homo-eurhodine,  $\alpha$ - $\beta$ -dimethyl-homo-eurhodine, and unaltered homo-eurhodine. After basifying, the mixture is again treated with methyl iodide, and this process is repeated until the product consists only of dimethyl-homo-eurhodine. This is practically carried out as follows:—About 26 kilos. of homo-eurhodine, 30 kilos. of methyl iodide, and 150 kilos. of methyl alcohol, are heated for four hours in an enamelled autoclave to 120° C. The melt is then diluted with water, the precipitate filtered off, and the product is treated in a fine state of division with 200 kilos. of alcohol and 42 kilos. of caustic soda-lye containing 28 per cent. NaOH. Then precipitate with water, wash, press, and dry, and again treat the dry residue with 30 kilos. of methyl iodide and 150 kilos. of methyl alcohol for four hours at 120° C., and work up as before. If the product still contains appreciable quantities of eurhodine and  $\alpha$ -methyl-eurhodine the treatment must be repeated. Their presence may be detected as follows:—The product is dissolved in just sufficient hydrochloric acid and carefully neutralised with ammonia, when any eurhodine, or methyl eurhodine separates as a yellow precipitate, whereas the dimethyl derivative remains in solution. The crude product obtained is boiled with 1,000 litres of water containing 0.25 per cent. of hydrochloric acid, and the filtered extract is precipitated with salt. In order to further purify it, it is dissolved in water, ammonia is added in slight excess, and after stirring half an hour the precipitate is filtered off and salt is added to the filtrate to throw down

the  $\alpha$ - $\beta$ -dimethyl eurhodine hydrochloride, which is filter-pressed and dried. The lower homologue from the eurhodine,  $C_{16}H_{13}N_3$ , can be obtained in a similar manner.

—T. A. L.

*Processes for the Production of Dyestuffs.* A. Bang, Leeds. From G. A. Dahl, Barmen, Prussia. Eng. Pat. 18,958, October 10, 1893.

BLUE to violet dyestuffs are obtained by the action of di- $\beta$ -naphthyl-*m*-phenylene diamine sulphonic acids on the nitroso derivatives of alkylated aniline or toluidine, or on certain amido-azo compounds and their sulphonic acids. A solution of 56.1 kilos. of sodium di- $\beta$ -naphthyl-*m*-phenylene diamine disulphonic acid in 500 litres of water, cooled to 5°–10° C. and acidified with 20 kilos. of 30 per cent. acetic acid, is slowly mixed with 28 kilos. of nitroso-dimethyl-aniline hydrochloride. When the nitroso compound has disappeared, the solution is neutralised with soda and the dyestuff salted out. It dyes wool deep blue from an acid bath. A similar dyestuff is obtained by heating together to about 90–95° C. a mixture of 49 kilos. of sodium dimethyl-amido-azo-benzene sulphonate, 58 kilos. of sodium di- $\beta$ -naphthyl-*m*-phenylene diamine sulphonate, 600 litres of water, and 20 kilos. of 30 per cent. acetic acid for about four hours. The solution is neutralised with soda, and the dyestuff separated by adding salt.—T. A. L.

*Improvements relating to the Production of Pyrocatechine.* J. H. Baum, Frankfort-on-the-Maine, Germany. Eng. Pat. 21,853, November 15, 1893.

PYROCATECHOL is produced from  $\alpha$ -phenol disulphonic acid by fusing it with about an equal weight of caustic soda and hydrolysing the pyrocatechol sulphonic acid formed by heating to a high temperature with 25–30 per cent. sulphuric acid. About 10 kilos. of sodium  $\alpha$ -phenol disulphonate are fused with 10–15 kilos. of caustic soda in an autoclave for 8–10 hours at a temperature of 280–300° C. and a pressure of 2–3 atmospheres. The melt is dissolved in dilute sulphuric acid, neutralised with chalk, evaporated, cooled, and filtered, and the mother-liquor is heated in an autoclave with 10 kilos. of 50 per cent. sulphuric acid to 180–220° C. Steam is then blown through the solution obtained until all the phenol is removed, and after having been decolorised with animal charcoal the pyrocatechol is extracted with ether. The yield is said to be 50 per cent. of the theoretical.—T. A. L.

*Manufacture of Polyoxanthionine Colouring Matters Dyeing on Mordants.* O. Imray, London. From "The Society of Chemical Industry in Basle," Basle, Switzerland. Eng. Pat. 12,214, June 23, 1894.

THE nitroso derivatives of 2,3'- and 2,2'-dihydroxy-naphthalene on treating with sodium bisulphite and hydrochloric acid, are converted into amido-dihydroxy-naphthalene sulphonic acids, which on oxidation with nitric acid yield hydroxy-naphthoquinone sulphonic acids. Colouring matters are obtained from these compounds by heating them together with the thiosulphonic acids of aromatic *p*-diamines in acetic acid, or the nitroso derivatives of the secondary or tertiary aromatic amines may be condensed with the hydroxy-naphthoquinone sulphonic acids in presence of thiosulphates. Nitroso-dihydroxy-naphthalene obtained from 400 kilos. of 2,2'-dihydroxy-naphthalene is stirred into 2,000 kilos. of a solution of sodium bisulphite or 36° B. at 20–30° C. The solution is then filtered, made acid with hydrochloric acid, heated to 50° C., and left to stand for 10 hours. The 1,2,2,4'-amido-dihydroxy-naphthalene sulphonic acid separates out and crystallises from water in needles. By oxidation with 30 to 60 per cent. nitric acid, it yields hydroxy-naphthoquinone sulphonic acid, of which the potassium salt can be precipitated by adding potassium chloride to the nitric acid solution. The formation of a dye-stuff therefrom is illustrated as follows:—A concentrated solution of 7 kilos. of sodium nitrite is

mixed with 107 kilos. of a 28 per cent. solution of methylbenzyl-aniline sodium sulphate acidulated with 21 kilos. of hydrochloric acid of 21 B. After standing 12 hours, 35 kilos. of 40 per cent. acetic acid and a solution of 50 kilos. of sodium thiosulphate are added, the whole being then warmed to 80—100 °C. until the nitroso compound has disappeared. A concentrated solution containing 30 kilos. of the potassium salt of 2'.1.2.4-hydroxy-naphthoquinone sulphonic acid is then added, and the whole is heated for 2—3 hours. The new dye-stuff separates from the dark-coloured liquid as a green crystalline powder. It dyes wool mordanted with chromium salts from an acid bath a pure bright blue, fast to light, washing, and fulling.—T. A. L.

## V.—TEXTILES: COTTON, WOOL, SILK, Etc.

*Treatment of Tussah Silk before, during, and after Dyeing.* H. Silbermann. *Färber Zeit.* 5, 1894, 198—201, 216—217, and 234—236.

See under VI., page 880.

*The Influence of Weighting on the Specific Gravity of Silk.* Chem. Zeit. 18, 1894, 744.

## PATENTS.

*Improvements in Apparatus for Gassing Yarn and other Threads.* S. Clough, Steeton, Yorks. Eng. Pat. 10,736, June 2, 1894.

The invention consists in an improved burner with small apertures in the side, so placed that the flame is emitted horizontally. The thread thus passes through the whole length of the flame, the singeing dust is blown away, and can neither fall into the burner nor adhere to the yarn.

—R. B. B.

*Improvements in or appertaining to Apparatus for Sizing Yarn.* J. Maag, Winterthur, Switzerland. Eng. Pat. 11,013, June 6, 1894.

A saving in cost is effected by applying the size direct in the cold condition, instead of boiling it before use. To prepare the yarn for sizing, the threads from the warp rollers pass directly to a receptacle, in which they are subjected, by means of an injector or otherwise, to a current of moist air. Thence they are led into the size-box, excess of size is removed by squeezing-rollers, and the threads pass into the upper part of a drying chamber, where they meet with air of moderate dryness and warmth; by means of rollers they take a circuitous course, passing gradually downwards, encountering hotter and drier air as they descend, and leaving the chamber close to the source of heat. To separate threads which are stuck together, they are led to a set of polished rollers arranged like a furnace-grating; the threads pass alternately above and below these rollers, and are finally wound on a common warp-beam.

—R. B. B.

*Improvements in the Process of and Apparatus for Scouring and Degreasing Wool.* W. E. Heys, Manchester. From G. Malard, Paris, France. Eng. Pat. 11,754, June 18, 1894.

The principal object of this patent is to obtain the solution resulting from wool-scouring in a state of higher concentration than is usual at present. The machine consists of a long travelling apron, underneath which are a number of tanks containing the scouring liquid. The liquid is pumped from these tanks on to perforated distributors, which shower it down upon the wool. It falls into a trough or shoot, so pivoted between two compartments that the liquid may be allowed to fall either into the compartment from which it was pumped or into the next. The fresh scouring liquor is led into the tank nearest to the delivery end of the apron, and the liquor increases in density passing towards the feed end. A portion of the liquid pumped from the tank at the feed end is diverted from the distributor into a small box in which floats a hydrometer. When the liquid reaches a certain density the hydrometer in rising closes the contact of an electric circuit, and rings an electric bell. The attendant then operates a rod, which turns the shoot above the last tank, so that the liquid passes into a special tank for receiving concentrated liquor; and at the same time, by means of a float in the last tank, the next shoot diverts liquid from the last but one into the last, and so on; fresh liquid from a supply vessel filling up the emptied tank at the delivery end. When the electric bell ceases, the attendant reverses the rod, and the liquid again flows through the wool into the vessel whence it was pumped, until the required density is once more attained.—R. B. B.

## VI.—DYEING, CALICO PRINTING, PAPER-STAINING, AND BLEACHING.

*Treatment of Tussah Silk before, during, and after Dyeing.* H. Silbermann. *Färber Zeit.* 5, 1894, 198—201, 216—217, and 234—236.

The tussah silk does not contain silk-glue encircling the individual fibres and binding them together, but the whole fibre is impregnated with the bast; the same applies to the colouring matter, which is not separate as in real silk, but penetrates through the whole fibre. The raw tussah fibre contains 5 to 6 per cent. of mineral compounds, which are reduced to 0.25 per cent. by removing the bast. These salts consist of potash, soda, silicates, carbonates, and sulphates of lime, magnesia, and alumina. The organic constituents of the bast consist largely of oxidised tannin compounds in combination with iron, which are of a brownish colour; a lime salt, which is precipitated by a tannin solution in the presence of acetate of soda; and a wax-like fat of an acid character (about 1 per cent.), which can be easily extracted with alcohol. The acid character of the bast renders it necessary to employ alkaline chemicals for its removal, while a neutral soap answers the purpose with genuine silk. The alkaline treatment with potash, soda, and ammonia was early adopted in Europe (Riot, Eng. Pat. 1609, 1855). The following successful method of removing the bast is now adopted:—

*Removal of Fatty Substance or Stripping.*—This treatment consists in removing from the fibre the fatty and gummy matters and also a certain quantity of the natural colouring matter. The cocoons are softened in boiling water before unreeling, and the cleansing bath contains crystal soda in the proportion of 10 per cent. of the weight of the silk with 20 to 30 times as much water. Commencing with tepid water, it is gradually raised during a quarter of an hour to 40° C., the tussah being agitated, first quickly and then slowly, until the bath assumes a dirty-brown colour, when it is run off. After half an hour's agitation the silk is removed and freed from water by

wringing or by centrifugal machines, losing by the treatment about 8 to 10 per cent. of its raw weight. For certain purposes, as insulating telephone wires, &c., it is unnecessary to remove the bast entirely from the tussah, simply washing in three baths of tepid water to free the fibre from fat and dirt, drying and stretching being sufficient.

**The Boiling off.**—A special method for a thick thread tussah is as follows:—After removing the fat, the silk is put in a fresh bath of 30 per cent. of crystal soda at 10° to 15° C., and raised during half an hour to 85° to 90° C., at which temperature it is boiled for 1 to 1½ hours. After running off and thoroughly washing, it is, with the usual precautions, treated in a boiling bath of 10 per cent. fuming hydrochloric acid for about 10 minutes. It is a fact that part of the brown colouring matter, which at 60° to 65° C. is removed from the bast, fixes itself upon the fibre when the temperature reaches 80° to 90° C., and the boiled tussah becomes a deeper shade of brownish-yellow by the action of the acid.

By this treatment (a better one for fine silks, though more costly) the fat is removed in a soda bath (10 to 15 per cent. crystal soda), heated to from 50 to 60° C. The silk is then put into a boiling soap bath and well agitated without further heating. After three-quarters of an hour the bath is again raised to 95° C. For silk of fine fibres less soap is required; generally about 30 per cent. of good olein soap suffices. The removal of the bast is performed in about 1 to 1½ hours. If the slightest quantity of soap remain on the fibres they will have a greyish tint. Careful testing and observation show that the employment of soap gives a more favourable result with regard to the strength than soda, while the latter produces a fibre with greater elasticity. Where strength and elasticity have to be considered a mixture of soap and soda is therefore preferable. A solution of sodium hydrate, 6 to 8 per cent. of the weight

of silk, removes the bast in about half an hour at 60° C. The fibre, after boiling, has a high gloss, and is only slightly affected in strength and elasticity, but it has to be treated quickly and with care, otherwise the lye has a deleterious effect. The addition of soap to the lye is not so advantageous as to submit to soaping after boiling. The soap used for thus removing the bast, is 3 to 5 per cent. of the weight of silk, allowing for the hardness of the water employed, and the time, about half an hour at 35° to 40° C.; after this the material is well washed.

The accompanying illustrations represent microscopical views of the fibres of real silk (Fig. 1), of Indian (Fig. 2), and China tussah (Fig. 3). In each *a* indicates the raw fibre covered with the bast, *b* indicates the cleaned fibre, *c* a section of the raw, and *d* of the silk cleansed from bast.

**The Samingor Acid Treatment.**—This operation consists in treating the tussah in an acidified water bath mainly to remove any mineral matter remaining.

The bath is used at about 30° to 40° C. for soaped tussah, and at boiling temperature with 10 per cent. fuming hydrochloric acid for fibre that has been treated with soda. The strength of the fibres is weakened somewhat by this operation, while the elasticity is increased about 10 per cent. China tussah of European spinning (China Filatur) is by the boiling acid treatment improved both as to strength and elasticity, probably because it contains comparatively little inorganic compounds, while Indian and ordinary China tussah contain a larger percentage. The latter silk by treatment with hydrochloric acid is freed from these mineral ingredients, and naturally becomes weaker as to textile strength, though the elasticity is increased by the removal of these brittle salts.

The bleaching of tussah silk, like that of other textile fibres, consists in oxidising the natural colours with the formation of colourless derivatives.

Fig. 1.

Fig. 2.

Fig. 3.

The results obtained by all previously devised and tedious operations were no better than the present method of using simply hydrogen peroxide. To hasten the bleaching it was proposed to saturate the fibre with turpentine oil and expose it to the light for the generation of ozone.

An English method (Eng. Pat. 1414, 1878), consisting of the use of hydrogen peroxide mixed with ammonia and ammonium hypochlorite, confirms the advisability of using a hypochlorite salt. A chlorate salt has also been recommended. For 100 kilos. tussah there is prepared, for example, a bath of 500 litres of 3-volume hydrogen peroxide, 5 kilos. ammonium carbonate, 5 kilos. potassium chlorate, and 3 kilos. sodium nitrite. The fibre is left in the bath 12 hours, dried by a current of air at 20° to 25° C., returned to the same bath another 12 hours, and then dried.

The present methods of employing hydrogen peroxide with the addition of water-glass, soda, ammonia, &c., are worth mentioning. For 100 kilos. tussah a bath is prepared of 500 litres of 3-volume hydrogen peroxide (or, for example, 150 litres of 10-volume hydrogen peroxide), 20 litres ammonia of 22°, and 2 to 3 kilos. sodium hydrate. The treatment takes 24 hours; the material is then washed, and, if

necessary, returned to a warm bath. The quantity of caustic employed is in proportion to the acidity of the commercial hydrogen peroxide.

Another method is to use 150 to 160 litres of 10-volume hydrogen peroxide, 3 kilos. potash, 5 kilos. ammonium carbonate, and a quantity of ammonium hypochlorite obtained by decomposing 2 kilos. ammonium sulphate with calcium hypochlorite ( $\text{CaCl}_2 \cdot 2\text{Ca}(\text{ClO})_2$ ), from which the calcium chloride is removed by Glauber's salt.

In some works the bleaching is first performed with peroxide of hydrogen with the addition of water-glass, followed by an aqueous solution of sulphurous acid, or the gas itself.

The bleaching action of the peroxide of hydrogen is increased if the tussah, without being washed, is hung up in the air for several hours, whereby the evaporation concentrates the bleaching liquor, making it more effective, and the air and light give rise to the formation of ozone.

A peculiar but effective operation consists in bringing the peroxide of hydrogen and alkali together upon the fibres while suspended in the air. This is done by impregnating the fibres with hydrogen peroxide and then suspending them in a room hermetically sealed, and upon the floor of which vessels are placed containing ammonia. The material is

hung for 12 to 24 hours and the operation repeated until sufficiently bleached. The fibres appear to be attacked less by this treatment than by bleaching in a bath.

Another process consists in impregnating the fibre with concentrated peroxide of hydrogen and then steaming under pressure, by which means the bleaching is effected in an hour or two. Zinc-dust or a weak electric current is occasionally employed to hasten the bleaching, and powdered sodium peroxide instead of hydrogen peroxide has been recommended, and will probably be more generally adopted. (Compare *Färber Zeit.* 1891-92, 263; this *Journal*, 1892, 814; 1893, 329.) Cheaper oxidising agents than hydrogen peroxide, such as potassium permanganate, bromine water, &c., do not give satisfactory results, besides attacking the fibres somewhat strongly.

Electrolytic and electro-ozone processes may possibly have a great future before them as a means for bleaching tussah silk. Between tussah and genuine silk there are two important points of difference, which largely influence the dyeing of the fibres. Tussah has a much smaller affinity for colours than genuine silk, and differs considerably in its physical structure. Whilst real silk takes the dye very easily, the tussah shows a much less power of absorbing it—a property in which it resembles most vegetable fibres. The difference is also seen in its solubility in cuprammonium solutions, zinc chloride, hydrochloric acid, &c., as compared with the mulberry silk; and also in its power of resisting chemical agents in general. To dye tussah fibre it is necessary that the bath should be hotter and contain more acid than with real silk; it should be introduced at 60° to 70° C., and finished at the boiling temperature. Permanent colours are used when possible, and azo colours, diamine colours, &c., have recently been introduced for dyeing tussah, with success. With diamine colours the dyeing is performed in pure water with the addition of common salt and Glauber's salt, while soda and soap are employed for the diphenyl colours. Light and clear shades are generally produced with the usual colours; all the rose shades, from the most yellow to the most blue, in a weak soap bath with rhodamine and phosphine, or rhodamine with alkali violet; all the light blues with alkali blue, &c.

Other kinds of tussah silk, as the Indian *Eria* silk of *Attacus ricini* behave in the dyeing operation similar to tussah, while some, as the Moonga silk of *Antheraea assama* behave like genuine silk. The most difficult colours to dye tussah fibre are the lightest and darkest. Although both the raw and the cleansed fibre appear to be uniform in texture, its irregular and uneven structure shows itself after bleaching. Even in the same skein different parts are bleached and dyed with varying degrees of intensity. The light shade which the tussah has after bleaching is due to oxidised derivatives of the natural colouring matter, which cannot be removed with a stronger bleach without injuring the fibres. Sometimes a short, energetic, hot boiling in a soap bath after the bleaching, has a good effect, but this soaping affects the fibres, and should not be continued more than 10 to 15 minutes. With light colours, as white, sky-blue, &c., there is a tendency to become striated, but with cream and pink shades it is not so to the same extent, as the yellowish shade of the bleached tussah has less effect upon creams and pinks. It is therefore preferable to employ a soap bath in dyeing light shades, of course using basic dyes and the alkali colours, such as may be employed with neutral or alkaline soap, alkali blue, neutral diamine dyes, or the more alkaline, substantive tetrazo colours.

A difficulty in dyeing tussah lies in the fact that the fibres never take the darkest shades—as marine blue—sufficiently deep, owing to the great resistance the fibre offers to colouring matter. The fibres of tussah silk are not cylindrical like genuine silk, but are flattened, and the substance of which they are composed is not homogeneous like the structureless fibre of the mulberry silk. Tussah silk consists of a number (15 to 25) of fine fibrils running parallel and bound together in bundles, a structure which is distinguished under the microscope, and gives the surface of the tussah an uneven striated appearance. The beautiful gloss peculiar to genuine silk is absent in tussah. The method of dyeing tussah black is similar to that em-

ployed for real silk, and being rather important and difficult a few details may be given. The tussah fibre is treated for several hours with basic sulphate of iron mordant at 30° B., washed twice, and then with a catechu bath (20 to 25 per cent. catechu), to which is added some fustic extract. A catechu bath is very beneficial to genuine silk, but great care must be observed with tussah that the temperature does not exceed 65° to 70° C., otherwise the catechu leaves the fibres and returns to the bath. This temperature must be retained for about three hours. After washing, it is dyed with logwood and soap at 55° to 70° C. for two to three hours, with the addition of gelatin, and cleared with acetic acid. Another method for blue-black is to treat the fibre for an hour with iron mordant, rinsing, mordanting for two hours in an alum solution of 4° to 5° Baumé, rinsing, and dyeing in a bath (for 10 kilos. tussah) of 6 to 7 kilos. logwood 300 grms. fustic, and 2 kilos. soap.

For a deep, full black, although more costly, the following method may be used:—Mordant during six hours in an iron mordant of 30° Baumé, soaping, blueing (with 12 per cent. yellow prussiate of potash and 9 per cent. hydrochloric acid), washing, treating in an alum bath of 5° Baumé, washing, treating with ferrous sulphate 24 per cent., and dyeing in a boiling vat containing 60 per cent. logwood, 15 to 25 per cent. fustic (according to the shade), and 25 per cent. soap. To finish, one can employ with success the method adopted for *seru* silk, that is, alternately treating with chestnut extract and iron pyrolignite until the desired depth of blue colour is obtained.

With each of these methods it is an advantage to treat the tussah before dyeing with a weak solution (according to the strength of the fibre, 3° to 1½° Baume) of hydrofluoric acid. Hydrochloric acid may be used, but it gives inferior results. This treatment removes the inorganic compounds of the tussah which resist the mordant. The finished dyed tussah, like Schappe and organzine, is brightened and cleared with oil—olive oil for fine tussah fibre, or cheaper vegetable oils may be used if made into an emulsion (by well shaking with carbonate of potash lye) and added to a tepid acidified clearing bath. The bath is well agitated and the tussah drawn quickly through for about five minutes, and, after winding, freed from water in a centrifugal machine. The quantity of oil used, is according to the silk and the purpose for which it is to be employed; more is used for throwu silk than for *tram*, generally 5 to 8 per cent.; whereas for *grège* rarely more than 3 per cent.

—S. P. E.

#### *The Use of Benzidine Colours in Discharging Indigo.* G. Stein. *Färber Zeit.* 5, 1893-94, 269.

MANY of the benzidine colours can be used in producing coloured discharge prints on dyed indigo cloth, both by the chromate and acid process and by the ferriyanide and alkali process, the latter giving the better results. Brilliant Geranine B, Chloramine yellow, and Chrysophenine may be applied in the acid way; whilst in the alkaline process Chloramine orange, Brilliant Geranine 3 B, Heliotrope 2 B, the Congo and Mikado oranges, and the Benzo-browns may also be used. In applying the alkaline process, the colour may be added to a discharge paste containing potassium ferriyanide, and the discharge be effected by a passage through caustic soda solution; or the colour may be mixed with the ferriyanide and carbonate of magnesia, and the discharge effected by one hour's steaming. The process may be varied by dyeing all over with indigo and a benzidine colour and discharging in the acid or alkaline way. Thus with Chloramine orange an orange print on a black ground is produced; with Congo orange G an orange figure on a bronze ground, &c.—W. E. K.

#### *Resists with Tannin Mordants.* Ch. Casanovas. *Färber Zeit.* 5, 1894, 233-234.

THE following operations are suitable for this method of treatment:—(1) Printing the resists and drying; (2) blocking in the tannin and drying; (3) fixing the tartar emetic and washing; (4) dyeing with basic coal-tar colours,

washing, bleaching, and drying. The best means for resisting appears to be tartar emetic (potassium antimonious tartrate), but the tannin-antimony lake fixes itself more or less upon the fibres and afterwards colours them. Owing to the tannin, after blocking, penetrating the fibres before the tartar emetic has time to act as a resist, the parts which should remain white take the dye, and the subsequent soaping and bleaching is ineffectual to make them perfectly colourless. The resist of Prud'homme for steam aniline dyeing, by adding common salt to the resist to obtain a more concentrated tartar emetic, does not give a better result, besides being very hygroscopic, and in the tannin blocking running and not remaining clear and distinct, especially when treated in the "hot-blue." The easily-soluble resist thus gets on the crown of the printing roller, and ultimately comes off.

Magnesium acetate does not give a good result; the resisting parts are, after dyeing, very much coloured. Basic antimony oxalate used as a resist gives a better result than the means proposed by Jaquet, viz., to mix directly with tannin steam-dyes. Freshly precipitated and concentrated antimony hydroxide does not resist. Kertesz proposed to fix the tannin steam-dyes by means of freshly-precipitated antimony oxide. Zinc salt does not appear to resist for steam aniline colours any better than tartar emetic. More suitable than zinc salt and tartar emetic is the antimony salt of de Haen, which, together with tannin, could be used for cloth and calico were it not so expensive.

A process devised by Lamy and Kopp consists in the treatment with iron mordant, dunging with cow-dung, then treatment in sumac, and afterwards dyeing with basic coal-tar colours. This process can also be used as a resist for printing under or upon an iron mordant; the parts thus treated for resisting subsequently take no colour when dyed with aniline colours; the treatment is well known and satisfactory.

Alumina throws down the tannic acid, and with this mordant lighter shades can be dyed, such as lilac, rose, &c.; the iron, however, produces cloudy effects by forming a lake with the tannic acid. It is said that English goods, although dyed twice, are cheap, but they are not all one could desire in a genuine article.

Blocking in the tannin (20 grms. per litre), treating with tartar emetic (5 grms. per litre), and dyeing in a bath with an iron salt would give the same shade. The result of this method of resisting is satisfactory, and if in the dyeing with tannic acid a little is fixed upon the white parts, these will be restored to their natural whiteness by the chlorine treatment after the second dyeing. Treating with tartar emetic or steaming after dyeing does not improve the result. Owing to the difficulty of producing white with tartar emetic resist, the method of Koehlin frères with caustic soda was introduced, by means of which a beautiful product is obtained. Still the strong caustic lye which is employed renders the fibre liable to the danger of acquiring affinity for the dye and producing an imperfect white. Relying upon the Davy method of estimating tannin quantitatively, and upon the improved modification of Ichberg for titration of the tannic acid, the author has proposed the following as a suitable resisting agent:—900 cc. of thickening of British gum 20 grms. of gelatin, dissolved in 100 cc. of water and added to the thickening, to which are added, cold, 80 cc. of nitrate of alumina of 15 Baumé.

Stamping, drying, blocking in a somewhat concentrated solution of tannin, fixing with tartar emetic, and dyeing with aniline colours and washing follow. (More gelatin may be used, but it is better to boil the gelatin until it ceases to run when cold; it precipitates the tannin.)

In this manner a perfect result is obtained, and the same as with aniline colours that are fixed with tannin and tartar emetic.—S. P. E.

*Cotton-dyeing with Benzidine Colours.* J. Mullerus. *Färber Zeit.* 5, 1894, 234.

In the *Chem. Zeit.* 31, 1894 (this Journal, 1894, 124—125), an interesting article appeared in which Dr. C. O. Weber speaks of the possibility of obtaining an organic lake-forming compound which would furnish a means for

dyeing with benzidine colours upon cotton fibres as with wool. Weber says he has not succeeded, after many attempts, in obtaining with egg albumin or blood albumin lanugine acid, or with an insoluble salt of the sulphonic acid of a dye, the desired lake-forming amine or amido-acid. Weber does not appear to have experimented with albumin alone; he only mentions that the blood albumin, at least in a coagulated form, has the property of fixing sulphonic acid colours. As the fastness in cotton-printing with albumin-fixed benzidine and diamine colours is so striking, the idea that the function of the albumin is only that of an indifferent mordanting agent, is conceivable. Weber's supposition seems to endorse this view. For three years the author has employed blood albumin with sulphonic dyes for the production of colours resistant to light, with "Rouge de St. Denis." Before dyeing he prepares the cotton in a bath containing 10 per cent. of blood albumin 1:1 and 10 per cent. Turkey-red oil of 60 per cent., drying and dyeing as usual. The stuff thus prepared takes the colour better and is fuller, and stands water and light well. It is noticeable that by the use of albumin solution alone, even with double the quantity, an inferior result is obtained.—S. P. E.

*The Influence of Weighting on the Specific Gravity of Silk.* H. Silbermann. *Chem. Zeit.* 18, 1894, 714.

See under XXIII., page 907.

#### PATENTS.

*Improvements in Apparatus for Dyeing Slubbing or Slivers of Fibrous Material.* J. Rhodes and A. E. Perkins, Bradford, Yorks. Eng. Pat. 13,379, July 13, 1893.

THE object of this invention is to uniformly expose the material to the dyeing liquor, without treatment liable to derange the fibres. The apparatus consists of a tube or series of tubes, each tube being as long as the height of the building will allow. The tubes are arranged in pairs over vats containing guide rollers, and the dye liquor, as well as the material, passes down one tube into the vat, and rises in the second tube, at the top of which the slivers pass between squeezing rollers, and may then be carried through one or more further pairs of tubes, similarly supplied with dyeing liquor, to complete the dyeing operation. The slivers are attached to an endless flexible apron. The flow of the liquid through the tubes may be either in the same or the reverse direction to that of the material; or the liquid may be stationary in the tubes during the passage of the material.—R. B. B.

*Improvements in Machinery for Washing and Scouring Wool, Worsted, Yarn, Slubbing, and other Fibres.* Brintons, Limited, and L. Hanson, Kidderminster. Eng. Pat. 14,865, August 3, 1893.

THE object of the invention is to construct a self-acting washing and scouring machine without the use of reciprocating forks. The materials are carried along on a series of endless aprons; below each apron is a vessel containing the washing liquid, which is pumped from here into a shallow vessel, with a perforated bottom, above the apron, and thence showered down upon the material. A series of four or more such machines should be in use together, the wool being treated with the dirtier scouring liquor from previous lots in the first machine, and with fresh clean water in the last. At the delivery end of each apron the wool passes between squeezing rollers.—R. B. B.

*Improvements in the Process for Producing Fast Colours from Direct Dyes on Cotton.* O. Imray, London. From The Farbwerke vormals Meister, Lucius, and Brünig, Höchst-am-Main, Germany. Eng. Pat. 15,326, August 11, 1893.

A GREAT defect of many "direct cotton" dyes is their want of fastness to washing, and the readiness with which they

bleed on to the undyed portions of the fibre. According to this patent, the colours are made fast to soap by treatment of the fibre, after dyeing, with a solution of a chromium salt, preferably at the boil. The colouring matters most suitable for this treatment are those simple and mixed azo colouring matters which dye directly on cotton, and which contain as components salicylic acid, ortho- and meta-cresotic acid (hydroxy-toluic acid),  $\alpha$ -hydroxy-naphthoic acid, or dihydroxy-naphthalene-mono- and disulphonic acids derived from 1,8-dihydroxy-naphthalene.

Basic chromium salts are best suited for this purpose. A nearly complete formation of the chrome-lake will be obtained, for example, by passing the goods for a few minutes through a boiling solution containing 0.5 gram. of basic chromium chloride per litre. The following is an example of the manner of carrying out the invention:—

*Fast Yellow on 20 kilos. of Cotton Thread.*—The previously well-boiled thread is boiled for three-quarters of an hour in a bath containing:—

0.8 kilo. cotton yellow G.  
2 „ sodium phosphate.  
0.2 „ soap.  
2 „ common salt.  
600 litres water.

It is then taken up, left to cool, well wrung, and worked for half an hour at the boil in—

600 litres of water,  
0.5 kilo. basic chromium chloride;

after which it is slightly rinsed and, if necessary, soaped.

—R. B. B.

*Improvements in Apparatus for Treating Fibrous Materials, Yarns, or Threads with Mordanting, Preparing, Dyeing, or other Liquids.* T. P. Miller, Cambuslang, Lanark. Eng. Pat. 16,038, August 25, 1893.

THE fibrous materials in an unspun condition are placed on an endless web of cotton cloth, and carried through a long trough containing the liquid. At the middle part of the trough there are a number of beetles, which are lifted by reciprocating metal pieces, but drop by their own weight on to the materials. By means of a ratchet-wheel feed, the endless web, with the materials on it, is moved forward at each ascent of the beetles, and, after passing under these, carries the materials between a pair of squeezing rollers at the delivery end of the trough.—R. B. B.

*Improvements in Dyeing Wool with Sulphonic Acids of Anthraquinone Colouring Matters.* O. Imray, London.

From The Farbwerke vorm. Meister, Lucius, and Brüning, Höchst-am-Main, Germany. Eng. Pat. 17,544, September 18, 1893.

A FURTHER application of the process described in Eng. Pat. 15,310 of 1892 (this Journal, 1893, 825). The wool is dyed in an acid bath with the sulphonic acid, and subsequently converted into colour-lake by treatment with metallic salts. The sulphonic acids employed may be those not only of alizarin, but also of anthraquinone colouring matters containing more hydroxy-groups, and of their nitro-, amido-, &c., derivatives. The method of dyeing is fully described in the previous patent.

The advantages claimed are: (1) only one bath is required; (2) greater uniformity of shade, more thorough dyeing, and shades faster against rubbing; (3) the possibility of employing the alizarin dyes in new branches of the industry.—R. B. B.

*Improvements in Rotary Washing and Dyeing Machines.*

J. W. Crabtree, Bradford, Yorks. Eng. Pat. 19,769, October 20, 1893.

THE machine consists of a fixed outer cylinder and an inner cylindrical cage, which is revolved alternately in opposite directions, and which is partly solid and partly perforated, the perforations being narrow slots cut in the

direction of rotation. Within the inner cage are a number of U-shaped longitudinal chambers, one half of the U being perforated, the other half solid. During the rotation of the cage these chambers carry liquid from the bottom, and when near the top discharge it in a spray on the fabrics. The chambers are placed with the perforations in opposite directions, so that half of them work in each direction of rotation. Inside the cage also, a number of perforated pipes are arranged for the introduction of steam in a series of fine sprays.—R. B. B.

*Improvements relating to Dyeing Wool with Chromium Lakes.* E. Hoffmann, Leipzig-Lindenau, Germany.

Eng. Pat. 11,077, June 7, 1894.

THE dyestuffs are applied in a single bath, together with the chromium salt of an organic acid, which may be tartaric, citric, oxalic, succinic, lactic, benzoic, salicylic, or malic acid. Or the organic salt is mixed with some other chromium salt, e.g., the chloride, sulphate, nitrate, fluoride, acetate, &c.—R. B. B.

## VII.—ACIDS, ALKALIS, AND SALTS.

*Notes on the Manufacture of Sulphuric Acid in America.* G. Lunge. Zeits. angew. Chem. 1894, 133—137.

THE growing demand for superphosphates has favourably reacted on the American sulphuric acid industry, and it is stated that the yearly output of acid is represented by a money value of some 6½ million dollars. The works producing the same are as a rule well erected and compare advantageously with similar European establishments.

Very little can be said about the construction of the chambers. At one of the works the author noticed a set of 12 chambers each only 8.2 metres long, and here the chamber space required and the nitre consumption were said to be very low. At another works a set of three chambers was erected, 18, 15, and 12 metres long respectively, with a plate tower inserted between each chamber. This arrangement is, however, not at work yet, and no details can be given as regards the efficiency of the plate tower in this position.

Among pyrites-kilos that of Speuce, although labour-saving, is said to be too troublesome to work. Johnson's kiln (similar to McDougall's) receives greater praise. But in the author's opinion the Frasch kiln is the best apparatus hitherto constructed for roasting pyrites. Falding's improvement (this Journal, 1893, 1032) is also remarkable; here the bricks are hollow and form channels for the circulation of air, which keeps the brickwork cool, and the heated air may be afterwards passed below the bars.

The draught is produced by means of fans of hard lead, or of wood covered with lead, fixed on rotating iron shafts, which run in lead bearings, without stuffing-boxes. They are driven by electromotors and are greatly to be recommended.

A siphon of very practical construction may be mentioned here. Its shorter leg *c* opens into a bulb *A*, which is provided on the bottom with a short exit-tube closed by means of a glass ball *a*. When setting the siphon, air is blown into the tube *b*, the acid rises into the tube *c*, and overflows from *d*. From this moment the siphon becomes self-acting and the acid enters through *a*.

The concentration of sulphuric acid is chiefly effected in platinum vessels, often in combination with cast-iron vessels, which latter are either retort-shaped or provided with a leaden lid cooled from outside (as proposed by Faure and Kessler). The gold-lined platinum vessels of Heraeus are extensively used, and are said to be a success when working with not too impure an acid. Where first cost is a consideration, cast-iron retorts are used, either wholly or in combination with platinum vessels. Thus, at one of the works the acid is concentrated up to 93.5 per cent. monohydrate in platinum vessels, and from this point up to

98 per cent. in round iron vessels of about 0.9 metre diameter and made of 5 cm. metal. The life of such a pan is about two months, and but little iron goes into solution.

Another evaporating plant consists of two platinum pans for concentrating up to 166° Tw., and of an iron pan for 169° Tw. acid. This acid is consequently somewhat impure, and is used for purifying oils. The heating is effected by means of liquid fuel. The waste heat passes over other pans and concentrates there acid from 116° Tw. to 146° Tw. It is stated that 100 kilos. of 169° Tw. vitriol require 7.5 kilos. of oil, costing about 2½d., whilst platinum stills require for a similar quantity 15–20 kilos. of coal. The iron pans last for three months.

Another combination, yielding a 98 per cent. vitriol, consists of two platinum vessels with lead covers, of which the upper vessel containing the weak acid is heated direct, and of two separately heated iron retorts provided with lids. The whole is completely surrounded with fire, which passes first below the pans and returns over the top lids.

At the California Powder Works, Pinole, California, a cast-iron pan is in use measuring 1.68 m. × 0.46 m. × 0.254 m. deep, and divided by means of partition walls into three channels, each 0.127 m. wide, for the circulation of the acid. The acid is finally delivered into Johnson and Matthey's platinum cooling apparatus, from which it is obtained perfectly clear. The vitriol resulting from 6,000 cub. metres chamber space passes through two Delplace apparatus into the iron pan, which is heated by means of mineral oil. The pans last about 4–6 months, and the resulting acid is remarkably free from iron.—H. A.

#### *The Electrolytic Production of Potassium Chlorate.* C. Häussermann and W. Naschold. Chem. Zeit. 18, 1894, 857–858.

EXPERIMENTS were made to determine the conditions most favourable to the production of chlorates, the apparatus used consisting of a quadrangular vessel of sheet iron, which served also as cathode, the anode being of retort carbon or of platinum enclosed in a porous clay cell. The capacity of the anode cell was 0.5 litre and that of the cathode compartment 1 litre. The current was produced from a dynamo with a voltage of 110, the strength being maintained at 5 amperes by means of added resistances. The duration of each experiment being three hours, the current value was equal to 15 ampère hours; the temperature was regulated by immersing the apparatus in a water-bath. After every experiment the volumes of the anode and cathode solutions were measured and the liquids analysed. Of the cathode solution 100 cc. were boiled and diluted to 500 cc.; one part was then titrated with semi-normal hydrochloric acid, using methyl orange as an indicator, whilst another part, just acidified with dilute sulphuric acid and neutralised by digestion with zinc oxide, was used after filtration for the estimation of chlorine by decinormal silver solution. In the anode solution the total chlorine was determined as above; to determine the chlorate a part of the boiled and then diluted solution was mixed with excess of decinormal ferrous salt and dilute sulphuric acid and heated, the excess of ferrous salt being titrated back with potassium perman-

ganate solution. 1 ampère hour should yield theoretically 0.55 g. 0.75 gm.  $\text{KClO}_3$ , or 0.208 gm.  $\text{KOH}$ . In the first experiment a 10 per cent. solution of  $\text{KCl}$  at 15° C. was used alike for the anode and cathode cells, the effective carbon anode surface was 150 sq. cm., and the current density 0.033 ampère per sq. cm., while the voltage ranged from 1.5 to 5. But after the three hours only 0.9 gm.  $\text{KClO}_3$  was found in the anode solution, equal to 0.06 gm. per ampère hour, or 8 per cent. of the theoretical yield. In a second experiment, otherwise similar to the first, 100 grms. of a 30 per cent. potash solution were run into the anode cell, charged as before, at such a rate that free chlorine was always distinctly present. In spite of the loss of chlorine 0.38 gm. of  $\text{KClO}_3$  per ampère hour were obtained, or 50 per cent. of the theoretical yield. In a third experiment the 100 grms. of potash solution were so added that the reaction throughout was slightly alkaline. The anode was of platinum sheet (210 sq. cm. in effective surface), and the voltage averaged four. The result was better, 0.5 gm.  $\text{KClO}_3$  per ampère hour (= 67 per cent. of theoretical) being formed at the anode. By substituting potassium hydroxide for the potassium chloride in the anode cell only 33.5 per cent. of the theoretical result was obtained, which accords with the observation that the chlorate is produced by a secondary action of chlorine on caustic potash, and not by that of electrolytic oxygen on potassium chloride. By substituting platinum wire for sheet a greater current density per sq. cm. of anode surface was obtained, and a distinct smell of ozone was observed; yet in this experiment, and in others in which a higher temperature (up to 85° C.) or a stronger solution of potassium chloride were used, no appreciable alteration in the result was observable, nor was there any change in the yield of chlorate when potassium hydroxide was substituted for the chloride in the cathode cell. From these experiments it would seem that the highest yield of chlorate is obtained when the anode solution is kept faintly alkaline, while it is lower if a weak acid or strongly alkaline solution be used; on the other hand, it is not greatly affected by a moderate alteration in temperature or concentration. Nevertheless, a stronger solution and a higher temperature are more conductive and therefore more economical. On a large scale, therefore, the solution should be concentrated and warm (80°); platinum is the best material for the anode, but lead or lead peroxide might possibly be substituted. In practice, instead of using fresh caustic alkali, the cathode liquid might be caused to flow at a suitable rate into the anode cells. The chlorate is obtained from the anode liquid by crystallisation, followed by washing and recrystallisation. It is still an open question whether the direct production of chlorate in this way is more economical than the process in which electrolytic chlorine is employed. Much depends upon the possibility of obtaining a diaphragm of low resistance capable of resisting the action of chlorine and of alkalis. Sodium chlorate may be formed in like manner to the potassium salt.—W. G. M.

#### *The Action of Sodium Peroxide upon Acids in Alcoholic Solution.* J. Tafel. Ber. 27, 816.

COMMERCIAL sodium peroxide, although acting violently upon many organic bodies, does not seem to react with alcohol. With very dilute alcohol, and even with acids in alcoholic solution, little or no oxygen seems to be evolved. In the case of concentrated alcoholic hydrochloric acid, although there is no visible evolution of gas, a crystalline powder is deposited.

The product must be either a mixture or a combination of sodium chloride with a body of the composition  $\text{NaIO}_2$ . The following equations probably represent the reactions:—

By action of heat—

On treating with water—

The equations only generally represent the reactions taking place.

Sulphuric acid and nitric acid act in a similar way with commercial sodium peroxide.

The hydrate  $\text{NaO}(\text{OH})$  does not seem to have the property of forming salts with either hydrochloric, sulphuric, or nitric acid.

With acetic acid, sodium peroxide behaves quite differently. If the peroxide of sodium be thrown into acetic acid, the latter immediately bursts into flame. But if it be added, with certain precautions, to a solution of acetic acid in alcohol, it gives a clear solution, from which a colourless salt crystallises out. This salt gives off oxygen at a low temperature, and with water gives a solution which behaves in many respects like a solution of hydrogen peroxide, and which is neutral.

On heating this product, oxygen and water are given off, and the residue is nothing but sodium acetate. It is therefore possible that by the action of sodium peroxide upon acetic acid, sodium acetate is formed with hydrogen peroxide in the form of water of crystallisation. This would explain the behaviour with heat and with water. But the author thinks there must be a similarity in the reaction which takes place when acetic acid, and when mineral acids act upon sodium peroxide. The explanation above given cannot apply to the product of the action of the peroxide on hydrochloric acid, since, according to analysis, this product evolves too little water to correspond with the amount of oxygen, if both were present in the state of  $\text{H}_2\text{O}_2$ . He thinks it more probable that the following reaction takes place—

Thus the hydrate  $\text{NaO}(\text{OH})$  seems to form a salt with acetic acid, but not with mineral acids.

In conclusion, the author has found that commercial sodium peroxide is changed by pouring alcohol upon it. Part of the substance goes into solution, from which, concentrated hydrochloric acid precipitates nothing but sodium chloride. The remainder, which is insoluble in alcohol, forms with alcoholic hydrochloric acid a salt which in appearance cannot be distinguished from the salt obtained directly from commercial peroxide, but which, according to analysis, contains sodium chloride and the hydrate, in the proportion of approximately 1:1.—H. M.

*The Behaviour of the Woods of Conifera to Solutions of the Chlorides of Copper.* E. Jensch. Zeits. angew. Chem. 1894, 153—155.

WHEN extracting copper from its ores according to Hoepfner's process (this Journal, 1889, 401), great difficulties have been encountered owing to the carbonising action of the hot cuprous chloride solutions on the timber of the conical rotating drums such as are used in the extracting process. After 22 days' work the fir staves were found to be carbonised to a depth of 4—5 mm., and the pitch-pine staves to a depth of 12—16 mm. It was, in fact, quite impossible to keep the apparatus liquor-tight. Further experiments proved that slowly-grown Bavarian fir shows greater powers of resistance than pitch-pine to the action of hot cuprous and cupric chloride solutions.—H. A.

## PATENTS.

*Improvements in or relating to the Treatment of Sodium Chloride, and to the Method of Utilising the Products in the Manufacture of White Lead, and of Soda, Chlorine, and their Derivatives.* R. Haddon, London. From Compagnie Electro-Chimique de St. Bérn, Paris, France. Eng. Pat. 13,406, July 10, 1893.

THESE improvements relate to methods of dealing with the products set free in the electrolysis of salt solution; the chlorine and soda solution being brought together outside the electrolytic apparatus for the production of hypochlorite of soda; or the chlorine being given off is converted into useful derivatives, and the caustic soda solution, containing 120 grms. of caustic soda per litre, brought into contact with litharge in a digester, mechanically agitated, the solution of the litharge being assisted by heat, and the hot solution carbonated in a series of carbonators, insoluble white lead being precipitated and separated by a filter-press; the alkaline liquid being further carbonated for production of insoluble bicarbonate in solution of sodium chloride, which mother-liquor is returned to the electrolyser. The same process and apparatus may be employed for carbonating the alkaline liquid direct from the electrolyser, the chlorine being employed for production of chloride of lime.—J. C. R.

*Improvements in the Electrolysis of Iodides, Bromides, Nitrates, and other Salts.* J. Hargreaves, Farnworth-in-Widnes, and T. Bird, Cressington, Liverpool. Eng. Pat. 14,130, July 21, 1893.

THIS invention relates to the decomposition of iodides, bromides, nitrates, and other salts by the electrolytic method, and consists in the employment of apparatus of the kind described in the specification of Eng. Pat. 18,871 of 1892 (this Journal, 1894, 255, and 528) for use in the manufacture of alkali. The inventors find that electrolytic apparatus of the kind referred to is applicable for use in the decomposition of various substances besides sodium chloride, such salts as above mentioned, yielding iodine, bromine, and nitric acid next the anode respectively.—J. C. R.

*Improvements in the Electrolysis of Chlorides, Iodides, Bromides, Nitrates, and other Salts, and in Apparatus therefor.* J. Hargreaves, Farnworth-in-Widnes, and T. Bird, Cressington, Liverpool. Eng. Pat. 14,131, July 21, 1893.

THESE improvements relate to developments of the process contained in Eng. Pats. 18,871 of 1892, 5197 and 5198 of 1893 (this Journal, 250, 255, and 528 of 1894), wherein a cathode is employed in contact with, or forming part of, a porous partition in apparatus for the electrolysis of alkali salts. The present objects are to secure a more efficient and convenient construction of apparatus in the direction of modifications of the methods employed in forming the porous diaphragm, of lime and asbestos on wire gauze, dried, and steeped in phosphate of soda, &c. solution, thus converting the lime or baryta into insoluble phosphate, the soda being "left free." In some cases the alkaline earth is carbonated before being treated with phosphate or silicate, and the density of the diaphragm may be varied by treatment with solution of lime, baryta, or magnesia, drying, and again treating with phosphates or silicates.—J. C. R.

*Improved Process and Apparatus for the Manufacture of Cyanides.* A. Gordon and J. Gordon, Loanhead, Midlothian. Eng. Pat. 16,750, September 6, 1893.

THE blast furnace in which the process is conducted, has its lower part shaped like an inverted truncated cone, formed as an iron water-jacket, several inches wide, through which

water is kept flowing, the tuyère openings being into the lower part. The jacket may be continued up the barrel of the furnace, which has an outlet a short distance above the hottest part. The fumes are drawn through this outlet by an exhausting apparatus so as to traverse a series of metal pipes, to which water may be applied externally. There are bottom boxes to the pipes that can be heated from fireplaces when it is desired to draw off the fumes in a fused state. There is also a wet fume condenser, similar to that described in Eng. Pat. 5239 of 1878. The top of the furnace is provided with an outer iron cup and cone; the cup of the usual description; but the cone has an aperture above, closed by an iron ball, actuated by a hand lever, opening out to a box or hopper, into which the alkaline materials for producing cyanides are placed. When the cone with its hopper is depressed, the fuel falls from the larger hopper, about the circumference of the furnace, leaving the inner part vacant for the materials, which are introduced to the centre from the cone. By this arrangement injurious action on the brickwork walls of the furnace is obviated.

In manufacturing potassium cyanide, for instance, potassium carbonate is intimately mixed with carbonaceous matter, preferably nitrogenous, such as animal substances, coal, pitch from shale, and the like, for introduction to the furnace interior. Ammonia may be passed into the furnace along with the blast. The heat maintained is high enough to volatilise the cyanide as it forms, so that it is conducted as fume into the condensing apparatus.—E. S.

#### *Improvements in the Manufacture of Sulphocyanides.*

H. W. Crowther, West Bromwich, and E. C. Rossiter, Smethwick. Eng. Pat. 17,846, September 22, 1893.

CALCIUM sulphocyanide is obtained by digesting together ammonia, carbon bisulphide, and lime, preferably approximately in the proportions indicated by the equation—

but a slight excess of both ammonia and lime is used. The ammonia is taken at 7 to 15 per cent. aqueous solution, which is charged into an iron autoclave, fitted with stirrer and steam-jacket, the latter admitting of cold water being run in for rapid cooling. The lime solution is then added, and when these are well mixed, the carbon bisulphide. The pressure is allowed to rise to 15 to 25 lb. per square inch before shutting off steam, after which the pressure may rise to 60 to 90 lb. When the pressure has fallen, the vessel may be again heated. Other bases may be substituted for lime; namely, baryta, strontia, magnesia, and the caustic alkalis. The solution of calcium sulphocyanide and sulphhydrate obtained, is run into a series of vessels described in Eng. Pat. 8666 of 1887, for treatment with carbonic acid, preferably limekiln gases, to convert the sulphhydrate into carbonate or bicarbonate. The hydrogen sulphide evolved may be utilised in making sulphuric acid or sulphur. The calcium carbonate is filtered off. When alkali sulphocyanides are wanted, it is preferred to obtain these from the calcium sulphocyanide by means of the alkali carbonate or sulphate.

Sulphides may be substituted for hydroxides in the process. The following equation represents the proportions used when barium sulphide, for instance, is taken:—

Reference is made to Eng. Pat. 5354 of 1891, according to which manganese dioxide or ferric hydroxide is used in the manufacture of sulphocyanides.—E. S.

#### *Improvements in the Process of Concentrating Sulphuric Acid in Lead Vessels.*

W. Wolters, Borowitzchi, Russia. Eng. Pat. 18,831, October 7, 1893.

LEAD sulphate is added to the sulphuric acid to be concentrated, and is kept in suspension by suitable agitation, so that the material of the vessel is protected from corrosion by the acid. The vapour given off is taken to leaden

chambers for condensation. Most of the lead sulphate dissolved by the acid, separates on cooling and may be used again.—E. S.

#### *Improvements in the Elimination of the Oxides of Zinc, Iron, and Copper from Cobalt Oxide, and Apparatus therefor.*

E. A. E. Weinberg, Dornafvet, and R. Curriek and J. G. Johanson, both of Gelle, Sweden. Eng. Pat. 24,900, December 27, 1893.

THIS invention relates to the elimination of the oxides of zinc, iron, and copper from cobalt oxide by the use of hydrochloric acid. The impure oxide having been washed in boiling water to free it from alkaline salts, is dried, crushed, and sifted through a 50-mesh sieve. It is then mixed with 10 per cent. of crude hydrochloric acid, and the paste thus produced is placed in a fire-brick muffle or oven and heated to about 900 °C., care being taken that the atmosphere has free ingress and egress, and that the mixture is well stirred. The oxides are converted into chlorides, all of which being volatile with the exception of the chloride of cobalt, pass off, leaving the latter behind. The temperature is then increased to about 1,150 °C., when the chloride is transformed into the dark blue cobalt oxide, which on being washed in boiling water, dried, and pulverised, is ready for the market.—A. W.

#### *Improved Apparatus and Process for Electro-Chemical Decompositions.*

H. Carnichael, Malden, Mass., U.S.A. Eng. Pat. 8061, April 24, 1894.

See under X1., page 891.

#### *Improvements in Methods of Treating Lead Ores.*

A. G. Fell, New York, U.S.A. Eng. Pat. 9536, May 15, 1894.

See under X., page 889.

#### *An Improved Method, Means, or Process of Producing Caustic Soda and Chlorine Gas or Caustic Potash and Chlorine Gas by the Electrolysis of Common Salt in Solution or Chloride of Potassium in Solution.*

T. Drake, Huddersfield. Eng. Pat. 11,661, June 16, 1894.

THESE improvements consist in wrapping metallic gauze or perforated metal sheeting round a porous pot, and making cathode connection direct thereto. This gauze, preferably of copper, is treated with a salt of mercury sometimes, and so becomes amalgamated; but whether amalgamated or not is intended for use as a cathode in the electrolysis of salt, &c., the salt solution being placed in the porous pot, and water in an outer iron vessel to collect the soda from the cathode. In other respects the apparatus resembles that described in Eng. Pat. 7985, 1894 (this Journal, 1894, 744), the gauze replacing the bath of mercury.—J. C. R.

#### *Improvements in Apparatus for Obtaining Ammonia and Ammonia-Salts from Nitrogenous Organic Matters.*

H. H. Lake, London. From L. Sternberg, Jersey City, U.S.A. Eng. Pat. 12,881, July 3, 1894.

THE retorts are vertical, and in groups of four, each group having a common feed chamber at top. There is a feed pipe to each retort, having two slide-valves, by use of which the feed can be effected with the minimum admission of air. There is also a common discharge chamber to each group, also provided with two valves. Each retort has a vertical screw of coarse pitch, the thread of which is secured to an elongated drum mounted upon a hollow shaft, for admission of non-oxidising gases and steam, which enter by a hollow stuffing-box, and serve to cool the shaft, and so to protect the screw from overheating. The shafts are kept revolving. A fireplace is provided, but is chiefly used on starting, the necessary heat being maintained by combustion of the gas produced in the process. The materials for the production of the required products having been charged into the retorts, and duly heated, the effluent gases are led from the

receiving chamber below into an absorber, where ammonia is withdrawn by sulphuric acid, and the ammonia-freed gases are pumped into a gas service pipe, from which, by suitable valves, they are led, either for storage of excess, into a gas meter, or directly to a series of branched pipes, through which the gases pass, partly, as already described, into the hollow shafts, and partly into the heating chambers surrounding the retorts, where their combustion maintains the required temperature. Provision is made for the injection of steam as required. There is reference to a former patent, 21,723, 1892 (this Journal, 1893, 263).—E. S.

bottom of the seggar is cut away, thereby reducing its weight and enabling such articles as basins and dishes to be placed so as to protrude through the bottom of the seggar, or, if inverted, through the bottom of the seggar in the row above. Either arrangement effects an economy of space in the kiln.—V. C.

*Improvements relating to the Manufacture of Filters.* H. H. Lake, London. From Bittel and Co., Worms-on-the-Rhine. Eng. Pat. 19,873, October 21, 1893.

See under 1., page 872.

## VIII.—GLASS, POTTERY, AND ENAMELS.

*The Manufacture of Porous Cells.* D. Titaner. Central-Auzeiger f. Ziegel- u. Kalkind. 1894, 13, 47.

THE author discusses the composition and preparation of the mixtures employed in the manufacture of porous galvanic-battery cells. The addition of chalk to the mass results—owing to the escape of carbonic acid during firing—in a high degree of porosity. Such cells are, however, not proof against the action of strong acids. For this purpose, lime must be absent.—H. T. P.

*Transparent Cement for Porcelain.* Deutsch. Töpfer u. Ziegler Zeit. 25, 1894, 220.

CAOТСНОУ (75 grms.) is dissolved in 60 grms. of chloroform and 15 grms. of mastic added. The mixture is allowed to remain in a closed flask until solution is complete.

—A. R. L.

## PATENTS.

*Improved Means or Process for Operating upon Glass for General Ornamentation and Embellishment Purposes.* A. A. Gibbs, S. A. Gibbs, and W. T. Gibbs, London. Eng. Pat. 15,341, August 11, 1893.

THE following is an example of the means of carrying out the inventors' process:—A coat of acid resist is laid upon the glass; from the parts forming the background to the design the "resist" is removed with a stencil; soda and hydrofluoric acid are then poured upon the surface. Hydrofluoric acid is next applied; the resist is then removed and the glass is cleaned. The glass is next coated with stain, and by means of a stencil the ornament is freed from the stain, which remains as a protection for the background. The stain is then burnt into the glass. The glass is then taken from the kiln, cleaned, and the required outline traced upon the glass, the background being filled with acid resist. The solution of soda and hydrofluoric acid is again poured on so as to leave a white "mat" on the whole ornament, leaving the outline, which is protected by the resist, clear. The shading-in is then done according to the ordinary process of the trade.—V. C.

*Improved Seggars for Use in Enamelling, Hardening on, Lustre and Majolica Kilns.* C. Copeland, Tunstall, Staffordshire. Eng. Pat. 18,388, October 2, 1893.

THE object of this invention is to make seggars which will hold a larger quantity of ware than those of the ordinary pattern. Each seggar is provided with upright pillars at suitable distances near the outer periphery, the pillars being furnished with grooves on their inner surface to serve as supports for various articles. A portion of the

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

### PATENTS.

*Improvements relating to the Manufacture of Artificial Stone.* A. McLean and C. W. Wilson, London. Eng. Pat. 17,322, September 14, 1893.

THE clinker from refuse-destroyers is ground to the size of small shot, mixed with a binding material, such as Portland cement, and water added; the proportions being approximately three parts clinker to one part Portland cement. The mixed materials are then subjected to a pressure of from 250 to 500 tons to the square inch. The material obtained has the advantage of being non-slipping.

—V. C.

*Artificial Plaster of Paris made from the Lime Residue resulting from the Reduction of Sulphate of Ammonia.* J. L. Kerr, Manchester. Eng. Pat. 8475, April 28, 1894.

THE hydrated sulphate of lime formed as a by-product in the above process is dried by waste heat in suitable kilns and heated for a considerable time to a temperature of 300° F. until all the water of crystallisation is driven off. It is then ground to a fine powder and stored in air-tight barrels. It is claimed that the plaster of Paris thus made is a distinct novelty, and is equal to that now obtained from gypsum.—V. C.

*Improved Stoneware for Building Blocks, Tiles, Ornaments, and other Articles and Objects.* J. C. Sellars. Birkenhead, and C. A. Ropes, Liverpool. Eng. Pat. 9241, May 10, 1894.

THE ware comprises, first, a granular substance, such as sand; secondly, the silicate or borate of soda or potash; and lastly, a compound of aluminium, preferably alum. The solution of silicate or borate is mixed with the granular material to a plastic consistency, the plastic material being then placed in moulds, from which it is readily removed when required. The moulded article is then dried and soaked with solution of alum.

THE ware thus produced will resist atmospheric action and temperatures such as are reached in an ordinary fire-grate. If desired, the articles thus made may be coated with cement or enamel. V. C.

## X.—METALLURGY.

*The Tortimolite Process.* Iron and Coal Trades Rev.  
1894, 238.

THIS is a new process, for improving pig-iron after it is cast, now being tested at the Little Bell furnace in Bessemer, U.S.A. It is called the Tortimolite process, and consists in running pig metal into chills heavily coated with a wash of impure graphite, apparently containing about 75·11 per cent. of carbon. The metal is supposed to absorb some of the carbon and become stronger and softer, probably somewhat on the principle of cementation. It makes a very smooth, clean pig, and shows slightly less chill than untreated metal in chills. Tests so far made seem to indicate a gain of strength in test bar and in pig, and a slight increase of carbon in the metal as well as slight changes in the other chemical constituents. Tests made at the Howard Harrison Pipe Works of this metal, as compared with untreated pig of the same cast, are said to have shown decided superiority in fluidity and strength for the Tortimolite metal.

*The Variations in the Silicon Percentage of different Samples of Pig-Iron from the same Tap.* H. Rubricius.  
Chem. Zeit. 18, 1894, 1005.

A SERIES of tests shows that the percentage of silicon in pig-iron is lowest in that part of the metal which is nearest to the bottom of the blast furnace, and increases in the same charge as the upper portion nearest the slag hole is approached—sometimes to the extent of 1 per cent. But it is not yet possible to correlate the initial silicon percentage and the rate of increase, as it often happens that a sample in which the lowest portion contains but little silicon is unusually rich in that element in the upper part. The difference cannot be accounted for by the lower specific gravity of the silicon, yet the phosphorus and sulphur do not show the same variation. The results of eight tests are quoted below:—

Test.	Percentages of Si from below upward.						
	1.	2.	3.	4.	5.	6.	7.
1	1·13	1·15	1·15	1·19	1·33	1·40	1·42
2	1·38	1·44	1·45	1·60	1·63	1·72	1·79
3	1·15	1·34	1·43	1·57	2·17	2·18	2·20
4	1·40	1·50	1·54	1·66	1·82	1·84	1·88
5	1·95	2·09	2·13	2·45	2·70	2·72	2·76
6	1·81	1·83	1·84	1·86	1·89	2·16	2·20
7	2·72	2·74	2·77	2·79	2·85	2·88	2·89

—W. G. M.

*The Ligation of Silver Copper Alloys.* E. Matthey.  
Proc. Roy. Soc. 55, 265—269.

THE author refers to the difficulty of obtaining a plate of standard silver (925 parts of silver in 1,000) of uniform standard, and, as a result of many trials, he concludes that the best means to ensure this is to cast the alloy in very thin plates and subject them to slow and uniform cooling. Thick plates by rapid or slow cooling are sure to have points of local richness. A bar was cast into a "skillet" mould to produce a casting 30 cm. in length, 13 cm. in width, and 6 mm. in thickness, weighing 5 kilos. Assays of various parts of this plate, after slow and uniform cooling, showed a very slight tendency for the silver to liquefy to the centre. Another bar in the same mould cast at a higher temperature showed a depreciation of silver at the centre.

The mould was ultimately reduced to 1 mm. in thickness, and the results then obtained showed that liquation, although not entirely prevented, had practically disappeared.

—A. W.

*The Pneumatic Pyrometer.* H. Motton. Engineering,  
1894, 251.

See under I., page 869.

## PATENTS.

*Improvements in the Treatment or Preparation of Pulverised or Finely-divided Ores, or the like Material containing Iron, for Use in the Blast Furnace for the Production of Iron.* W. Thonkinson, West Hartlepool.  
Eng. Pat. 13,769, July 15, 1893.

THE materials, after pulverisation when necessary, are consolidated into lumps by incorporation with a pulp of finely-ground slag or other suitable matter and subsequent drying or setting.—J. H. C.

*Improved Method of and Apparatus for Pickling Metal Articles.* S. O. Cowper-Coles, London. Eng. Pat.  
15,507, August 15, 1893.

WEAK acid pickling solutions are used in combination with currents of electricity, which are frequently reversed so as to loosen and detach the scale; heat being used when necessary, as also magnets variously applied. The scale is removed by continuous pumping and filtering or other convenient method.—J. H. C.

*An Improved Process and Means used therein for the Disintegration of Agglomerated Minerals.* W. S. Lockhart, Blackheath. Eng. Pat. 16,724, September 5, 1893.

THE agglomerations are treated by water or other liquid under pressure, either by jets applied *in situ* or in closed stationary or revolving chambers. The disintegration may be aided by alternate freezing and thawing in some cases.

—J. H. C.

*Improvements in the Manufacture or Production of Metals from their Ores, and in Plant or Apparatus therefor.* W. F. Berner, St. Petersburg. Eng. Pat. 19,375, October 14, 1893.

THIS patent is for a complicated furnace, having for its object the smelting and refining of ores. In the case of iron, the furnace consists of two shafts having a common hearth and a refining furnace adapted to be placed in communication with such hearth, one half of the furnace being first worked as a blast or reducing furnace, whilst the other half is worked as a decarburising furnace by the hot gases escaping from the first half. The regenerative principle is brought into play so that the relative functions of the two halves of the furnace can be reversed. Various devices are described for regulating the supply of air, gases, &c., according to the requirements of the furnace, so that almost any emergency can be met and provision made for smelting almost any ore, the whole smelting and refining being carried out in one operation, and in one furnace.—A. W.

*Improvements in Methods of Treating Lead Ores.* A. G. Fell, New York, U.S.A. Eng. Pat. 9536, May 15, 1894.

GALENA or other ore is crushed to a fine powder and treated with water containing a mixture of sulphuric and hydrochloric acids, or sulphuric acid and a chloride. Heat is applied for from 2 to 6 hours, the operation terminating about 30 minutes after the evolution of sulphuretted hydrogen has ceased, when more water is added and the mass stirred and allowed to settle. The sedimentary lead compound is washed free from acid and is then agitated

with a solution of monocarbonate of soda and moderately heated. After settling, the solution of soda salts is drawn off, and the resulting lead compound is then treated according to the commercial product required; for instance, with nitric acid for the nitrate, acetic acid for the acetate, and so on. If the oxide is required it is mixed with a small quantity of nitric acid, dried, and heated with varying intensity, according to the kind of oxide required.

If silver be present in the galena it is extracted by treating the compound after the soda treatment with a hot solution of sodium chloride previous to the final treatment for the production of the lead salt or oxide.—A. W.

*An Improved Flux for Use in Soldering Aluminium and other Metals.* W. P. Thompson, Liverpool. From O. Nicolai, Wiesbaden, Germany. Eng. Pat. 11,148, June 8, 1894.

THE object is to solder aluminium to itself or other metals with a suitable solder, such as zinc, tin, or cadmium, or an alloy of these or similar metals, and with the use of a flux consisting of a cadmium salt, preferably one of the haloid salts.—A. W.

*A Means or Apparatus for Producing Pure Castings.* H. R. Müller and F. O. Müller, Löbtau, Saxony. Eng. Pat. 11,574, June 14, 1894.

THE apparatus consists of a peculiarly arranged inlet and collector for separating and retaining all mechanical impurities, such as slag, &c., so that no portion of it can enter the mould.—J. H. C.

*Improvement in the Method or Process of Treating Gold and Silver Ores, and a Composition or Matter for the same Purpose.* E. D. Kendall, Brooklyn, U.S.A. Eng. Pat. 11,797, June 18, 1894.

THE pulverised ores are treated with sodium dioxide and potassium or other suitable cyanide, generally in the form of solutions, and previously mixed in suitable proportions. They are then leached and filtered in the ordinary way, and the metals precipitated by electrolysis or other suitable means.—J. H. C.

*Improvements in or relating to the Treatment of Sodium Chloride and to the Method of Utilising the Products in the Manufacture of White Lead and of Soda, Chlorine, and their Derivatives.* R. Haddon, London. From Compagnie Electro-Chimique de St. B'ron, Paris, France. Eng. Pat. 13,406, July 10, 1893.

See under VII., page 886.

*Improvements in Electrolytes for Primary Batteries.* W. H. Longsdorf, London. From G. Hewett, New York, U.S.A. Eng. Pat. 14,056, July 20, 1893.

THE following formulae are given for producing two kinds of powder for use in primary batteries: the first for use in single fluid batteries or next the carbon in batteries having porous cells; the second for use as an excitant in the compartment containing the zinc element in porous cell batteries:—

I. 8 fluid oz. commercial nitric acid, 36° B.;  
3 pints commercial sulphuric acid, 66° B.; the mixture heated to 136° F.; and  
8 lb dry bichromate of soda dissolved therein. The compound on allowing to cool solidifies, and can then be ground to powder. The mass should be cooled rapidly, protected from the atmosphere, and subsequent exposure avoided.

H. 15 oz. powdered chloride of sodium;  
1 oz. bisulphate of mercury; and mix thoroughly.

The powders are for use in solution, being readily soluble.  
—J. C. R.

*Improvements in the Electrolysis of Chlorides, Iodides, Bromides, Nitrates, and other Salts, and in Apparatus therefor.* J. Hargreaves, Farnworth-in-Widnes, and T. Bird, Cressington, Liverpool. Eng. Pat. 14,131, July 21, 1893.

See under VII., page 886.

*Improvements relating to Thermo-Electric Batteries, and to Apparatus for Use in the Manufacture of the Same.* J. B. C. Dion, Paris, France. Eng. Pat. 17,493, September 16, 1893.

THESE improvements relate to a thermo-electric battery, consisting of a series of elements composed of antimony, zinc, and a small quantity of tungsten and arsenical cobalt (100 parts antimony, 50 to 70 parts zinc, to which is added the tungsten and arsenide of cobalt), obtained by casting the metal into moulds. These elements are connected with each other by metallic strips, and placed in superposed crowns or in spirals round a furnace, the temperature of which is kept constant in an automatic manner by a thermometer arranged so that the mercury arriving at a certain height closes a circuit which electromagnetically works a lever regulating the admission of air to the furnace. Each crown is insulated from the others by asbestos discs, sunk into a suitable cement which covers about one-half of the elements. The other extremity is free, in order that a current of air may cool this outer portion, while the inner extremity of these same elements is heated to the highest degree.—J. C. R.

*An Improved Manufacture of Electric Accumulators.* L. W. and G. E. W. Schöffer, Gelnhausen, Germany. Eng. Pat. 17,866, September 22, 1893.

THESE improvements relate to the manufacture of electric accumulators, in which the active covering material of the positive electrode consists of a mixture of metallic lead

finely pulverised, with an electrically indifferent substance in the form of powder. This is either (1) separated by the acid in proportion as the conversion of the lead into peroxide progresses, and thus gives room for the increase of volume. Such substances are zinc-dust, starch, and the like. (2) Or the proposed substance is or becomes sufficiently yielding to permit of the expansion of the particles of lead in their conversion into peroxide of lead, and to receive the pressure produced. Such substances are pumice stone, blast-furnace slag, glass, cork, wood, &c., in the form of powder.—J. C. R.

*Improved Apparatus and Process for Electro-Chemical Decompositions.* H. Carmichael, Malden, Mass., U.S.A. Eng. Pat. 8061, April 24, 1894.

This specification deals rather extensively with the subject of the electrolysis of alkali salts, particularly chloride of sodium solution, for obtaining chlorine and soda, and aims at the better separation of the ions set free at the electrodes, partly (1) by the employment of porous partitions, arranged generally horizontally or on the slant; (2) the introduction of fresh electrolyte at a point or zone to prevent diffusion upwards of soda towards the products of the anode at the top, *i.e.* just below the anode; and (3) maintaining a lower temperature at the bottom than at the top of the electrolyte, and generally working the apparatus to obtain efficiency. Several forms of apparatus and their working are explained. The anodes of carbon may rest upon platinum wires or platinum pins connected to insulated mains. The electrolysis of sulphate of soda is also dealt with. There are 30 claims.—J. C. R.

*An Improved Method or Means or Process of Producing Caustic Soda and Chlorine Gas or Caustic Potash and Chlorine Gas by the Electrolysis of Common Salt in Solution, or Chloride of Potassium in Solution.* T. Drake, Huddersfield. Eng. Pat. 11,661, June 16, 1894.

See under VII., page 887.

## XII.—FATS, OILS, AND SOAP MANUFACTURE.

*Ekenberg's Process of Refining Fats, Oils, &c.* R. Benedikt. Zeits. angew. Chem. 1893, 672—676.

In Ekenberg's process for refining fats, oils, &c., a centrifugal emulsor of the Separator Co. (of Stockholm) is combined with a Laval separator to form a battery or a number of batteries through which the fats and oils are passed, being alternately intermixed intimately in the centrifugal emulsor with the reagents (or wash-water), and subsequently separated in the Laval separator.

The author has studied this process both in the laboratory of the Separator Co. and in his own, with apparatus supplied by the company, and now gives the following description of process:—

The combination of one emulsor with one separator is termed an "element." In case the emulsion obtained in the former separates very easily a Laval apparatus may be dispensed with, and conveniently replaced by a Florentine receiver. The number of "elements" necessary to form a "battery" naturally depends on the number of washes required in each individual case.

As a rule, the emulsion formed in the emulsor may be run at once into the separator, the intermixture with the reagents being so intimate that refining is effected instantaneously. In case longer interaction be required, suitable receivers are interposed to alternately receive the mixtures.

The mixtures are heated or cooled, as the case may be, by a plate-warmer or a plate-cooler, and are moved from one element to the following by means of centrifugal pumps driven from the same shafting as the elements themselves.

The plates of the emulsors and the drums of the separators are made of "acid-steel" ("Saure-stahl"), resisting the attack of concentrated sulphuric acid and of alkalis. For dilute acids brass plates are used, and drums covered with an alloy of lead and antimony.

A battery, consisting of emulsors and separators of ordinary size, is able to work 3 to 6 tons *per diem*, the quantity depending on the nature of the oil, &c. In the case, however, of oils containing large proportions of free fatty acids, say up to 25 per cent., the output is smaller.

The following examples will serve to illustrate the manner in which the process is worked:—

*I. Refining of Vaseline Oils and Heavy Mineral Oils.*

—These oils are refined in the usual manner by washing with 8—25 per cent. of concentrated sulphuric acid, and washed subsequently with dilute alkali, and finally with water.

The crude oil is washed with once-used acid in the emulsor and separated, the now twice-used acid running into a tank. The chief object of this washing with acid, which has become reduced by the preceding operation to from 1.5 to 1.6 sp. gr., is to dehydrate the crude oil. The dried oil is next emulsified with fresh acid, the emulsion separated, and the separated acid conducted to the first separator. The oil is then washed with either already used or fresh caustic soda lye, as may be necessary, and finally with water; the emulsion is then allowed to separate in a Florentine receiver.

The empyreumatic resins do not separate, as in the ordinary processes, in the shape of large, hard lumps, but form a homogeneous emulsion with the acid. The waste acid is worked up in the usual manner by dilution with water and conversion into ammonium sulphate. If the separators are properly adjusted, rarely more than 0.1 per cent. of oil will be found in the wash-water.

*II. Refining of Fatty Oils.*—For refining fatty oils with sulphuric acid, as in the case of rape oil, only three elements are required, the oil being treated with acid in the first, and washed in the second and third with cold and warm water.

*III. Preparation of Neutral Oils.*—A plant for the preparation of neutral cocoa-nut or olive oil (even containing as much as 25 per cent. of free fatty acids) is described. It consists of six "elements," in three of which Florentine receivers have been substituted for centrifugal separators. The oil is washed first with alkali, then with water, next with alkali for the second time, afterwards with dilute alkali, then with very dilute acid, and finally with warm water.

As the emulsor works in a very satisfactory manner the emulsions are not always completely separated in the separator. This may not only be owing to faulty adjustment, but also to other circumstances peculiar to the nature of the emulsions, and it may happen that emulsions are formed which cannot be separated by the separator. Such emulsions, termed "critical" by Ekenberg, may be resolved into two layers by altering the concentration of the reagents, by addition of common salt, &c. From this it will be evident that a battery erected for a certain oil cannot be used for another without paying due regard to the peculiarities of the case.

The following advantages, besides continuous working, are claimed for the Ekenberg system:—The crude oil may be freed from tissues, &c. by a preliminary wash with water. In refining processes by means of acids there is a saving of from 40 to 60 per cent., considerably less oil being saponified. The acid is separated down to 0.2 per cent., and the consumption of alkali is, consequently, very small.

—J. L.

*Detection of Disguising and Perfuming Media in Oils and Fats.* D. Holde. Mittheilungen aus den konigl. tech. Versuchsanst. zu Berlin. 1894, 31.

See under XXIII., page 906.

*Properties of Sunflower Oil.* D. Holde. Mitt. aus den k. k. techn. Versuchsanst. zu Berlin, 1894, 36.

In the purpose of examination the oil was prepared in the laboratory from sunflower seed by extraction in a Soxhlet

apparatus with petroleum ether, boiling at 50° C. The following table, giving the properties of the oil, shows its great similarity to poppy oil, which has almost identically the same characteristics as those here given for sunflower oil:—

Observer.	Percentage of Oil in the Seeds.		Appearance. Smell and Taste.	I <sup>o</sup> = Viscosity Degree according to Engler (Water at 20° C. = 1).		Behaviour on Cooling.	Specific Gravity at 15° C.

*The Examination of Linseed Oil.* F. Filsinger.  
Chem. Zeit. 18, 1894, 1005—1006.

SINCE the specific gravity, iodine number, and saponification equivalent of linseed oil are liable to vary even in unadulterated samples, the author has experimented with the optical test proposed by Aignan (Comptes rend. 1890, 110, 1273; this Journal, 1890, 903), as this indicates the

presence of rosin oils, which are dextro-rotatory, and which are the most likely adulterants, owing to their cheapness and the difficulty in detecting their presence. In the following table the author quotes the results of testing two samples of known purity expressed from German and Indian seeds, and of other commercial samples. In estimating the iodine number, a large excess of iodine was allowed to act upon the oil for from 18 to 20 hours:—

	German Seed.		Dutch Oil.		English Oil.

### PATENTS.

*Improvements in extracting Oil from Oil-containing Plants and Fruits, and in the Production of Fodder from the Residual Matter.* W. Spindler and C. Stautz, Darmstadt. Eng. Pat. 16,987, September 9, 1893.

THE raw materials containing oil are mixed with a solution of salt, containing 2 to 5 per cent., and boiled for a short time. Instead of a saline solution, a solution of sugar or syrup, &c., might be used, but it is too expensive, and the fodder produced is inferior. The mass is placed in a press, and a slight pressure applied, when the saline solution flows at first of a milky colour, together with almost all the soluble portion of the material. Upon increasing the pressure, the oil is expressed, which may be allowed to float upon the saline solution, and separated in the usual way. The compressed material is then allowed to dry for use as fodder.

—J. J. K.

*Improvements in Apparatus to be Employed in the Clewing of Cotton Seeds.* W. A. Tattersall and W. E. Pearson, Cleckheaton. Eng. Pat. 17,808, September 22, 1893.

THE object of this invention is to remove all adhering cotton or floss from the seeds by special apparatus, preparatory to their being crushed for the extraction of oil, &c. The improved apparatus is provided with a hopper for the reception of the raw seeds, which pass therefrom into a concave tapered dish, perforated from the outside, so as to leave projecting burr edges in the interior, which serve as a holding surface for the seeds whilst they are acted upon by a taper roller covered with card teeth. The revolution of the card-covered roller serves to comb or card the cotton from the seeds, and the roughened interior of the dish prevents too much freedom in the motion of the seeds. The dish and taper roller are set at a slight incline, so that the seeds gradually fall towards the lower edge, where they are discharged.—J. J. K.

## XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, Etc.

### (A.)—PIGMENTS, PAINTS.

#### PATENTS.

*An Improvement in the Manufacture of Sulphate of Lead Pigment.* A. Macdonald, Notting Hill. Eng. Pat. 11,972, June 17, 1893.

THE fumes of lead sulphate, if condensed in water, are filter-pressed, and then, wet or dry, are heated in the presence of air to a temperature of about 230° C. to destroy impurities.—F. H. L.

*Improvements in the Manufacture of Oil Paints and Compositions from Carbonised or Calcined Ironstone or Iron-ore.* A. Angell, Southampton. Eng. Pat. 7465, April 14, 1893.

THE pigment is heated to a temperature of about 150° C. after a preliminary grinding and before mixing with the oil, in order to remove moisture and as much air as possible from its capillary spaces. In the case of black "polarite," the heat should not be allowed to exceed 145°, and the mixture with the oil should take place at about 40° C.

—F. H. L.

*Manufacture of Coated Metallic Powders.* O. Inray, London. From J. Sachs, New York. Eng. Pat. 12,382, June 26, 1894.

"THIS invention relates to the manufacture of metallic powder, each particle of which consists of a core of one metal and a shell of another, the powder thus produced being applicable to purposes to which bronze powders, flitters or flakes, and metallics or large granules are applied, but at a less cost." Ordinary zinc powder is cleaned and immersed in a solution of zinc and copper in potassium cyanide and ammonia, with continual agitation until it is uniformly coated. The proportions of the copper and zinc may be varied according to the colour, &c. desired, or other metals may be employed, with or without heat and an electric current.—F. H. L.

### (B.)—RESINS, VARNISHES.

#### PATENTS.

*Improvements in Covering Lead Surfaces to Protect Water and other Potable Liquids in Contact therewith from Contamination.* A. McDougall, Southport. Eng. Pat. 14,586, July 29, 1893.

THE surfaces are coated with a mixture of equal parts of cotton-seed pitch dissolved in carbon bisulphide, and caoutchouc dissolved in naphtha.—F. H. L.

*Improvements in the Manufacture of a Drying Medium for Paints, and of Oil Varnish.* J. E. and C. S. Bedford, Leeds. Eng. Pat. 17,581, September 19, 1893.

THE fatty acids obtained from the hydrolysis of linseed oil or the mixture of such acids and unaltered oil produced by treating the latter with alkali insufficient in amount to saponify it completely, are submitted, in the presence of a small quantity of litharge, to the action of air or oxygen at a temperature not exceeding 70° C. in an apparatus such as that described in Eng. Pat. 18,628, 1889 (this Journal, 1890, 1046). Treated in this manner, they gain considerably in viscosity, and finally become almost insoluble in turpentine and petroleum spirit, but still remain miscible with oxidised or boiled linseed oil. To prepare a quick-drying varnish for use in floorcloth manufacture, the acids themselves, after oxidation, are diluted with 10 per cent. of turpentine or other solvent, heated to 70°, 5 to 15 per cent. of the moist hydrate of barium, strontium, calcium, or magnesium added, and the whole stirred vigorously till the soap has dissolved. Such a product when spread upon oil-cloth, with or without pigments, and placed in a stove heated to 60°–70° will dry in 12 hours without tackiness. To make a thinner varnish the mixture of oil and fatty acids, after oxidation, is cooled, and 50 per cent. of turpentine, &c., together with 3–7 per cent. of calcined magnesia added, and the whole thoroughly mixed.

One advantage claimed for these varnishes is that they yield smooth, glassy films free from wrinkles.—F. H. L.

*A New or Improved Furniture Polish.* A. P. Horn, Hamburg. Eng. Pat. 12,305, June 25, 1894.

THE inventor replaces the methylated spirit usually employed in the final operation of French polishing—know

as "spiriting-off"—by the following mixture:—8 kilos. of gum-benzoin and 16 of sandarac are dissolved in a mixture of 240 kilos. of alcohol and 120 of acetone, and, after filtering, 440 kilos. of "benzine" are added.—F. H. L.

#### (C).—INDIA-RUBBER, &c.

*Improvements in Apparatus for Separating Foreign Substances from Waste Rubber, Bark, Grain, and other Materials.* J. Anderson, jun., Manchester. Eng. Pat. 17,477, September 16, 1893.

See under L, page 871.

## XIV.—TANNING, LEATHER, GLUE, AND SIZE.

*Refined Fish Tallow.* W. Eitner. Leather Trades Circular and Review, 1894, 1035.

Fish tallow is the solid grease which is separated at a low temperature from different kinds of fish oil; being a cheap and suitable material it is used in many tanneries, chiefly as "dégas." The fish tallow obtained from whale-blubber does not require much refining, and is as good for leather-dressing as is ox tallow; that from Japanese train oil contains a substance which has been termed fish glue, but is, in reality, closely allied to resin and india-rubber. This foreign matter is fatal to the successful employment of the fish tallow as imported in cakes from Japan; it prevents the grease from penetrating the skin, and remains as a sticky mass on the surface of the leather when the dubbing is applied on the table, although in the stuffing drum the effects of this resinous matter are not so serious. The refined fish tallow now placed on the market is free from this objectionable constituent, and is of a much brighter colour than the crude substance. It melts at 42° and is not so stiff as ox tallow. The market form of the refined fish tallow is that of pressed cakes, having an odour similar to that of chamois-dégas. It is much extolled by the author as a substitute for ox tallow.—A. G. B.

*Canaigre as a Substitute for Bark in Tanning.* Board of Trade Journal, September 1894, 262.

As supplementing the information already available on the subject of the use of canaigre as a substitute for bark in tanning (see also this Journal, May 1894, 650), the United States Vice-Consul-General at Vienna, in a recent report to his Government, supplies the following additional particulars:—

Eitner, director of the experimental station for the leather industry in Vienna, has made numerous experiments with the newly introduced American tanning material canaigre, and states that it has the property of tanning leather in a short time, and of giving it a brighter, clearer orange colour than has been obtained by any other tanning material. The leather is soft, neither shrinks nor swells, and although rapidly dyed, is strong, and not at all brittle.

Canaigre has also been used with good results at the Levinische Fabrik, Trieste, in the tanning of sole leather, particularly sole leather for the finer kinds of ladies' shoes. In the treatment of leather for ladies' shoes, the canaigre is added to pine bark. It affects the leather first, and causes the pine to act more quickly and evenly than it would otherwise do. In the Levinische Fabrik, in the final tanning process of skins which are to be used for sole leather, the skins are treated with a powerful mixture of extracts. In the first bath, to which the skins are subjected for 16 days, 7 German lb. of oak bark and 2 lb. of canaigre

or valonia are used. In the second bath, which lasts 24 days, there are 6 lb. of oak bark and 3 lb. canaigre; and in the third, which lasts 30 days, 5 lb. of oak bark and 3 lb. of canaigre or valonia. Very strong skins sometimes receive a fourth bath.

In tanning with extracts, canaigre seems to have a special value in giving colour and strength. Even when used in small quantities, with other powerful extracts, there is a noticeable difference if canaigre is used instead of valonia, the leather having a brighter yellow colour.

Canaigre is better than any other material for retanning leather which has been imperfectly tanned.

Canaigre is very similar to gambier in its tanning properties, and if it is ever to be exported in large quantities to Europe it will have, for the same amount of tanning power, to be as cheap or cheaper than the last-named article. It is for this reason that gambier has a particular importance for anyone interested in the sale of canaigre.

The firm of Blau and Schindler, of Hamburg, has imported more canaigre than any other continental firm, but, according to its own statement, has only imported it in small quantities, as it is not cheap enough at present to compete with gambier. Practically, the entire crop of gambier is shipped from India to England, and thence exported to the other European countries and to the United States. Gambier proper sells in Vienna or Hamburg at 8 dols. per 100 kilos. (220·46 lb.), while cutch, or wood gambier, is cheaper.

##### PATENTS.

*Improvements in the Manufacture of Leather for Gloves and other Purposes.* L. Cöhn, Johannegeorgenstadt, Germany. Eng. Pat. 12,518, July 2, 1894.

THE flesh side of the kid or other leather destined for the manufacture of gloves is to be rendered as smooth and soft as the grain side, which is usually made the outside surface of the glove. The flesh side (inside of the glove) is also to be tinted either of the same or of another tint as that employed for the grain side. In this way the finished glove will be of a better appearance and will keep cleaner than is at present the case.—A. G. B.

*An Improved Method or Process of Fastening the Colours upon and within Coloured Leathers.* J. T. Hardy, A. Brownson, and F. J. Bradley, Nottingham. Eng. Pat. 18,349, July 4, 1894.

THE skins, when dyed, are struck out and dried in the usual manner, and the grain is then covered with chrome-alumed gelatin, prepared by dissolving 1½ lb. of gelatin in three gallons of water and adding to the hot liquid ½ lb. of chrome alum dissolved in one pint of water. A mixture of glue (48 parts) and chrome alum (2 parts) with water (50 parts) may be substituted for the gelatin mixture. When the concoction has set to a jelly it is brushed over the skins, which are then exposed to the light, whereby the gelatin becomes insoluble. The seasoning and finishing processes are then effected as usual.—A. G. B.

## XV.—MANURES, Etc.

*The Solubility of the Phosphoric Acid contained in Bone Meals.* L. Gebek. Zeits. angew. Chem. 1894, 193–197.

It is well known that the manurial value of the phosphoric acid in bone meals is comparatively small, and not at all in accordance with the results to be expected from analytical data. Certain observations, as, for instance, the fact that a considerable portion of the  $P_2O_5$  is "citrate-soluble," indicate the presence of dibasic calcium phosphate—a compound very generally accepted as being of value for

plant-food. Indeed, from the author's analyses—the results of which are given in a series of tables—it appears that the bulk of the phosphate in bone meals is citrate-soluble. In practice, however, he finds that the amount of  $P_2O_5$  extracted by ammonium citrate (Wagner's solution; this Journal, 1894, 219, and also 769) depends very greatly on the degree of subdivision of the material under examination. For example, a series of bone meals when finely powdered yielded on an average over 80 per cent., and in two cases over 90 per cent., of their  $P_2O_5$  to the solvent; whilst from coarse meals, just able to pass through a sieve with meshes 1 mm. wide, only about 50 per cent. were extracted. On the other hand, ignition of the meals was found to materially alter their constitution, the soluble  $P_2O_5$  being reduced to 30 per cent. The extraction of the gelatin by steaming has a similar effect, although less marked (soluble  $P_2O_5$ , 68 per cent.). It is obvious, therefore, that investigations concerning the nature of the mineral constituents of bone must not be made on bone ash. For such researches Gabriel's method of removing the gelatin (by heating to 200° C. with glycerol and subsequently washing) proved very satisfactory, since the percentage of citrate-soluble  $P_2O_5$  is not sensibly altered thereby.

From his results the author concludes that only a small proportion of the  $P_2O_5$  of bones can exist as tricalcic phosphate; and he suggests, as more probable, that the bulk exists as dibasic phosphate, the remainder being in the form of a tribasic phosphate in which part of the lime is replaced by an organic base. On ignition, the organic base would be destroyed, its place being taken by lime derived from calcium carbonate.—H. T. P.

*Method for the Volumetric Estimation of the Phosphoric Acid Soluble in Water, contained in Superphosphates.* W. Kalmano and K. Meissels. Chem. Zeit. Rep. 18, 1894, 180.

### XVII.—BREWING, WINES, SPIRITS, Etc.

*The Ready-formed Sugars of Malt.* E. Ehrich. Chem. Zeit. Rep. 18, 1894, 70.

The sugars occurring in barley-malt are cane sugar, invert sugar, and maltose. Isomaltose is not present.

The average percentage of these sugars is—Cane sugar, 4.54; invert sugar, 0.71; maltose, 0.82; total, 6.07.

The figures are looked upon as more accurate than those of O'Sullivan and Heron.

Malt is digested with water after treatment with strong alcohol, and, besides the estimation of the total weight of sugars by means of fermentation, the cupric reducing power and rotatory power can be determined. There are, however, present in the aqueous extract bodies other than sugars, which have a decided reducing power and rotatory power, and hence these determinations must not be taken as due entirely to sugars.—T. A. G.

*The Kiln drying of Malt as judged by the Colour of the Malt Combs.* Franz Uerny. Oester. Brauer- und Hopfen-Zeit. 7, 1894, 1.

It was found that under exactly similar conditions of curing the combs of a regularly-grown malt are darker than those of an overgrown malt, whilst the worts from the latter are the darker. Malts were cured without reference to the thermometer, and it was repeatedly found that with equal colours of malt-combs the malts gave worts differing greatly in colour. This difference is to be attributed to the different lengths of acrospire. Samples were taken at different stages from the malting-floor, and all cured under the same conditions at 100–105° C. The results indicate that the colour of a malt is not always indicated by the colour of the combs, but that the chief criterion of colour should be the acrospire. It follows then that younger and less fully-grown malts (as judged by the acrospire) should be kilned to yield darker combs than malts grown for a longer period or in which the acrospire is more fully developed.—T. A. G.

*The Composition of Hops and their Relation to Wort.* L. Aubry. Zeits. ges. Brauw. 17, 1894, 1.

The estimation of the alcoholic and water extracts is found to be useless, since two very dissimilar hops gave almost identical extracts. These two hops were extracted with petroleum ether, and the resin, ethereal oil, bitter principle, and nitrogen estimated both before and after removal of the resin.

The results show that very little nitrogenous matter is removed by water, hence it is of little importance in the wort. Worts boiled with the two kinds of hops yielded the same amount of total nitrogen; also the albuminoids in the worts boiled with resin-free hops were the same as in those boiled with normal hops. Petroleum ether removes no bodies from hops which could cause a precipitation of albuminoids.

Worts were boiled with completely ripe hops and hops containing many unripe cones, and the worts as well as the resulting beers were analysed. No difference could be detected in the beers on analysis, nor did the degree of hop-ripeness affect the degree of fermentation. Unhopped worts fermented less vigorously than hopped worts. The quality of hops has little influence on the composition of the wort and no influence on the extent of fermentation.—T. A. G.

*The Albuminoids contained in Worts and Beers.* Wahl and Hantke. Amer. Brewers' Review, 7 [32].

The authors have made a series of experiments on the albuminoids in worts, and also in fermented worts and beers.

They divide the albuminoids into the three classes, protein, peptone, and amide, and separate each class as follows:—

The protein albuminoids are separated by means of copper hydrate, lead or ferric acetate, or simply by heating with a few drops of acid, the results given in each case agreeing very closely.

The peptone albuminoids are separated either by means of tannin or phospho-tungstic acid, the tannin giving slightly larger results.

The amide albuminoids are estimated after the elimination of the two previous groups.

The authors also find that after the fermentation of worts the quantity of yeast obtained at the finish is considerably in excess of that used at the commencement, and during its growth that the yeast has absorbed a considerable quantity of the nitrogen of the albuminoids present in the original wort, the albuminoids which chiefly disappear being the non-coagulable or amide albuminoids. They also find that a larger amount of amide nitrogen disappears the higher the temperature at which fermentation takes place.—O. F. R.

*The Effect of Albuminoids in the Manufacture of Beer.* Wahl and Nilson. Amer. Brewers' Review, 1894 [38], 42.

The authors have made a series of experiments to find out which of the known albuminoids affect the stability, permanency of head, and maturity of a beer, and also whether these albuminoids have any disadvantageous effects, and whether the method of mashing in any way alters the character of the albuminoids.

*Influence of the Mash Temperature.*—The temperature at which the greatest amount of albuminoids is extracted is 110° F., the greatest sugar extract at 131°, and the greatest possible extract at 149°, at temperatures from 149° up to 152° F. the conversion of the starch becomes complete.

*Influence of Duration of Mashing.*—At 149° the quantity of albuminoids in the wort is not altered, whether the malt is mashed  $1\frac{1}{2}$  or 3 hours, but at temperatures below 140° the amount of albuminoids is greater after 3 hours' mashing than after  $1\frac{1}{2}$  hours.

*Coagulation of the Albuminoids.*—A greater amount of coagulable albuminoids is formed at a temperature ranging between 95 and 104° than at a high temperature such as 140—176°, the wort breaking much better in the former case.

*Effect of Concentration of Wort.*—The amounts of albuminoids and sugars extracted, do not vary between the limits of 1 part malt and 8 parts water, and 1 part malt to  $2\frac{1}{2}$  water, but at greater concentration the amount of albuminoids extracted, increases.

*Influence of Concentration and Temperature on Bodies containing the Amido Group.*—The proportion of amides to non-amides is a constant for different concentrations and temperatures.

When malt is poured into boiling water, the insoluble albuminoids or amides, are converted into soluble albuminoids, which are mainly composed of peptones.

—O. F. R.

*"Maltol," the Substance obtained from Crystallised Malt which gives, apparently, the Salicylic Acid Reaction.* Braud. Wochenschr. f. Brauerei 11, 1894, 514.

It has been previously shown that high dried and crystallised malts contain a substance which gives with ferric chloride a violet coloration similar to that afforded by salicylic acid. In this communication the author has isolated this substance, which he calls "Maltol," by extracting worts and beers, made from crystallised malts, with ether; "Maltol" is also found in pale malts to a small extent.

"Maltol" is a crystalline substance, which dissolves easily in water and all the usual organic solvents except petroleum spirit. It is not a true acid, although it dissolves in alkali and is precipitated by acid, but has rather the properties of a phenol; it also reduces Fehling's solution. The author gives it the formula  $C_6H_6O_3$ , and supposes it to be formed from the carbohydrate  $C_6H_{12}O_6$  by loss of  $3H_2O$ .

—O. F. R.

See under XXIII., page 908.

## PATENTS.

*Improvements in Apparatus for regulating the Temperature of Fermenting Liquids.* E. N. Collios, Great Yarmouth. Eng. Pat. 16,692, September 5, 1893.

AN arrangement of horizontal flattened tubes, communicating at each end with a water space, is supported by means of tubular trunnions on tubular pedestals within the vessel containing the fermenting liquid. The cold water passes up one pedestal into the adjacent water space, then alternately to and fro through the tubes to the opposite water space, and thence out through the pedestal. The mounting on trunnions enables the apparatus to be readily cleansed.

—J. G. W.

*Improvements in Apparatus for the Manufacture of Beer.* A. W. Billings, London. Eng. Pat. 17,912, September 23, 1893.

THE converting vessel described in Eng. Pat. 8952, 1892, is provided with a heavy iron or steel bottom in which are the usual discharge openings. Over these is fixed a moveable slotted or perforated straining plate. The inventor claims that the apparatus may be used as a converter, boiling kettle, hop back, or cooler. For use as a converter the straining plate is removed and the mash made in the usual way and discharged into the filter tub. The straining plate having been fixed in position the clear liquor is now pumped back again, the hops added, and steam passed into the jacket so as to raise the contents to boiling. The author has found it advantageous to keep the stirrers in motion during boiling. Steam is then shut off and cold water run through the jacket to cool the wort, which is then strained off from the hops, leaving them in a suitable position for reboiling with fresh wort.—J. G. W.

*Improvements in the Treatment of Hops.* J. T. Connell, Edinburgh. Eng. Pat. 19,043, October 10, 1893.

It has been found that after hops have been employed in brewing they are not "spent," as is supposed, but may be revived so as to be fit for use a second time in brewing beer. They may in fact be "recured" by heating them suitably in a hop or malt kiln in the same manner as freshly picked hops, and it is claimed that they can then be used instead of new hops in brewing if a greater proportion be employed.—J. G. W.

*Aerated Wines and Spirits.* J. W. Fenn, London, and E. Abraham, Ripon. Eng. Pat. 4086, February 26, 1894.

CARBONIC acid gas is forced under pressure into wines or spirits, and is claimed to effect an improvement in quality and flavour.—J. G. W.

*Improvements relating to the Manufacture of Sugars, Syrups, Alcohol, and Beer.* H. H. Lake, London. From A. L. Tedesco, Paris. Eng. Pat. 9054, May 7, 1894.

THESE improvements are claimed to obviate the slight caramelisation which takes place during the saccharification of starch or amylaceous substances under high steam pressure. In the inversion of starch by acids, air is forced into the saccharifying vessel through the body of the contents, the temperature of which is not allowed to rise above 120° C. For converting worts by the agency of malt diastase the necessary quantity of malt is added to the wort, which is at a temperature of 60° C., contained in a closed saccharifying vessel, air or compressed gases being then forced into it. The employment of nitric acid in small

quantity under high pressure is also a ready method of inverting amylaceous materials. The amylaceous wort, to which one-half per cent. of nitric acid has been added, is liquefied by steam at a temperature of 100° C. The steam is then shut off and air forced into the vessel. When saccharification is complete the liquid is freed from acid by concentration in a vacuum apparatus.—J. G. W.

## XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY AND WATER PURIFICATION, DISINFECTANTS.

### (A.)—CHEMISTRY OF FOODS.

*Discrimination of Drinking Waters.* D. Vedrádi. Chem. Zeit. 18, 1894, 585–586.

THE activity lately shown in certain districts of Hungary in the construction of deep wells has enabled the author to observe the interesting fact that the waters drawn therefrom were almost without exception of a nature usually considered as impure, containing, as they did, large amounts of organic matter, nitrates, ammonia, and in many cases even nitrites. The possibility of such contamination being derived from the influx of impure surface-waters was entirely negated by the nature and extent of the strata (mostly clay) passed through. Recent boring operations at the town of Debreczin put the author in a position to throw some light on the question. Although the depth attained was 840 metres, water was not found. Chemical examination of samples of the dry clay, sand, &c., excavated at various depths revealed the fact that organic matter (0.009 to 0.21 per cent., estimated by permanganate) was present at all depths, the maximum occurring at 650 metres. Chlorine and nitrous acids were found generally only in more or less strong traces; whilst ammonia and nitric acid were present in large amounts down to a depth of 200 metres: below that in traces. It is obvious, therefore, that the impurities in the class of water under consideration are derived from the soil itself, and are not due to pollution by sewage, &c. The author is of opinion that it is inexpedient to judge the fitness of such waters for drinking purposes by the usual standards; and that too much stress should not be laid on the presence of—otherwise inadmissible—proportions of organic matter, &c.—H. T. P.

*Poisonous Fodder Plants.* John R. Jackson. Chem. and Druggist, 1894, 267–268.

*Indian Peas (Lathyrus sativus).*—Artier has discovered the presence in the seed, of a volatile liquid alkaloid probably produced by some proteid ferment. The toxic action of the seeds was found to be destroyed by heat. The chief symptom is paralysis of the extremities, which in many cases becomes permanent.

*Sophora Secundiflora.*—A narcotic poison is found in the seeds of this species. It is a small tree or tall shrub growing in Mexico or Texas, forming dense thickets on the borders of streams. The seeds are rather larger than a haricot-bean and of a bright red colour. The Indians in the neighbourhood of San Antonio use them as an intoxicant. Half a seed produces exhilaration followed by narcosis extending over 2–3 days, whilst a whole bean is fatal. The principal is an alkaloid—*Sophorine*.

*Gastrolobium.*—Several species are commonly known in Australia as “Poison Bushes,” especially *G. bilobum*; *G. calycinum*; *G. callistachys*; *G. ocylobioides*; *G. spinosum*; *G. trilobum*; and *G. obovatum*. Large numbers of cattle are annually lost in Western Australia through eating these plants. The first symptom is *dyspnea*; the animals then stagger, fall, and die. The blossoms are most saturated

with the poison, though the young shoots even are poisonous. Sheep and cattle are killed by it, whilst wild pigeons eat blossoms or leaves with impunity.

*Gastrolobium grandiflorum* is a species found in Queensland and Northern Australia. It is known as the “Desert Poison-bush.”

*Gompholobum uncinatum.*—A leguminous plant, nearly allied to the *Gastrolobiums*. It is a small shrub of New South Wales, and is very poisonous.

*Tiphosia purpurea* and *T. rosea*, leguminous plants of South Australia, New South Wales, and Northern Australia. Also poisonous.

*Swainsonia.*—Several species of this kind have an evil reputation in Australia. The active principle has not yet been isolated. On drying the plants it is decomposed.

*Swainsonia galegifolia*, the “Darling Pea,” or “Indigo plant,” of Australia, is one of the plants most dreaded by stock-owners.

*Swainsonia Grayana* causes even more serious effects. The principle remains yet to be isolated.

*Trachymen australis*, an umbelliferous plant of Australia, known as the “Wild Parsnip.” It is terribly powerful, and no remedial measures are known.

*Sarcostemma australe*, the “Caustic Vine” of Queensland, is a plant belonging to the Asclepiadaceæ. Very poisonous.

*Erenophila maculata.*—Known in Queensland as the Native Fuchsia. Belongs to the natural order Myoporinæ. To this plant, it is said, though at first poisonous, stock may become accustomed. It is said to be more powerful after rain, and most dangerous when in fruit.

*Euphorbia Drummondii*, the “Caustic Creeper,” or “Milk Plant,” of Queensland. If eaten by sheep in the early morning before the sun has dried it up, it is almost certain to prove fatal.

*Stypandra glauca.*—A liliaceous plant, common around Sydney, the Blue Mountains, and other parts of New South Wales. It is known as the Candy Poison. It acts upon the eyes and causes blindness, but is not very fatal. The effects are known in Western Australia as “blind disease.” —W. S.

*Further Note on the Determination of the Fat in Bread.* M. Webull. Zeits. angew. Chem. 1894, 199.

See under XXIII., page 908.

### PATENTS.

*Improvements in the Manufacture of Gelatin.* E. S. Spencer, London. Eng. Pat. 14,491, July 27, 1893.

GELATIN in the form of sheets or in other solid, dry state is granulated or crushed, and, after the fine powder has been separated, the coarse granules are rolled between smooth rollers in such a manner that each granule is flattened into a thin flake. The object of the process is to reduce the cost of the manufacture of gelatin in a readily-soluble form, and to render the gelatin better adapted for resisting climatic influences.—A. G. B.

*Improvements in the Treatment of Eggs.* J. Fordred, London. Eng. Pat. 15,762, August 19, 1893.

THE essential feature of this invention is the use of sugars (preferably glucose, maltose, dextrose, &c.) under certain conditions for the preparation of the contents of eggs, in such a state which will enable the compound to be kept for a considerable time of uniform consistency, without deterioration, and readily miscible with water and other liquids. The yolks and whites of 1,200 eggs are carefully removed from the shells and well mixed or beaten; 100 lb. of this are placed in a pan fitted with stirring apparatus. This pan is fitted into a water-bath, the temperature of which should be from 160° to 170° F., so as to maintain the contents of the pan at about 145° F.; 50 lb. of sugar are then gradually added and stirred. The heat and

stirring is now continued until the mixture has lost 30 per cent. of its weight in five hours, when a deep and rich orange colour is produced. It is then strained through a hair sieve, and when cold, should be translucent and fit to be packed. The yolks or whites can be treated separately in the same way. It is also proposed to mix 3 parts of the above compound with 2 parts of condensed milk of commerce.—J. J. K.

*Improvements in Extracting Oil from Oil-containing Plants and Fruits, and in the Production of Fodder from the Residual Matter.* W. Spindler and C. Stautz, Darmstadt. Eng. Pat. 16,987, September 9, 1893.

See under XII., page 893.

*An Improved Food.* C. Morfit, London. Eng. Pat. 17,636, September 19, 1893.

This invention relates to the improvement of skim milk, whereby its deficiency in fat is restored. 100 gallons of the milk with 50 to 200 lb. of white sugar are boiled in a vacuum pan to one-third or even one-fourth of its bulk. The mixture is transferred to another pan, and 1½ to 2 oz. of refined cotton-seed oil are added, and the whole stirred until thoroughly blended. This artificial milk is termed "lactola." The admixture of coffee, cocoa, tea, or extract of meat with "lactola" is also claimed.—J. J. K.

*Improvements in and in Apparatus for the Preparation or Treatment of Alimentary Substances.* E. Maris, Monancourt (Eure), France. Eng. Pat. 17,732, September 20, 1893.

THE object of this invention is the preparation, in a highly-assimilable condition, of alimentary substances suitable for consumption by the human race and animals. To do this the substances are submitted to a preparatory treatment by crushing and artificial digestion, or reproducing as nearly as possible the different phases of natural digestion. The ground substance is put into digesting troughs together with three or four times its weight of water slightly acidified with hydrochloric acid, and sea salt, after which the necessary ferment (as pepsin, trypsin, invertin, amylase, and mineral ferment from grains, cellulose, &c.), to the extent of 5 per cent., are added, and the contents kept at a temperature of 35° C. for 12 hours, after which they are transferred to a digester, in which they are allowed to remain for two hours under steam pressure. The temperature is first raised to 65° C., and finally to 130° C. to destroy ferments and germs. The composition of a fodder, made from wood in this way, and which resembles that of good meadow hay, is—

Water.....	13.00
Albuminoid matter.....	8.74
Fatty matter.....	2.62
Non-nitrogenous extracts.....	38.64
Ligneous matters.....	31.00
Mineral matters.....	6.00
	<hr/> 100.00

—J. J. K.

*Process for Manufacturing a Food which increases the Production of Milk with Milk Animals.* T. Kluten-tröter, Magdeburg, Germany. Eng. Pat. 8360, April 27, 1894.

THE claim is for the manufacture of a milk-increasing food, by mixing 80 parts of basic phosphate of lime with the following mixture of 2½ parts of albumin, 2½ parts of yolk, and 15 parts of powdered sugar. The mixture is then ground. A daily dose of 75 grms. of this food are said to raise the production of milk by two litres.—J. J. K.

*Improved Means for Production of Effervescent Beverages.* R. Wichmann, Hamburg. Eng. Pat. 12,503, June 27, 1894.

"A CONTINUALLY acting effervescent mixture, consisting of comfit grains of desired size according to the duration of the effervescence." One half of the mixture is a salt, like bicarbonate of soda, enclosed within a layer of sugar. The other half consists of an acid, like tartaric or citric acid, similarly enclosed.—J. J. K.

## (B.)—SANITARY CHEMISTRY AND WATER PURIFICATION.

*Hermite's Process for Purifying Drainage Waters by Electricity.* Elektrotechn. Zeits. 1894, 15, 84.

A COMMISSION appointed by the "Conseil Central d'Hygiène" of Havre to investigate the above process, report that sterilisation is not effected rapidly enough to serve as a guarantee of its efficiency for disinfecting drainage waters. The process appears to be capable of destroying the unpleasant odour of certain chemical products.—A. R. L.

## PATENTS.

*Improved Antiseptic and Preserving Agents.* P. Håkansson, Esköf, Sweden. Eng. Pat. 10,465, May 27, 1893.

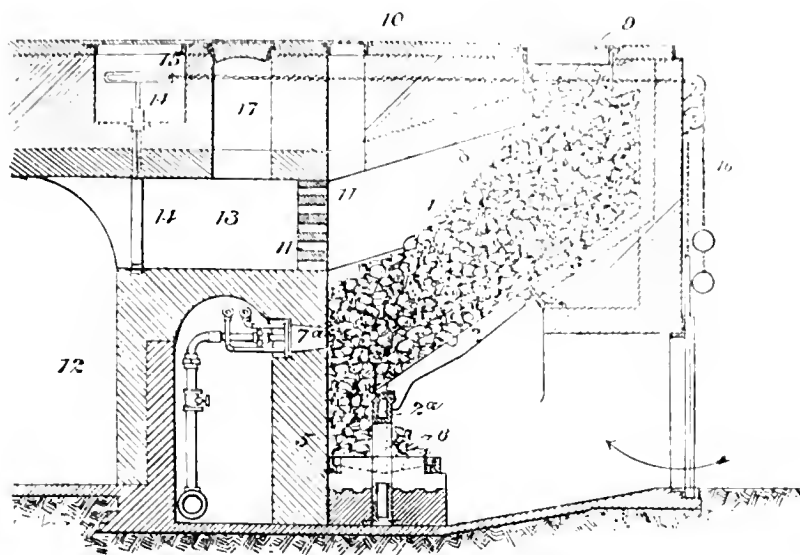

A MIXTURE of acetic ether and alcohol, with or without acetic acid, constitutes the new antiseptic and preserving agent called "salubrine." Suitable proportions are: acetic ether, 10—40 per cent.; alcohol, 20—50 per cent.; acetic acid, 2—3 per cent.; water, 68—7 per cent. When the above percentages are 25, 50, 2½, and 22½ respectively, the preparation is suitable for definite purposes, and is termed "salubrine A." A number of variations in strength for special purposes is quoted. Salubrine may be evaporated in a room to be deodorised; it may be used as a hair remedy, in which case aromatic oils are added; or it may be used as an insecticide to be applied to plants, in which case the acetic acid is omitted; when it is applied to the skin, glycerol, oil, or fat should be added.—A. G. B.

*Improvements in Furnaces for Burning Refuse Material, such as Town's Refuse.* J. B. Alliot and J. McC. C. Paton, both of Nottingham. Eng. Pat. 15,717, August 18, 1893.

THE figure shows a sectional elevation of this destructor furnace in which 1 is the main combustion chamber, 2 the firegrate, the lower end of which is carried on a hollow bearer 2a, through which water is circulated to keep it cool. The lower grate 6 is of sufficient length to prevent clinker, &c., which fall on to it from the upper grate, from falling over its front end. The clinker, &c. remains on this lower grate until more completely burnt and partially cooled, when it is raked off over the front end. 7, 7a, and 7b are tuyères through which air, in addition to that entering through the firebars, is forced; 7 and 7b, on either side of 7a, are not visible in fig. 3 is a drying-hearth on to which the refuse to be burnt is fed through the aperture 9. The stoking-hole 10 permits the introduction of an iron bar for keeping the grate and back wall 5 from getting clinkered up. The products of combustion are drawn through the openings 11, 11, which are at the hottest part of the fire, into the main flue 12, through an intermediate chamber 13, fitted with a damper 14. Three modified forms of the destructor are also described. The claims made in a furnace of this kind are for the combustion chamber, having a hearth so inclined that refuse and clinker thereon will move downwards automatically or with little help; for the fire grate, similarly inclined, and through which air is admitted to the combustion chamber; and for the back wall with inlet or inlets to admit air, to aid that admitted

through the inclined grate; also an opening or space behind the back wall and the adjacent end of the inclined

grate. Provisions for feeding refuse on to the upper grate, and for introducing air into the combustion chamber

FURNACE FOR BURNING REFUSE MATERIAL.

opposite to the feed end, as well as provision for the escape of products of combustion from the hottest part of the furnace, are further claimed. Finally, the intermediate chamber 13, as arranged, is claimed.—R. B. P.

**Improvements in and Retort Apparatus for Treating Town Refuse or Excrementitious or like Matter, and obtaining useful Products therefrom.** J. Hanson, Wakefield. Eng. Pat. 16,368, August 30, 1893.

According to this invention, a closed retort or vessel is provided, into which the refuse to be treated is introduced, and in which it is subjected to heat by which it is converted into an inodorous and innoxious carbonaceous residue (which may be stored, and is suitable for fuel) and an inflammable gas, which may either be stored in a holder and used for heating purposes as required, or at once used for firing the retorts.

The patentee proposes to use vertical retorts fitted at the top with hoppers for receipt of the refuse, and shoots at the bottom for the discharge of the carbonaceous residue. Each retort is furnished with means whereby the contents may be stirred during heating and adherence of carbonised matter to the sides thus prevented. This stirring apparatus may consist of a shaft running through the retort and furnished with arms, where the retort is charged and then closed during treatment of the charge; or of an Archimedean screw where (as is preferred) the refuse is supplied, treated, and expelled continuously. A steam jet may be introduced into the retort to produce a partial vacuum and thus help the operation or to aid in the production of inflammable gas, or a fan or other means of producing a reduction of pressure in the interior of the retort may be employed.—L. T. T.

**Improvements in the Purification of Sewage.** L. Archbutt and R. M. Deeley, Derby. Eng. Pat. 18,416, October 2, 1893.

THE effluent from a plant in which sewage is treated by the methods described in previous patents (this Journal, 1892, 595; 1893, 942) still contains albuminoids in solution, which are incapable of removal by chemical precipitation, but are destroyed by the agency of the nitrifying organism and other bacteria. The improved process is carried out as

follows:—The impure water is mixed in a tank with the chemicals necessary for precipitation, agitated with the precipitate from previous operations, and allowed to settle; the clear liquid is then transferred to another tank, treated with fuel gases in sufficient quantity to convert all free alkali into bicarbonate, and turned on to a filter bed. This treatment with fuel gases prevents the clogging of the filter bed and promotes the growth of micro-organisms. The filter bed consists of a layer of 8 inches of coarse gravel in which drain-pipes are laid, 5 inches of fine pea-gravel, and 5 feet of coarse mortar sand; it is of such an area that the whole contents of the carbonating tank shall have drained away before the next contents are ready for filtration; in this way the filter bed will be kept well aerated.—A. G. B.

**Improvements in Means for Treating the Refuse of Inhabited Areas.** R. C. Sayer, Bristol. Eng. Pat. 1452, January 23, 1894.

THE object of this invention is to treat refuse by heat so as to render it innocuous, and to utilise the residues. The refuse is treated in closed destructor furnaces, with or without the addition of fuel, whereby a gas is obtained. Part of the furnace-heat is used for generating steam, which drives an air compressor. Part of the compressed air from this is heated and injected through tuyères into the furnace, whilst another part, together with some of the gas from the furnace, is circulated through pipes to the houses in the district served by the plant. The gas and air mixture is supplied to and utilised in "cabinets," in which the solid and liquid human excrement is separated. The excrementitious matter is reduced by heat raised by burning the gas, and by the air, until the residue is drawn away by suitable means through pipes. The residue unites with the foul air from rooms, and with the products of combustion from house fires, after they have been purified with water, and is drawn back to the destructor along suitable conduits. It is further reduced in these by jets of gas and air. The dust residues obtained are used as manure, and the gaseous ones, after being washed with water, pass through a chimney into the atmosphere. The purifying water is used again after filtration through a combustible material. The latter, when saturated, is burnt in the destructor as fuel.—R. B. P.

*An Improved Method to Precipitate the solid Animal, Mineral, and Vegetable Matter contained in Sewage Water.* A. Mosley, London. Eng. Pat. 11,484, June 13, 1894.

When water which is colder than the sewage to be treated, is thrown upon the surface of such sewage water, the suspended matters settle to the bottom more rapidly than would otherwise be the case. To apply the principle, the sewage, to which chemicals have been added, would be warmed by hot-water pipes during its flow through the culvert leading to the settling tanks, and when it had arrived in these tanks, cold water would be sprinkled or poured on its surface.—A. G. B.

### (C.)—DISINFECTANTS.

#### PATENTS.

*Improvements in the Process of Obtaining Aqueous Solutions of Phenols and other Substances.* L. O. Helmers, Hamburg, Germany. Eng. Pat. 20,245, October 26, 1893.

By the action of sulphuric acid upon the sulphuretted or non-saturated constituents of mineral and similar oils, such as are described in Eng. Pat. 19,502, 1890, sulphonated carbon compounds of a nature similar to ichthyol, thiol, tumenol, and like substances are obtained; these or their alkali salts are soluble in water. Such sulphonated carbon compounds consist of two different substances, of which the one (sulphonate) is *per se* soluble in water, whilst the other (sulphone-like body) is *per se* insoluble in water (compare Eng. Pat. 6044, 1893). The separation of these substances is effected either by extracting the former with alcohol or the latter with benzene. When the sulphone-like bodies are mixed with the sulphonates they become soluble in water. From this the patentee inferred that these sulphonates, made by neutralising the reaction-product obtained by treating mineral or similar oils with concentrated sulphuric acid or its substitutes, would enhance the solubility of other substances which are themselves insoluble in water. This proved to be the case.

To render a solid soluble by means of these sulphonates, both the solid and the sulphonate must be dissolved in alcohol, the alcoholic solutions must be mixed, and the alcohol distilled off. Among substances thus rendered soluble are cresol, guaiacol, thymol, and other phenols; many hydrocarbons, such as benzene, terpenes, and mineral oils; ethereal oils; camphors; iodine; nitrobenzene; aniline. The quantity of pure sulphonate required to render such a substance soluble depends on the nature of the substance; thus an equal quantity will suffice to render the cresols soluble, whilst benzene requires a threefold and camphor a tenfold quantity. When the mixture obtained by neutralising the product of the action of concentrated sulphuric acid on an oil is used, a much larger quantity is required for the purpose of rendering substances soluble, because the solvent action is already partially satisfied by the sulphone-like substance which is present.

The products thus prepared are claimed as therapeutical and disinfecting agents.—A. G. B.

*An Improved Disinfecting Apparatus.* H. K. Andersson and D. Sjöström, Stockholm. Eng. Pat. 10,328, May 28, 1894.

THE apparatus consists of a cylindrical receptacle of sheet metal with a much smaller central cylinder. The outer cylinder is filled with water, and a red-hot and closely-fitting plunger is introduced into the inner cylinder. When this plunger becomes cooled it is removed, re-heated, and reintroduced, and this is repeated till the water boils. The steam then issues from an opening to which is affixed a hose and jet, so that it may be directed to any point. The volatile disinfectant is dissolved or suspended in the water. In the second form the disinfectant is introduced into the

inner cylinder and is volatilised by the plunger, which in this case only fits loosely and is pointed at the bottom. The vapour so generated issues from a jet in the side of the inner cylinder, which terminates in the centre of the steam outlet from the outer cylinder. The steam thus produces suction on the inner cylinder, and it is claimed that a thorough admixture of the disinfectant with the steam is effected.—L. T. T.

*Improvements in Disinfecting and in Apparatus therefor.* S. Pitt, Sutton, Surrey. From La Société Anonyme de l'Institut Raoul Pictet, Fribourg. Eng. Pat. 11,097, June 7, 1894.

THE patentee introduces the articles to be disinfected into a large vessel capable of resisting atmospheric pressure. This vessel is then exhausted by means of an air-pump, and sulphurous acid, chlorine, or the vapour of any desired antiseptic introduced. These vapours or gases are left to react for a certain time on the articles to be disinfected, and are then again exhausted and led into a gas-holder for use in a subsequent operation, or, if vapours, they may be condensed. Air is now admitted into the disinfecting vessel and the articles removed. The patentee claims that disinfection is more thorough from the better permeation of the disinfectant, whilst the articles disinfected are less injured than is now usual.—L. T. T.

*A New or Improved Fumigant for Use in Horticulture! Buildings.* T. Smithson, Bristol. Eng. Pat. 12,628, June 29, 1894.

FIFTY parts tobacco waste, 3 parts cayenne pepper, 6 parts hellebore, 3 parts asafetida, 1 part lampblack, 5 parts sago flour, and 9 parts saltpetre are all finely ground and then thoroughly and intimately mixed and made up with a little water into a thick paste. This paste is either rolled and cut into shapes or moulded into convenient biscuits, and then dried in an oven. The patentee claims that this gives a fumigant which, whilst destructive to parasitic insects which infest vegetation, such as green-fly, thripp, red spider, and the like, may be used without injury to the most delicate plants.—L. T. T.

## XIX.—PAPER, PASTEBOARD, Etc.

*Commercial Cellulose Derivatives.* C. Beadle. Chem. Trade J. 1894, 128—129.

ONE of the most interesting class of cellulose derivatives is that of the thiosulpho-carbonates discovered by Messrs. Cross, Bevan, and Beadle. C. Beadle gave a communication to the Chemical Section of the Franklin Institute on this subject. (See also this Journal, 1893, 498—500.)

When alkali cellulose is treated with carbon-bisulphide vapour, at the end of three hours the mass will have changed to a deep golden yellow. This, when treated with water, swells up to a gelatinous mass and finally dissolves, yielding a very viscous solution resembling treacle. The reaction is expressed thus:—

Alkali cellulose. Cellulose xanthate.

where X represents the reacting unit of cellulose. The cellulose xanthate is soluble in water. This solution as it evaporates decomposes with a reversal of the above reaction as follows:—

Those solutions are most permanent which contain the smallest quantity of water. Sulphuric and most mineral acids at once precipitate the cellulose with evolution of  $\text{H}_2\text{S}$ . Acetic and many weak organic acids evolve  $\text{H}_2\text{S}$  without precipitation of cellulose, the solution becoming nearly white and colourless, but much more liable to rapid coagulation. Bisulphite of soda or sulphurous acid decolorises the solution without the evolution of sulphuretted hydrogen, if carefully added. Zinc sulphate or chloride precipitates the zinc salt in horny flakes, which can be washed and easily re-dissolved in weak soda. Alcohol or brine precipitates the cellulose as thiocarbonate, which can be washed free from by-products and dissolved in water. The solution is very viscous, and viscosity attains a maximum when treatment with  $\text{CS}_2$  immediately follows mercerising. Thus, when cotton is used in a 7 per cent. solution a viscosity equal to that of glycerol is attained, measured by rate of flow.

Increased temperature induces coagulation of the solution; thus, a solution that would last 40 days at 35° F. would coagulate in 25 days at 47° F., or in six days at 65° F. When a solution is spread on the surface of glass and exposed to a temperature of 250° F., coagulation only takes a few minutes. The mass, when washed free from by-products, comes off the surface as a transparent film.

Mass has a great effect on coagulation; a small sample of 30 grms. coagulates much quicker than a 400-lb. lot of the same solution, when both are kept at the same temperature. Coagulation is induced by exposure to air, probably due to the presence of carbonic acid, which aids dissociation of the cellulose thiocarbonate by forming sodium carbonate and liberating  $\text{CS}_2$ .

A solution once coagulated furnishes a substance which, although retaining the water required for its solution, is no longer soluble. If a coagulum contains much under 10 per cent. of cellulose it will contract on itself, retaining the form in which it was cast, and separating from the water and soluble by-products till it contains about 10 per cent. of cellulose and 90 per cent. of water. But if the coagulum contain a high percentage of cellulose it will expand and take up water.

This coagulum is not dehydrated by the action of alcohol. When the washed coagulum is taken out of the water and placed in air the mass contracts on itself until the whole of the water is eliminated. The resulting material is a hard, horny substance with a specific gravity of 1.5.

When a crude solution is treated with benzoyl chloride the cellulose is eliminated as a cellulose benzoate. Hence it may be right to ascribe the following formula to the compound:—

wherein X represents a cellulose residue of variable molecular weight, reacting as an alkali cellulose.

**Commercial Production.**—In preparing large quantities of this cellulose compound, a moist, disintegrated cellulose is taken, and incorporated with strong caustic soda solution by agitation under considerable pressure. The cellulose, when acted upon by the soda, swells up and absorbs all the solution, becoming flaky. This is passed through a sieve in order that it may be of uniform density and occupy as much bulk as possible. This process takes about 30 minutes, and 150 lb. of mercerised product is obtained at each mixing. One cubic foot of the material ready for treatment with the  $\text{CS}_2$  weighs about 15 lb. This is brought in contact with  $\text{CS}_2$  vapour when the mass has been carefully raised to 80° F. and kept in agitation. The reaction develops enough heat to raise the temperature to 105° F., when at the end of one hour the reaction is complete. The material still retains its former structure, but has changed in colour to a golden yellow. It is discharged into, and carefully mixed with, its own volume of water. In seven hours the mass has become a homogeneous stiff dough. To obtain a clear solution from this, it is passed, together with its own weight of water, through a centrifugal pump, and to free it from mechanical impurities it is passed under pressure through a filtering medium. The amount of caustic soda required is expressed

in its simplest terms by the ratio  $\text{C}_{12}\text{H}_{10}\text{O}_6 : 2\text{NaOH}$ . The proportion of  $\text{CS}_2$  used is expressed by the ratio  $\text{CS}_2 : 2\text{NaOH}$ .

The most favourable conditions for the interaction are:  $\text{C}_{12}\text{H}_{10}\text{O}_6 : 2\text{NaOH} : 2\text{CS}_2 : 35\text{H}_2\text{O}$ .

**The Production of Continuous Films.**—When dehydrating agents, such as brine or alcohol, act on the cellulose thiocarbonate solution, the effect produced is dependent upon the constitution of the solution. Thus, if a fresh solution be used and brine added, the flocculent precipitate obtained is entirely redissolved in water. If the solution has been made some days and approaching the point of coagulation, the precipitate so formed is during precipitation converted into insoluble cellulose. If some of this solution be spread as a varnish on a glass plate, and immersed in brine, the cellulose can in a few seconds be stripped off the surface in the form of a film. A machine has been devised which produces and reels a film in a continuous web. The thick solution, which has been kept till on the point of coagulation, is spread on the surface of a revolving cylinder, half immersed in a bath of brine. The solution is spread by means of an adjustable doctor, attached to side wheels which regulate the width of the film required. The film as it leaves the brine is stripped from the cylinder and passed through a series of vats for washing, decoloring, dyeing, and finishing. It can be dried by passage over steam cylinders and reeled. The film when in the web, before passing on to the drying cylinders, can be grained or stamped by rolls carrying designs in imitation of any surface. Cellulose films prepared by this method have an affinity for many aniline colours not shared by any other form of cellulose.

It becomes dyed so readily with some aniline colours without a mordant that the operation can be performed in the web as it passes over the machine. When dried and finished it becomes resistant and loses considerably its chemical activity.

**Commercial Production of Thick Films.**—(1.) From crude coagulum. In order to prepare thicker films the solid coagulum is cut up into pieces of any desired thickness. These are washed to free them from by-products, and treated for some time under pressure, and calendered. Calendering has a marvellous effect on the films, if they are not thoroughly dehydrated. The material of the film flows under great pressure, increasing the area and decreasing the thickness of the film, and the annealing it gets very much improves its texture and strength. It has recently been found possible to forego the process of washing out the by-products, and thus films sufficiently pure for some purposes have been obtained by the following process:—

(2.) From decolorised coagulum. To the crude thiocarbonate solution is added a weak solution of sulphurous acid, which has the effect of decolorising the by-products by converting them for the most part into sodium thiosulphate. The coagulum formed from this is a semi-opaque neutral jelly. This is cut up into pieces of the size required, and each piece is submitted to a process of annealing under pressure, which results in the dehydration and separation of the cellulose from the by-products. It has lately been found possible to pulverise the solid decolorised coagulum and cause it to go together into compact sheets under pressure; also to force several sheets together into one solid compact sheet. With all other mixtures failure had followed efforts to obtain a pulverised substance that would go together under pressure, when the above mixture was found to succeed. It is very difficult to explain this peculiar behaviour of a cellulose coagulum, and why the various mixtures should behave so differently. As a marked instance of what pressure will do in effecting a molecular change it has been found possible to stamp boxes direct from the coagulum, embossing and dehydrating them in one operation.

Films may also be produced by taking a continuous veneer from a revolving cylinder of the dehydrated substance.

**Inertness of the Dehydrated Product.**—This is well exemplified in its application to woven fabrics. Cotton and linen goods behave very differently in regard to their affinity for, and power of fixing, these cellulose derivatives. When the grey linen is passed through a weak solution of cellulose thiocarbonate it is easily fixed by

the film. It appears to penetrate the cell-wall and build itself up in the fibre. The cellulose so fixed is not removed by the various chemical treatments the cloth afterwards receives. The character of the solution used has a great effect on the finish of the cloth. It is possible to obtain a very marked difference in the feel by the addition of only 2 per cent., or to add to the cloth as much as 25 per cent., without making any marked difference. In all cases the cellulose derivative shows itself less acted upon by chemical treatment than the fibre of the cloth.

**Properties and Constitution.**—Where it reacts it does so in a different way from cotton and linen cellulose. Its carbon percentage is somewhat lower and its weight is somewhat greater than the cotton cellulose from which it is prepared. The original molecule appears to have undergone hydration in the ratio  $2C_{12}H_{10}O_{10}, H_2O$ . The hygroscopic moisture varies from 10 per cent. to 15 per cent., according to the method used for its production. It is turned blue by iodine solution.

## PATENTS.

**Improvements in the Manufacture or Treatment of Paper.** A. Yockney, Wilcove, Cornwall. Eng. Pat. 16,947, September 8, 1893.

THE inventor claims the use of boric acid or a compound of boron, such as borax, as a means for preventing paper from deteriorating in the hottest and dampest climates. The borax or similar compound may be added to the paper while in the pulp stuff condition, or after it is webbed and made into a sheet by soaking it in a solution of the acid or salt. A sizing is recommended consisting of 1 oz. of gelatin soaked in a quart of water, then boiled, allowed to stand for 24 hours, and reboiled. To this is added 1 oz. of boric acid solution, consisting of 20 grains of acid in 1 oz. of water. This size is said to be very suitable for high class papers, rendering them of a less perishable nature.

—S. P. E.

**Improvements in and relating to the Manufacture or Treatment of Paper.** E. J. Lushy, London. Eng. Pat. 18,538, October 3, 1893.

THIS invention consists in the treatment of paper, before or after webbing, with certain essential oils possessing medicinal and other beneficial properties. Creosote, oils of *pinus pumilio*, eucalyptus, and of any coniferous or resinous trees are recommended.—S. P. E.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

**Moist Iodoform.** G. Vulpius. Pharm. Central-II. N.F. 1894, 15, 259.

THE author has found in a sample of iodoform—otherwise normal—13 per cent. of water, and ascribes the fact to the practical difficulty experienced in drying this substance, especially when prepared according to one of the newer methods, viz., by allowing a dilute solution of sodium hypochlorite to trickle into a solution consisting of 50 parts of potassium iodide, 2 of caustic soda, and 2 of acetone in 2,000 of water:—

It will be well, therefore, in the examination of samples of iodoform, and in view of this possible method of preparation, to estimate the amount of water present. The author fixes the permissible maximum at 1 per cent.—H. T. P.

**The Occurrence of Copper in Extracts.** G. Hell. Pharm. Post. 1894, 27, 182.

THE author has examined numerous drugs and found in all of them copper in a soluble form. The requirement laid down in the pharmacopœia that extracts should be free from copper is, therefore, not tenable. As a matter of fact, all extracts contain copper as a normal constituent. The author suggests, therefore, that a maximum admissible limit be fixed upon, and some simple method be adopted for determining whether this limit has been exceeded.—H. T. P.

**Preparation of Alcohol from Apples.** Vivien and Dupont. Bull. Assoc. Chim. 11, 1894, 526 and 528.

IN view of the enormous harvest of apples this year, the authors have experimented as to the manufacture of alcohol from apples. 100 litres of apple juice weighing 106.4 kilos., contained 89.75 per cent. of water, 0.30 per cent. of ash, 2.04 per cent. of pectin bodies, and 2 per cent. of cane sugar, 2.97 per cent. dextrose, 8.50 per cent. levulose, and 0.84 per cent. of other sugars; total sugars, 14.31 per cent.

On adding phosphoric acid, potash, and ammonia (or sodium nitrate) the fermentation proceeds as quickly and completely as with turnip juice, and by this means 5 per cent. of alcohol is obtained from the apples. This alcohol was considered to be of better quality than the ordinary alcohol from cider. The grounds remaining compose 18 per cent. of the apples taken, and contain 2.5 per cent. of sugar.

—T. A. G.

**On  $\beta$ -Resalylin (Phenyldimethylpyrazolone  $\beta$ -resorecylate).**

A. Petit and A. Fèvre. Chem. Zeit. 18, 1894, 1094.

THE authors have isolated a compound by mixing concentrated aqueous solutions of one molecular proportion of  $\beta$ -resorecyllic acid with two molecular proportions of antipyrine. The new substance, having the formula—

crystallises from alcohol or acetic ether in colourless needles having a sweetish acid taste. It melts at 115° C., dissolves in 150 parts of cold and 20 parts of boiling water, and is easily soluble in alcohol, acetone, chloroform, and acetic ether, but insoluble in ether and petroleum ether. Its aqueous solution is acid to litmus, and when decomposed with soda lye, it yields sodium resorecylate and analgesine. Heated with phthalic anhydride to 220° C.,  $CO_2$  is given off and fluorescein is formed; whereas salipyrine, when similarly treated, gives a yellowish-red colouring matter. The new compound differs from resopyrine (resorcinol-antipyrine) in melting point and in the fact that it is precipitated by acids. Since, according to the analysis, two molecules of antipyrine combine with one molecule of  $\beta$ -resorecyllic acid, the reaction appears to be a function of the hydroxyl and not of the carboxyl groups, and the authors propose to investigate the behaviour of the ethers of phenol carboxylic acids in this direction. Gallic acid, which contains three hydroxyl groups, ought to condense with three molecules of antipyrine.—T. A. L.

**Cannabindon.** R. Kobert. Chem. Zeit. 18, 1894, 741—742.

A NEW substance obtained from Indian hemp (*Cannabis Indica*) by a process detailed at length, and consisting essentially in the successive treatment of the drug with various solvents, the insoluble portion (found in every case to be physiologically inactive) being at each stage rejected. The final product was a dark cherry-red syrupy liquid to which the name "Cannabindon" was assigned. Cannabindon is soluble in alcohol, ether, chloroform, benzene, fatty oils, &c., and has the composition expressed by the formula  $C_{11}H_{12}O$ . When heated with fuming sulphuric acid it dissolves, forming a product soluble in water with dark brown colour and an odour, both of which resemble those of a solution of lethyol. The aqueous

solution of *cannabindon sulphonic acid* when neutralised with soda yields precipitates with a large number of various metallic salts. *Cannabindon* reduces ammoniacal silver nitrate, alcoholic gold chloride, and Fehling's solutions; but is not itself appreciably reduced by treatment with sodium. Physiologically, *cannabindon*, in doses of 0.02 to 0.08 gm., exerts on human beings and cats a toxic action, which manifests itself chiefly in the shape of hallucinations, sometimes of a very disagreeable nature. By repeated use, however, the system becomes habituated to the drug. The substance does not appear to be particularly poisonous, for doses up to 1 gm. administered to cats did not produce fatal results.—H. T. P.

*The Influence of Alcohol, Glycerol, and Fatty Oils on the Bactericidal Action of Phenol and of Corrosive Sublimite.* M. Lenzl. Rev. d'hygiène et de police sanitaire, per Rep. Pharm. 1894, 111.

THE author confirms Koch and Wolffhügel's observation that phenol, when dissolved in alcohol or oil, has no antiseptic influence. The following conclusions are drawn:—Absolute alcohol destroys the bactericidal action of phenol and mercuric chloride on the spores of mildew. In the case of 0.1 per cent. corrosive sublimate solutions, an antiseptic action only becomes evident when the amount of water exceeds 2 per cent.; whilst 70 per cent. must be present in the case of phenol, and even then the destructive action is very slow, requiring 24–28 hours for its completion. A 2 per cent. solution of sublimate in glycerol requires, in order to become active, the addition of at least 4 per cent. of water, whilst 10 per cent. phenol in the same solvent must be diluted with 80 per cent. water. Phenol dissolved in oil entirely loses its disinfecting qualities.

—H. T. P.

*Note on Ipecacuanha.* J. Moeller. Pharm. Post. 1894, 27, 165.

*Carthagena Ipecacuanha*, also known as *Saranilla ipecacuanha*, has been obtainable for the past three years on the London and Hamburg markets. It is derived from *Cephaelis acuminata*, and is in every respect equal to the official Rio variety, from which it differs mainly in that it occurs in much larger pieces (6–8 mm.).

*False Carthagena Ipecacuanha.*—In opposition to Hartwich, the author is of opinion that this variety is identical with the true *Carthagena ipecacuanha*, and that the absence of alkaloid from the roots is attributable to the fact that they are not collected at the period of maturity. *False East Indian Ipecacuanha* occurs in grey and yellowish-brown sinuous pieces, 4–9 mm. in diameter. It possesses a feeble odour resembling that of the tonka bean. Its cross-section is white, floury, with a central, brownish, woody core, not sharply separated from the bark. The drug contains no emetin. Its derivation is, as yet, unknown, but judging from its structure it probably belongs to the *Aroideae*.—H. T. P.

*Quinaseptol or Diaphthol.* Guinard. Rép. Pharm. 50, 1894, 65.

QUINASEPTOL or Diaphthol is hydroxyquinoline-*m*-sulphonic acid. It consists of a powder which has a melting point of about 295° C., liberates free hydroxyquinoline on decomposition, and gives a green coloration with ferric chloride and a rose-red colour with uranium acetate. It possesses an antiseptic action, but its use is not permissible in surgical operations owing to its blackening action on the steel of surgical instruments. Sodium diaphthol is bright yellow and more strongly antiseptic than diaphthol itself, destroying many organisms in 30–50 minutes. On the other hand, diaphthol is not very poisonous, since 3 grms. were required to prove fatal to a dog of 1 kilo. in weight. The author believes that diaphthol should prove a valuable antiseptic for internal or external use.—T. A. G.

*A New Colour Reaction of Iridol.* E. Nickel. Chem. Zeit. 18, 1894, 531.

See under XXIII., page 906.

*The Examination of Liquid Extracts.* O. Linde. Pharm. Central-Bl. N.F. 15, 1894, 39.

See under XVIII. A., page 897.

## PATENTS.

*Production of Substances suitable for Manufacture of Perfumery and Aromatics.* J. C. W. F. Tiemann, Berlin. Eng. Pat. 17,539, September 18, 1893.

THE patentee has already described (this Journal, 1894, 272) the preparation of perfumes from pseudo-ionone, a substance formed by shaking a mixture of citral and acetone with barium hydrate. He now states that acetone may be replaced by its homologues, and the natural citral by artificial citrals obtained by the oxidation of the alcohols of the formula  $C_{10}H_{19}O$  and present in many etheral oils, such as geraniol, rhodinol, &c.; or by citronellone (citronellal), an aldehyde containing two more atoms of hydrogen, with equally useful technical results.—L. T. T.

*Production of Artificial Musk from Hydrogenated Aromatic Hydrocarbons.* A. Baur, Mulhouse. Eng. Pat. 17,703, September 20, 1893.

TRINITRABUTYLXYLENE, the artificial musk referred to in Eng. Pat. 4963 of 1889 (this Journal, 1890, 545), is obtained as follows:—108 grms. of hydrometaxylene are mixed with 500 grms. of carbon bisulphide and 92.5 grms. of butyl chloride (or equivalent weight of bromide or iodide), and about 20 grms. of aluminium chloride are gradually added. The butylated derivative formed is distilled with steam, and then fractionated, and the fraction 190–210° C. nitrated by introducing it into a mixture of one part fuming nitric acid and two parts fuming sulphuric acid containing 10–15 per cent. of sulphuric anhydride.—L. T. T.

*A Process for the Production of Artificial Musk.* A. Baur, Mulhouse. Eng. Pat. 17,781, September 21, 1893.

THE patentee has already shown (preceding abstract, and this Journal, 1889, 1004; and 1890, 545 and 964) that musk substitutes may be prepared by the nitration of homologues of benzene containing the methyl, ethyl, butyl, propyl, or amyl side groups. He now finds that many of the more complicated aromatic compounds on nitration yield the similar products, being split up during nitration. Thus dibutyliditolylmethane and tributyltritolylmethane yield trinitrobutyltoluene, whilst dibutylidixylmethane and tributyltrixylmethane give trinitrobutylxylene. Both of these compounds are crystalline substances smelling strongly of musk.—L. T. T.

*Improvements in Cinchona Preparations.* F. W. Fletcher, Enfield. Eng. Pat. 12,796, July 2, 1894.

THIS invention consists in the extraction of cinchona bark by hydrobromic acid, by which means an extract is obtained containing the whole of the alkaloids of the bark, together with the kinic, kinovic, and cincho tannic acids and the other natural and more or less undefined constituents of the bark, all of which possess valuable tonic, aromatic, and astringent qualities.

The extract is most advantageously prepared as follows:—The cinchona bark employed should be of the finest quality, and contain not less than 8–10 per cent. of total alkaloids. 15 lb. of this bark is ground to the degree of fineness technically known as No. 40. 27 fluid ounces of hydrobromic acid of sp. gr. 1.275 are diluted with distilled water to 6 gallons. The ground bark is thoroughly damped with half a gallon of this acid and left for six hours for the acid to permeate and the bark to swell. It is then packed in a displacement apparatus, and percolated with the remainder of the acid, and finally with distilled water till the latter extracts no more alkaloid. 30 fluid ounces of glycerin are added to the percolate, and the latter then evaporated to 240 fluid ounces. This concentrated extract is preserved in closely-stoppered vessels, 1 fluid ounce thereof containing all the soluble constituents of 1 ounce by weight of cinchona bark in intimate association and combination with bromine.—L. T. T.

### XXIII.—ANALYTICAL CHEMISTRY.

#### INORGANIC CHEMISTRY.—QUALITATIVE.

*The Detection of Boric Acid, especially in the Ash of Wine.* P. Kulisch. Zeits. angew. Chem. 1894, 147–148.

RUBER'S test for boric acid consists in dissolving the ash of 25–50 cc. of wine in 10 cc. of distilled water, adding 2 cc. of hydrochloric acid of sp. gr. 1.19, and testing with turmeric paper in the usual way. The present investigation shows that the delicacy of the reaction is affected chiefly by using unduly diluted solutions. Hence it is preferred that the ash should be treated with sufficient hydrochloric acid to render it distinctly acid, say by addition of 1–2 cc. hydrochloric acid of 1.12 sp. gr. The turmeric paper should be prepared from a strong solution of the dye. In dealing with small quantities, the colour may be best observed at the moment the paper is on the point of drying. The sensitiveness of the reaction is interfered with, more or less—even in an acid solution,—by the presence of salts.

—H. A.

#### INORGANIC CHEMISTRY.— QUANTITATIVE.

*The Volumetric Estimation of Gold.* G. B. Franceschi. Boll. Chim. farmac. 1894, 33, 35.

WHEN a gold chloride solution is boiled for some minutes with potassium oxalate in excess, the gold is all reduced and separates according to—

Evidently then, 8.3 parts of potassium oxalate precipitate 6.533 parts of gold.

The following are the reagents required:—

(1.) Solution containing 8.3 grms. potassium oxalate per litre.

(2.) Solution of potassium permanganate which is exactly reduced by an equal volume of potassium oxalate.

Oxalate in excess is added to the gold solution, and the mixture boiled for a few minutes. Cool, filter off the gold, and wash. The filtrate, after mixing with the washings, is rendered acid with sulphuric acid, and the excess of oxalate solution titrated back with permanganate. Then if—

$n$  = cc. of oxalate solution

$n_1$  = cc. of permanganate solution;

the gold reduced is represented by  $(n - n_1) 0.0065$ .

—T. A. G.

*The Estimation of Carbonic Acid in the Presence of Soluble Sulphides.* A. Wolkowicz. Zeits. angew. Chem. 1894, 165.

THE weighed quantity of the substance is treated in excess with a cupric chloride solution of 20 per cent. strength. The sulphur of the sulphides present in the substance thus becomes eventually transferred to the copper, forming the sulphide, insoluble in hydrochloric acid. Hydrochloric acid is next used to liberate the carbonic acid in the usual way. An ordinary Fresenius' apparatus is used, and the carbonic acid is absorbed by soda-lime.—F. M.

*Volumetric Estimation of Sulphuric Acid in Crude Commercial Hydrochloric Acid.* L. Rürup. Chem. Zeit. 18, 1894, 225.

COMMERCIAL hydrochloric acid always contains more or less sulphuric acid. When the latter amounts to about 1.5 per cent. of  $SO_3$ , it makes the hydrochloric acid unsuitable for use in preparing iron or steel articles for being galvanised. It causes black specks; that is to say, places where the zinc does not adhere to the iron. Hydrochloric acid containing more than, at the most, 1.0 per cent. of  $SO_3$  should not therefore be used. The author employs the following method of making a rapid estimation of the  $SO_3$  in hydrochloric acid. The results he obtains agree to 0.05 per cent. with gravimetric determinations.

He uses a glass tube similar to the tubes used in estimating phosphorus in iron and steel by the method of measuring the bulk of precipitate of phosphomolybdate

formed, and which is shown in the annexed figure. The tube is graduated by adding 0.4, 0.6, &c., up to 3 per cent. of sulphuric acid to portions of 10 cc. of pure hydrochloric acid. The acid is heated to boiling, rinsed into the tube with a little water, nearly neutralised with concentrated ammonia, and then the sulphuric acid is precipitated by a hot solution of barium chloride, the tube stoppered, and shaken for about two minutes. The precipitate of barium sulphate is then allowed to settle. Any particles attached to the side of the tube are detached by a glass rod with a piece of india-rubber tubing on the end; but such particles affect the result very slightly. A mark is made on the tube with a diamond at the level of the top of the precipitate, and the percentage of  $SO_3$  is also written on the glass at this mark with a diamond. By dividing the spaces between the marks, the percentage can be read to 0.05 per cent.

In carrying out a test, the author takes 10 cc. of hydrochloric acid out of every 10 carboys, by means of a glass tube, pours it into a small beaker, and nearly neutralises with

ammonia; then heats to boiling, and pours the liquid into the testing tube. About 5 cc. of boiling saturated solution of barium chloride are added, the tube closed with an india-rubber stopper, and shaken for two minutes, and after allowing the precipitate to settle, which takes about five minutes, the percentage is read off at the mark at which the level of the precipitate stands.—H. S. P.

*Note on the Valuation of Potashes.* O. Bernheimer, Chem. Zeit. 18, 1894, 742—743.

It is usual to proceed as follows:—From the total potash (determined as platino-chloride) the amounts existing as sulphate, chloride, and, in accurate analyses, as phosphate and silicate, are subtracted, the remainder being calculated into potassium carbonate. Then, the total alkalinity of sample (by titration with acid), less the potassium car-

bonate, gives the amount of sodium carbonate. The author shows that this method of procedure may yield results erroneous to the extent of several per cent. in the case of potashes prepared from distillery residues, &c., which occasionally contain nitrogen acids (0.75 per cent.  $N_2$  or more) combined with potash. It is necessary to make an allowance for the nitrogen thus combined (estimated by Kjeldahl's method), bearing in mind that  $N_2$  is equivalent to  $K_2CO_3$ .—H. T. P.

*The Estimation of Sulphur in Sulphides, with Simultaneous Determination of Arsenic.* P. Jannasch, Zeit. anorgan. Chem. 6, 1894, 303.

In the annexed figure, which almost explains itself, the tube *b* measures 9.8—10 cm. in length from *a* to *c*; 6.2 cm. from *c* to *d*; and 3.5 cm. from *d* to *e*. The bulb *i* contains

a 3 per cent. solution of hydrogen peroxide mixed with 5 cc. of strong nitric acid; *l* and *m* contain the same mixture diluted with an equal bulk of water. The flask *m* is covered with a perforated watch-glass, and is capable of holding from 900 to 1,000 cc. of liquid. For the analysis, from 0.6 to 0.75 gm. of the very finely powdered substance are introduced into *b*; it is here heated by the burner *r* in a stream of oxygen which has been purified by passing first through strong sulphuric acid and then over soda-lime, in an apparatus substituted for *A* and *B* in the figure. With the  $SO_2$  some of the arsenic is sublimed, and the condensed oxide is driven by a second gas-flame into the small tube *d e*. When all the  $SO_2$  has passed over, the tube is cooled, and then immersed in a dish containing water at  $100^\circ C$ .; then *A* and *B* having been connected, a gentle stream of pure hydrogen chloride gas is led over the warm substance for  $1\frac{1}{2}$ —2 hours. The apparatus is then disconnected, the solutions from *i*, *l*, and *m* are mixed with a little strong nitric acid, to prevent loss of arsenic, and evaporated down to a bulk of 20—25 cc. This is next diluted to 200 cc., and a known quantity of barium chloride is added to the boiling solution (8—9 cc. of a 10 per cent. solution to 0.5 gm. of arsenical pyrites), and when cool it is filtered. After rendering alkaline with ammonia, magnesium chloride (4—5 cc. of a 25 per cent. solution for 0.6 gm. of substance) is added, and the arsenic determined in the usual way; citric acid should also be employed if alumina be present. If sulphur should ever be retained in the tube *b* as calcium or barium sulphate, it may be rendered volatile by passing over it, when heated, air charged with ammonium carbonate, whereby ammonium sulphate is formed and afterwards caught in the condensing tubes.—W. G. M.

*A Volumetric Method for Estimating Sulphuric Acid.* Windisch. Wochenschr. f. Brauerei, 11, 1894, 607.

This method consists in precipitating the  $SO_3$  in a solution of the substance to be analysed, with an excess of a standard

solution of barium chloride, precipitating the excess of barium chloride with an excess of standard potassium chromate and estimating the excess of potassium chromate by means of standard arsenious acid and iodine, the end reaction being determined by the use of starch paste.

The author prefers the use of  $\frac{N}{50}$  to the usual  $\frac{N}{10}$  standard solutions.

The method appears to give excellent results, and may be used in estimating the  $SO_3$  in water. 100 cc. water are evaporated with a few drops of HCl and treated with 50 cc.  $\frac{N}{50}$  barium chloride and 50 cc.  $\frac{N}{50}$  potassium chromate solutions; the volume is then made up to 300 cc. and 100 cc. filtered off and shaken with 50 cc.  $\frac{N}{50}$  arsenious acid and a few drops of sulphuric acid; starch paste is added and a  $\frac{N}{50}$  iodine solution run in till a permanent blue coloration is obtained.

—O. F. R.

*Method for the Volumetric Estimation of the Phosphoric Acid soluble in Water, contained in Superphosphates.* W. Kalmann and K. Meissels. Chem. Zeit. Rep. 18, 1894, 180.

THE method depends upon the different behaviour of the phosphates towards methyl orange and phenolphthalein as indicators. 20 grms. of the superphosphate are dissolved and made up to a litre. Methyl orange is added to 100 cc. of the filtered solution, which is then accurately neutralised with semi-normal alkali; then, after adding phenolphthalein, the same liquid is titrated with a further quantity of the alkali; the number of cc. of the alkali used is represented by *a*. A second quantity of 100 cc. is now mixed with an excess of the semi-normal alkali in a 250-cc. flask and filled up to the mark. To 100 cc. of the filtrate from this, phenolphthalein is added, and the liquid is neutralised with semi-normal acid; after the addition of methyl orange it is

further titrated with the acid. The number of cc. used (*b*) multiplied by 2.5, represents the amount required for 100 cc. of the original superphosphate solution. The arithmetical mean of *a* and *b* multiplied by 0.0355 gives the weight of  $P_2O_5$  in 100 cc. of the original solution or in 2 grms. of the substance.—W. G. M.

*The Solubility of the Phosphoric Acid contained in Bone Meals.* L. Gebek. Zeits. angew. Chem. 1894, 193.

See under XV., page 894.

## ORGANIC CHEMISTRY.—QUALITATIVE.

*The Detection of Coal-Tar Dyes in Wines.* L. Sostegni and F. Carpentieri. Le Staz. sperim. agrar. ital. 1894, 26, 151.

An improvement on Possetto's modification of Arata's method. 200 cc. of wine are boiled to expel the alcohol, and 2—4 cc. of 10 per cent. hydrochloric acid added. A few strands of white wool (perfectly free from fat) are then immersed in the liquid and the boiling continued for five minutes, after which the wool is washed successively with water, very dilute acid, and again water, and subsequently digested at a boiling temperature with 50 cc. of water and 2 cc. of ammonia. The ammoniacal liquid is acidified with hydrochloric acid, boiled with a fresh portion of wool, and the latter finally washed and dried. The following results were obtained from pure wine to which 2 mgrms. per litre of various dyes had been added:—

Dye employed.	Colour of Wool.
Vinolin .....	Rose-red to violet.
Bordeaux red .....	" "
Ponceau red .....	Rose-red.
Magenta .....	Dirty white.
Safranin .....	Faint pink.
Tropaeolin ol. ....	Straw yellow.
Tropaeolin oo. ....	Faint orange.
Corallin .....	Dirty white.

For the purposes of identification, the colouring matter may be afterwards extracted from the wool by dilute ammonia, the solution evaporated to dryness, and the residue submitted to the action of various reagents, such as strong acids, alkalis, potassium bichromate and sulphuric acid, &c. In applying the latter test it must be noticed that wool absorbs appreciable quantities of hydrochloric acid, which appears in the above residue as ammonium chloride, and might in some cases modify the colour reaction. 92 specimens of pure Italian wines were examined by the above process. The colour of the wool was generally pure white; frequently, however, dirty white or faintly yellow or orange; but never pink or red. Magenta and corallin are not fixed by the fibre under the above conditions; for these, therefore, the method yields negative results.—H. T. P.

*A New Colour Reaction of Iridol.* E. Nickel. Chem. Zeit. 18, 531.

IRIDOL,  $CH_3 \cdot C_6H_4(OH)(OCH_3)_2$ , has only recently been prepared by Tiemann. Iridol, like vanillin, gives a characteristic reddish-violet coloration with Millon's reagent. Now the author has shown that vanillin gives a violet colour reaction with mercuric chloride in presence of nitrites, and he finds that the same is true of iridol. The reagent employed consisted of a solution of mercuric chloride (2 parts) and

sodium nitrite (1 part) in water (40 parts). Solutions containing only one-fifth of the above amount of nitrite act most delicately with vanillin solution, but iridol solutions are not so sensitive. The aqueous alcoholic solution of iridol or vanillin is treated with about an equal volume of the reagent, and the mixture heated to boiling, when after some minutes there is developed a beautiful violet coloration having a shade of blue. There is no essential difference between the colorations produced by these two compounds.—A. R. L.

*Detection of Disguising and Perfuming Media in Oils and Fats.* D. Holde. Mittheilungen aus den königl. tech. Versuchsanst. zu Berlin, 1894, 31—35.

NITRONAPHTHALENE,  $C_{10}H_7NO_2$ , is used to destroy the fluorescence of mineral oils, and nitrobenzene,  $C_6H_5NO_2$ , is employed to disguise any unpleasant or characteristic fatty smell. The latter may be readily recognised by its smell of bitter-almond oil. It is also worthy of note that strongly fluorescent American mineral oil loses its fluorescence at once on being shaken with nitrobenzene. Nitronaphthalene possesses the advantage over nitrobenzene of not being recognisable by its smell; it has a feebly aromatic, almost uncharacteristic smell, it crystallises in thin yellow needles, and when used to remove fluorescence in mineral oils it must be dissolved in the oil by warming. Oils so treated soon darken, which, as oils are commercially judged by colour, is a drawback to its use for hiding the adulteration of fatty oils with mineral oils.

The author recommends the two following reactions as a means of detecting the presence of nitrobenzene and nitronaphthalene in oils and fats:—

1. The aromatic nitro compounds of the general formula  $R \cdot NO_2$ , to which nitrobenzene and nitronaphthalene belong, are converted by the action of suitable reducing agents into red-coloured azo compounds. For this purpose the author uses concentrated alcoholic potash. According to Richter (*Chemie der Kohlenstoffverbindungen*, 1888, 627) nitronaphthalene forms an exception and is not reduced; and, according to Schultz (*Ber.* 17, 478), neither sodium amalgam nor zinc-dust and alcoholic potash, which reduce all the other nitro compounds, will reduce nitronaphthalene. The author finds, however, that when nitronaphthalene is boiled for 1—2 minutes with concentrated alcoholic potash a red colour is produced, which would point to the probable formation of azonaphthalene, although it is possible that the colour may be due to other products of reduction. With dilute alcoholic potash no red colour was obtained, and therefore the degree of concentration of the alcoholic potash is an important factor. Nitrobenzene gives a red colour even with dilute alcoholic potash. The alcoholic potash to be used in the test is made by dissolving 10 grms. of potassium hydrate in as small a quantity of water as possible and then diluting with 100 cc. of absolute alcohol. If a pure clear mineral oil be boiled from 1—2

minutes in a test-tube with from 2—3 cc. of concentrated alcoholic potash, a yellow or brownish-yellow solution is yielded, and most of the fatty oils behave similarly; only in the case of a few substances, *e.g.* train-oil, is a yellow-red or blood-red colour produced after long continued boiling. When oils or fats containing nitrobenzene or nitronaphthalene are heated in this way after boiling from 3—1½ minutes a blood-red or violet-red colour is produced, and it will be observed that on warming the upper part of the test-tube where there are adhering drops of the mixture of potash solution and oil just above the main bulk of the liquid, these drops at once become coloured reddish-violet. This last-named appearance the author has never obtained with any oil free from nitro compounds.

As all colour reactions with fatty oils are liable to be much modified by the nature of the materials present, this test is only recommended as a preliminary one, which, in the event of a negative result, may save much time. The author relies on the following method for definitely ascertaining the presence of nitronaphthalene and nitrobenzene.

2. By the action of strong reducing agents (*e.g.* nascent hydrogen) upon the nitro compounds they are converted into amido compounds—thus nitrobenzene,  $C_6H_5NO_2$ , yields aniline,  $C_6H_5NH_2$ ; and  $\alpha$ -nitronaphthalene,  $C_{10}H_7NO_2$ , yields  $\alpha$ -naphthylamine,  $C_{10}H_7NH_2$ .

The author has already shown (Mittheilungen, 1892, 186; this Journal, 1893, 527—528) how this reaction may be used for detecting nitrobenzene in fats, the aniline obtained being recognised by the characteristic colour it gives with bleaching powder. In a similar way naphthylamine may be obtained and recognised by its smell and by its colour reaction with ferric chloride—an azure-blue colour passing into red-violet.

A few cubic centimetres of the oil to be examined are placed in an Erlenmeyer's flask and boiled briskly for about 10 minutes "with zinc and hydrochloric acid (one part of concentrated and one part of dilute acid)." The naphthylamine formed goes into solution as hydrochloride, together with zinc chloride in the aqueous liquid, which is then separated by means of a separating funnel from the layer of oil, and filtered. The clear aqueous solution is then placed in another separating funnel and treated with as much caustic potash or soda solution as will redissolve the precipitated zinc hydrate. The solution is then cooled and shaken with from 10—20 cc. of ether. The ether extracts the  $\alpha$ -naphthylamine from the solution, and the presence of the base is indicated by the violet colour and fluorescence of the ethereal solution. The ethereal solution is then separated and evaporated to dryness, and leaves a residue of violet-coloured strongly-smelling  $\alpha$ -naphthylamine. On treating this with a few drops of hydrochloric acid the hydrochloride is formed and remains partially insoluble and partially soluble, but on evaporating the excess of acid a clear aqueous solution is obtained in which ferric chloride produces an azure blue precipitate. When filtered, this precipitate becomes purple-red, and the filtrate is blue-violet. Aniline gives with ferric chloride at first a green precipitate, which afterwards turns deep blue and does not become purple-red even on long standing, and the filtrate from the precipitate is yellow coloured. When  $\alpha$ -naphthylamine and aniline are present together, the precipitate is at first azure blue and afterwards a dirty red-brown, and finally purple-red, and the filtrate is violet. Aniline alone also dissolves readily on addition of a few drops of hydrochloric acid without previously evaporating the excess of acid.

By the above-described method the author has detected nitronaphthalene in Scotch mineral oil rendered non-fluorescent, in refined, almost odourless, and non-fluorescent rosin oil, and in grease for treating leather.

After this article was in manuscript there appeared in the Chemical News, December 22, 1893, 297, a short description by N. Leonard of a similar process.

Other means of reducing  $\alpha$ -nitronaphthalene may of course be used, *e.g.*, stannous chloride and hydrochloric acid, and other reactions for proving the presence of the  $\alpha$ -naphthylamine, *e.g.*, its colour reaction with azobenzene-sulphonic acid.—H. S. P.

## ORGANIC CHEMISTRY.—QUANTITATIVE.

*The Influence of "Weighting" on the Specific Gravity of Silk.* H. Silbermann. Chem. Zeit. 18, 1894, 744—745.

In determining the specific gravity of silk with the hydrostatic balance, the use of chemically pure benzene for the immersion fluid, as recommended by Vignon, is advised. This recommendation is given after due comparisons with the stereometer of Say, the volumometer of Regnault, and the mercury densimeter of Bianchi. Benzene is specially preferred, since it can be brought to ebullition easily under a pressure represented by 450 mm. of mercury at 10° C., and thus all gases and vapours in the pores of the silk can be expelled. Also the density of the benzene at temperatures between 0 and 30 is accurately known. (Heilstein, 2, 16.) The vessel containing the sample soaked in benzene is placed under the bell jar of the air-pump, and a partial vacuum is obtained corresponding to a pressure of 50 mm. of mercury. The vessel is then transferred to the hydrostatic balance. Thus the specific gravities of some textile fibres were estimated, as follows:—Wool, 1.28—1.33; cotton, 1.5—1.55; raw silk, 1.3—1.37; boiled-out silk, 1.25. (This Journal, 1892, 1002.) The specific gravity of silk varies in course of chemical treatment by dyeing, bleaching, and weighting, and in course of mechanical treatment by stretching, souping, &c.

In order that useful conclusions as to the approximate amount of weighting present in any given silk may be deduced from its specific gravity, the nature of such weighting and the process of dyeing used must be, at least, qualitatively known. For this purpose the author proceeds as follows:—Readily soluble materials, such as cane-sugar, glucose, glycerol, magnesium salts, &c., are estimated directly by boiling the silk with water, and testing the extract with Fehling's solution, &c. About 2—3 grms. of the silk are reduced to ash, and the latter tested by the usual methods of mineral analysis for tin (present in the fibre as basic chloride and stannic acid), chromium, iron, &c. Fatty matters, wax, and paraffin are detected by extraction with ether or benzene. The silk is soaked in warm, dilute hydrochloric acid (1:2). If by this treatment the fibre be almost decolorised, only a slight yellow tint remaining, whilst the solution assumes a deep brownish colour *not* changed to violet by lime-water, it is safe to conclude that the silk had been dyed by alternate passage through baths of iron and tannin. The yellow colour of the fibre is due to a residuum of tannin, and the precise shade (from greenish to brownish-yellow) enables one after some practice to form an idea as to the nature of the tanning material used (sumach, dividivi, catechu, &c.). Decolorisation of the fibre, the acid extract being pink, changed to violet by lime-water, indicates a logwood black (so-called "English black"). If the fibre retains a deep greenish tint and the solution be yellow unaffected by lime-water, the black is dyed on a Prussian blue ground. If the latter, as is often the case, has been produced during the final stage of dyeing, this is shown by its solubility in the acid. A green fibre and pink solution altered to violet by lime-water, point to a logwood black on a Prussian blue ground. In the hydrochloric extract metals, such as lead, tin, iron, chromium, and aluminium, may be estimated. Blacks produced by artificial dyes on an iron tannin or iron-blue catechu ground, are recognised by the coloration imparted to acid and sodium hydrate solutions. As regards blacks produced solely by the agency of aniline dyes, &c., treatment with a hydrochloric solution of tin-salt does not affect aniline and alizarin black; naphthol-black is altered to a reddish-brown colour, whilst wool-black becomes yellowish-brown. Aniline and alizarin blacks may be distinguished by means of sulphurous acid, which attacks only the former, turning it greenish. Tannin substances in general may be extracted by alkaline solutions and subsequently precipitated and distinguished by ferric acetate. To remove the whole of weighting material and dye, it is recommended that the silk be boiled with acid potassium oxalate, washed with dilute hydrochloric acid, and finally treated with soda solution. When iron and tin are both present in the fibre, it is well to previously extract the latter by means of an alkaline sulphide. In conclusion, the author gives the following

experimental results, which exhibit the relation existing between the density of silk and the percentage and nature of the weighting material. The figures for weighting and loss (during softening, boiling, &c.) are in every case referred to 100 parts of raw silk.

*Coloured Silk.*—A. Softened silk (Sample):—Unweighted; loss, 6 per cent.; sp. gr. 1.34. Weighted with tin chloride, 45 per cent.; sp. gr. 1.61; with tin chloride and tannin, 16 per cent.; sp. gr. 1.53; with tannin alone, 46 per cent.; sp. gr. 1.48.

B. Boiled silk (Unit):—Unweighted; loss, 20 per cent.; sp. gr. 1.33. Weighted with tin chloride, 21 per cent.; sp. gr. 1.52; with tin chloride and tannin, 22 per cent.; sp. gr. 1.54; with tannin, 26 per cent.; sp. gr. 1.48.

*Black Silk.*—A. Softened silk:—Weighted with Prussian blue and catechu, 126 per cent.; sp. gr. 1.74; with tin chloride, Prussian blue, catechu, and extract of nut-galls, 120 per cent.; sp. gr. 1.88.

B. Boiled silk:—English black on an iron ground, 28 per cent.; sp. gr. 1.58; mineral black, *nil*; sp. gr. 1.37; black on iron ground, catechu and pyrolignite, 20 per cent.; sp. gr. 1.10.—H. T. P.

*Estimation of the Titre of Tallow.* F. Wolfbauer. Chem. Zeit. Rep. 18, 1894, 28–29.

For this estimation 120 grms. of the fat to be tested are melted in a beaker with 45 cc. of 48 per cent. potash (sp. gr. 1.509) and heated at 100° C. until complete saponification is obtained, which is recognised by the complete solubility of the products in 50 per cent. alcohol. The soap is then decomposed by boiling with 165 cc. of sulphuric acid of sp. gr. 1.143 until the fatty acid has separated as a clear solution from the acid potassium sulphate solution; the latter is removed and the fatty acid digested in a covered vessel containing sulphuric acid (5 cc. per 100 cc. water) for 15 minutes.

The fatty acid is then washed by boiling with about 100 cc. of water, and dried for two hours at 100°.

The estimation of the solidification point is conducted in the usual manner.—T. A. G.

*Valuation of Crude Glycerol.* O. Heller. Ber. der pharm. Ges. 4, 1894, 17.

The distillation method of the author is described. A double-necked distilling flask of about 500 cc. capacity is required. Through one neck passes a thermometer and through the other, two glass tubes, one of which reaches to the surface of the glycerol and the other is cut off just below the neck. The latter tube is connected with four Erlenmeyer flasks provided with condensing coils. The last flask communicates with an air-pump and the glycerol is heated in an air-bath to 100°. As soon as this temperature is reached a current of air is drawn through, at first slowly and then more rapidly. The temperature is kept at 180° to 190° C., and the glycerol vapour, carried over by the air current, condenses in the flasks. These are exactly tared, so that it is only necessary to re-weigh them. The author recommends this method for other bodies not readily volatile, like aniline, heavy hydrocarbons, fatty acids, &c.—T. A. G.

*The Determination of Starch in Pressed Yeast.* F. Filsinger. Chem. Zeit. 18, 1894, 742.

According to the author the methods usually adopted for the above purpose are utterly unreliable. He recommends a process originated by E. Fickert, based on the fact that when starch containing yeast is suspended in water, the starch tends to settle down first. In practice 20–30 grms. of yeast are stirred up with 250 cc. of water, and sufficient iodine solution added to stain the starch and render it plainly visible (and also specifically heavier). After settling, the supernatant liquid is siphoned off, and carries with it a great deal of the yeast, the starch being left behind. The process of decantation is repeated until yeast cells are no longer discernible, and the starch finally

collected on a tared filter-paper, is dried at 105° C., and weighed. During drying, practically the whole of the iodine absorbed by the starch is expelled. According to C. Luders, the method gives almost absolutely accurate results in presence of 10 per cent. of starch and upwards. With smaller percentages the figures come out somewhat low.

—H. T. P.

*Further Note on the Determination of the Fat in Bread.*

M. Weibull. Zeits. angew. Chem. 1894, 199–202.

In a former communication (this Journal, 1894, 294) the author shows that the ordinary method for the estimation of the fat in bread by ether extraction always yields low results, owing to the fact that the fatty particles are so surrounded by starchy and dextrinous matters as to be quite inaccessible to the solvent. An improved method was therefore devised, according to which the bread is boiled with very dilute sulphuric acid to convert the starch into dextrose, then neutralised with powdered marble, the liquid and sediment, &c., being finally absorbed by and dried on a strip of filter-paper, and extracted by ether, as in Adam's process for milk analysis. The chemists of the German Board of Health in the main confirm the author's strictures on the old process, but failed to obtain higher figures by the new method; and it was suggested that the fat was again occluded by the dextrose during the drying of the inversion products. The author has therefore reinvestigated the subject, and in a table gives the results of a series of fat determinations in various flours and the bread baked there-with. The conclusions arrived at are:—

1. The fat in rye-bread, not directly estimable, may be completely extracted by the inversion method.

2. The ethereal extract from coarse or fine rye-flour is sensibly the same as that from the bread baked therewith, allowance being made for any difference in the percentage of moisture.

3. Coarse flours cannot be freed from fat by ordinary extraction; either the inversion process must be employed or the material must be reduced to fine powder prior to analysis.

4. In the case of brans also low results would probably be obtained by the ordinary method for fat determination.

—H. T. P.

*The Albuminoids contained in Worts and Beers.* Wahl and Hantke. Amer. Brewers' Review, 7 [32].

See under XVII., page 895.

*Methods of Estimating Free Tartaric Acid in Wines.*

A. Carpenté. Selmi, 1894, 4, 13.

The method recommended is this:—

20 cc. of wine are evaporated to 10 cc., and the residue shaken up with 50 cc. of ether-alcohol and allowed to stand for 12–18 hours. The clear liquid is then poured off and the precipitate washed with 15 cc. of ether-alcohol, and filtered. The washings are mixed with the first filtrate and decomposed with 0.01 gm. of tartaric acid dissolved in 1–2 cc. of water. Shake and let stand 2–3 hours in a cold place. If a crust of tartar crystallises out, the presence of acid potassium salts (malate, succinate, acetate) is established, and the presence of free tartaric acid negatived. If no crust forms the wine may contain free tartaric acid. In this case the ether-alcohol should be distilled off and the residue be dried in the flask, when any tartrates of magnesium, &c., will be rendered insoluble. On digestion with 50 cc. of ether-alcohol the free tartaric acid is dissolved. After some hours filtration follows, then addition of 4–8 drops of potassium acetate and the tartar formed is precipitated. The tartar is titrated with alkali and calculated to tartaric acid, when the amount thus found, less the tartaric acid added, equals that originally present in the wine.

—T. A. G.

*The Examination of Liquid Extracts.* O. Linde. Pharm. Central-H. N.F. 15, 1894, 39.

For the estimation of glycerol contained in liquid extract, Linde employed Proskauer's method devised for the examination of sweet wines. This method, however, was not applicable, because the resin contained in the glycerol forms line soaps with the calcium hydrate, which, especially in presence of glycerol, are soluble in water and ether-alcohol. The method also indicates too high results. The following method was successful:—10 grms. are evaporated to half bulk, taken up with 50 cc. of water, and lead acetate added gradually as long as a precipitate forms. After filtration, the filtrate is mixed with a few drops of dilute sulphuric acid and concentrated solution of tungstic phosphate added as long as a precipitate forms. After settling, filter, wash, neutralise the filtrate with dilute soda, evaporate to a syrup, and take up with 30 cc. of ether-alcohol. Filter again, wash with ether alcohol, and evaporate the filtrate in a long-necked flask until a constant weight is obtained.

Sometimes the resulting glycerol is slightly coloured, in which case it can be decolorised with animal charcoal, although the coloration is usually sufficiently slight to be negligible.

To detect glycerol obtained from extract:—

1. Render slightly alkaline with sodium carbonate, mix with powdered borax, and ignite on a platinum wire, when a green colour is obtained.

2. Red litmus paper is rendered blue by borax and dried, and on dipping it into the solution of glycerol and sodium carbonate the red colour is restored, immediately with strong and gradually with weak solutions.—T. A. G.

## ANALYTICAL AND SCIENTIFIC NOTES.

### *The Use of Sodium Peroxide for Analytical Purposes.*

T. Poleck. Ber. 27, 1051.

Sodium peroxide behaves similarly to the better known barium and hydrogen peroxides, but much more energetically. Silver, mercury, and gold salts are reduced with evolution of oxygen. Platinum chloride is only reduced when the compound  $\text{PtCl}_2\text{H}_2$  is decomposed by a silver salt. Then both the silver chloride and the platinum chloride are reduced to the metallic state. The same thing holds good with the platinum double salts of the alkalis and of the alkaline earths, reduction to metallic platinum only taking place after addition of a silver salt.

Treated with sodium peroxide, ferrous and ferric salts give ferric hydrate. Manganese and cobalt salts give manganese dioxide and cobalt oxide. Permanganic acid is reduced to manganese dioxide. Chromium oxide is oxidised to chromic acid. Uranium salts give sodium peruranate  $\text{U}_2\text{O}_5\text{Na}_4 + 8\text{H}_2\text{O}$ . Bismuth hydrate and its salts are oxidised to bismuth pentoxide.

Potassium ferriocyanide is reduced by sodium peroxide to ferrocyanide, and this reaction may be used for gravimetrically determining the purity of the peroxide. By this method the sodium peroxide used in the author's experiments was found to contain 83.62 per cent. of the pure product.

It may be used for the separation and estimation of iron and chromium, and of manganese and chromium. The iron and the manganese are precipitated as ferric hydrate and as manganese dioxide, whilst the chromium goes into solution as chromic acid, and may be reduced by alcohol and weighed as chromic oxide. In a mixture of known quantities of manganese sulphate and chrome alum, 99.96 per cent. of the former and 99.67 per cent. of the latter were found, and in a mixture of ferrous ammonium sulphate and chrome alum, 99.81 per cent. of the former and 99.93 per cent. of the latter were found by this method.

It may be used also for the separation and estimation of antimony, tin, and arsenic. The metals are precipitated by sulphuretted hydrogen, dissolved in ammonium sulphide, evaporated to expel excess of ammonium sulphide, or reprecipitated; then water and sodium peroxide are added until the yellow colour of the sulphur compounds has disappeared,

which takes only a few minutes. The metals and sulphur are thus completely oxidised and the oxygen compounds of the metals are separated by known methods. In two experiments with mixtures of tartar emetic, tin, and arsenic acid, the contents of which were known, the following percentages of the constituents were found.

	I.	II.
Tartar emetic .....	Per Cent. 99.67	Per Cent. 99.96
Tin .....	99.04	99.91
Arsenic acid .....	99.84	99.75

This method of oxidising the metallic sulphides is preferable to the ordinary nitric acid method in toxicological examinations, because it allows of "Marsh's" apparatus being immediately applied.

The fusing of minerals and ores with sodium peroxide for purposes of analysis, has been described by several investigators. The most complete oxidation takes place by using a mixture of equal parts of sodium carbonate and sodium peroxide, and this would be an excellent analytical method did not the choice of vessel for fusion present difficulties. Silver, platinum, and nickel are strongly acted upon. A platinum crucible lost 0.05—0.1 gm. in weight after each operation.

By the action of sodium peroxide on lead oxide in presence of water, not ortho- but meta-plumbate of soda is formed,  $\text{PbO}_3\text{Na}_2 + 4\text{H}_2\text{O}$ . The author was altogether unsuccessful in obtaining the orthoplumbate,  $\text{Pb}(\text{O}^+\text{Na})_2$ .

By heating iodine with sodium peroxide, the sodium periodate,  $\text{Na}_2\text{H}_3\text{IO}_6$ , is formed.

The oxidation of carbon compounds in alcoholic solution by sodium peroxide promises good results. Since alcohol is not attacked by it.—H. M.

### *The Action of Formaldehyde on Vegetable Tissues.*

J. Hofkett. Ber. d. Pharm. Ges. 1894, 4, 81.

FORMALDEHYDE, now commercially obtainable under the name "Formalin," is an excellent agent for hardening fresh vegetable preparations for the purposes of botanical research. A 4 per cent. solution of the reagent hardens vegetable objects more rapidly and effectually than absolute alcohol, and possesses besides two great advantages: it does not extract or otherwise affect the natural colouring matters of flowers, leaves, &c.; and, moreover, the tissues immersed in it do not appreciably shrink.—H. T. P.

## Trade Report.

### TARIFF CHANGES AND CUSTOMS REGULATIONS.

(From the Board of Trade Journal.)

#### RUSSIA.

##### Customs Divisions.

Dissolvable glass, with an admixture of glue, under section 71, point 5, letter a: duty, 2 roubles, gold, per pound.

Caterpillar glue (Ernisch) for preserving trees from noxious insects, prepared from tarry substances with an admixture of mineral salts, to be cleared under section 71, point 5, letter b: duty, 40 copecks, gold, per pound.

Salts of antimony (double antimonial nitrothioric acid salt), used in some instances in lieu of tartar emetic, to be cleared under section 112: duty, 1 rouble and 50 copecks, gold, per pound, gross.

Paranitraniline, not constituting in itself an aniline colour (pigment), to be cleared under section 112; duty, 1 rouble and 50 copecks, gold, per pound, gross.

Carbolic acid in a purified state or only partly purified, to be cleared under section 112; duty, 1 rouble and 50 copecks, gold, per pound.

Phosphite (a triturated mixture of tale and hydrous copperas), used for preserving vines and other plants from noxious insects and disease, to be cleared under section 125, point 2, letter *b*; duty, 35 copecks, gold, per pound, gross, if the admixture of hydrous copperas does not exceed 10 per cent. in quantity.

Zinc dust, under section 147, point 1; duty, 40 copecks, gold, per pound.

Tartar emetic, notwithstanding that it may have been slightly purified, under section 112; duty, 1 rouble and 50 copecks, gold, per pound.

#### UNITED STATES.

##### Customs Decisions.

Direct black, not a simple extract or decoction of a dye-wood, but a constructed dye and a chemical compound, is dutiable at 25 per cent. *ad valorem* under paragraph 76 N.T. as a chemical compound.

Oxide of cobalt, blues, satin-white, chromes, ochres, umbers, vermilion reds, white leads, verdigris, and other colours in oil, and in small tubes, commercially known as artists' colours, in tubes, are dutiable at 25 per cent., under paragraph 61.

Prune pure, a coal-tar colour or dye, produced by combining methyl with galloxyaniline, is dutiable at 35 per cent. *ad valorem* under paragraph 18 N.T.

Lanae, a preparation produced from wool grease, substantially free from alkalis, is dutiable at the rate of 25 per cent. *ad valorem* under paragraph 76 as a rendered oil.

"Curriers' fat blacking" is dutiable at 25 per cent. *ad valorem* under paragraph 11 N.T.

Business cards made of collodion or celluloid are dutiable at 60 cents per pound and 20 per cent. *ad valorem* under paragraph 21 N.T.

Crine, composed of a mixture of fine clay and a fat oil, and used by artists, sculptors, and others for modelling, not wax, is dutiable at 20 per cent. *ad valorem* under section 4 of the Tariff Act.

Essential oil of nutmegs is dutiable at 25 per cent. *ad valorem* under paragraph 76 N.T.

Sulphate of ammonia is dutiable at  $\frac{1}{2}$  cent per pound under paragraph 10 of the existing tariff.

Thin strip of magnesium about one-sixteenth of an inch in width, known as "magnesium ribbon," is dutiable at 45 per cent. under paragraph 215 N.T.

#### GENERAL TRADE NOTES.

##### OLIVE OIL INDUSTRY IN SPAIN.

The *Moniteur Officiel du Commerce* for the 26th July states, that according to the average of the last five years, the annual production of olive oils in Spain has been 2,976,584 quintals. The home consumption is distributed as follows:—Oils for purposes of food, 1,108,151 quintals; for factories engaged in the preserving industries, 53,713; for purposes of lighting, 467,200; for soap factories and other industries, 675,000; for oiling machinery, looms, ships, &c., 450,000; or a total of 2,754,064 quintals.

The annual exports amount to 222,320 quintals, distributed as follows amongst the countries of destination:—Spanish possessions, 63,486 quintals; France, 46,019 quintals; Portugal, 29,766 quintals; England, 17,126 quintals; Denmark, 16,893 quintals; Germany, 11,316 quintals; Asia and Africa, 15,529 quintals; America, 12,624 quintals; and other destinations, 9,561 quintals. Total, 222,320 quintals.

##### DISCOVERY OF SALINES IN MEXICO.

The French Minister at Mexico in a recent report states that immense salines have recently been discovered in the district of Astapa, State of Tabasco. A powerful American company is about to be formed for the purpose of working them.

##### RUSSIAN ALCOHOLIC PRODUCTION.

The Russian *Gazette du Commerce et de l'Industrie* states that from the 1st January to the 1st June 1894, the production of the Russian alcohol distilleries amounted to 29,282,951 vedros of pure alcohol against 26,604,345 vedros in 1893. The vedro may be taken as equivalent to 2.7 imperial gallons.—*Ibid.*

##### ON A NEW DEPOSIT OF PHOSPHATES IN THE SOUTH OF FRANCE.

In 1882, while engaged in the study of the geological structure of the valley of the Aude, on the north-eastern flank of the Pyrenees, the author undertook the investigation of the deposits in a series of caverns contained in the limestone cliffs of the River Cesse. These limestones, which are of Eocene date, form elevated barren tablelands known as "causses," rising to about 1,000 ft. above the sea-level, and, where cut through by the streams, are seen to lie at a low angle upon hard siliceous limestones of Devonian age. The surface of junction is irregular, and the upper strata near the contact are eroded into long ramifying galleries whose roofs and sides are in the nummulitic rock, while the floors, apart from the filling material, are formed by the Devonian rock. The most important of these caves, known as the Grotte de Minerve, situated near the village of the same name, about 17 miles from Narbonne and 22 miles from Carcassonne, is a system of two principal galleries from 25 to 30 ft. wide, and 30 to 33 ft. high, which cross obliquely and extend for about a total length of 3,600 ft., following the dip of the nummulitic strata. The floor is covered with cave earth and bone breccia, containing worked flints, pottery, and other prehistoric antiquities, the bones of the cave bear and other quadrupeds to a depth of 10 to 15 ft., below which concretions of phosphoric, and other forms of phosphates, both of lime and alumina, are found in quantities; the deposits, proved by numerous trial pits, varying from 15 to 50 ft. in depth, being estimated to contain from 120,000 to 300,000 tons of phosphatic minerals, which differ in many respects from the ordinary phosphorites of stratified formations. Among these, one of the most interesting is brushite, a hydraulic dibasic calcium phosphate ( $2\text{CaO}, \text{P}_2\text{O}_5, 5\text{H}_2\text{O}$ ) which had only been known previously as a secondary product incrusting the rock guano of Aves Island and Sombbrero in the West Indies. It contains phosphoric acid 43 per cent., lime 34 per cent., and water 23 per cent., and, as a rule, occurs in crusts upon and filling fissures in the limestone rocks, and in the purest form is a bright powdery substance made up of thin crystalline plates exactly similar to those described by the discoverers of the original mineral. The bulk of the deposit is, however, made up of mixtures of tribasic calcic phosphate and neutral phosphate of alumina, which vary within rather wide limits, but frequently are in nearly equal proportions, about 24 to 25 per cent. of each, containing about  $27\frac{1}{2}$  per cent. of phosphoric acid, which is mostly all soluble in weak acids. A third, and previously undescribed substance, to which the name of minervite has been given, is a hydrated aluminic phosphate ( $\text{Al}_2\text{O}_3, \text{P}_2\text{O}_5, 7\text{H}_2\text{O}$ ) which was found as a white plastic mass, filling a vein from 2 to  $2\frac{1}{2}$  ft. thick.—*Annales des Mines, through Engineering and Mining Journal.*

##### ALKALI LANDS IN NORTH CHINA.

A correspondent of the North China *Herald* gives the following information concerning the alkali lands in the north part of that country:—

Chinese may often be heard to say, in the north especially, that certain ground is useless on account of alkalinity. The following report shows that this land has a value of its own which will probably be appreciated hereafter.

During the dry time of the year the surface of the land in many parts of the north of China is covered with a white incrustation of salts, called *chien* by the natives, which easily dissolves in water, and therefore disappears during the rainy season. A sample collected in the neighbourhood of Peking, a few li to the S.W. of the city, contained:—

	Per Cent.
Chloride of sodium (common salt) .....	23.8
Carbonate of sodium (soda) .....	12.4
Sulphate of sodium (Glauber's salts) .....	63.8
	100.0

I obtained large quantities of these salts, by having the ground swept with a broom, and lixiviating the sweepings with warm water. Over a third of the material thus collected proved to be soluble matter. It may be separated from the solid residue either by filtering or by siphoning the supernatant liquor and evaporating the saline solution, which shows a strong alkaline reaction on account of the carbonate of sodium contained in it. When sufficiently concentrated, the liquid, on cooling, deposits a large mass of crystalline matter, which for the most consists of sodium sulphate, a part of it, together with the sodium carbonate and chloride and sodium, remaining in the mother-liquor. The latter, on being evaporated by dryness, yields a brownish-

looking substance, the colour being due to organic matter—which, on being treated with vinegar, shows a brisk effervescence. It is, to all intents and purposes, the same substance as the one called *Tzu-chien* by the Chinese, which is an impure carbonate of soda extensively used in dye works. Not only does it serve for the cleansing of textile fabrics, but is also used as a mordant, for instance, in colouring cotton cloth with a solution of indigo, &c.

Judging from the above, there appears to be an abundance of sodium sulphate in some parts of China, which may become valuable some time or other when, with the introduction of foreign industries, such as the manufacture of glass and soap, a greater demand is created for this chemical substance than exists at present. As there is plenty of limestone and coal in many places, all the materials wanted are possessed in abundance. This, in addition to the cheapness of labour, makes it not improbable that, at some time or other, China will become one of the chief producing countries of soda.

In the table below I give an analysis of each of the four kinds of soda distinguished in trade. The samples were obtained from one of the great depôts outside the city. For comparison, the English commercial "degrees" have been added. Taking the quotations of a London trade report, I find that, on the whole, prices in Peking, at present exchange, do not rule much above those at home.

Colour.	Water.	Carbonate of Soda.	Chloride of Sodium.	Sulphate of Sodium.	English Commercial Degrees.	Price per 100 Catties, or 1 Picul.
<b>K'ou-chien (from Kalgan):—</b>						
1. P'ien chien, yellowish white .....	Per Cent. 15.61	Per Cent. 53.00	Per Cent. 1.33	Traces	31.41	49.4 Tiao; Shanghai Tls., 3.8
<b>Hsi-k'ou-chien (from Shansi):—</b>						
2. Pai chien, white .....	52.60	45.71	1.07	Traces	27.09	46.8 Tiao; Shanghai Tls., 3.6
3. Tzu chien, first quality, dirty yellow ....	28.65	11.61	6.29	23.46	21.66	39.0 Tiao; Shanghai Tls., 3.0
4. Do., second quality, brown .....	17.30	53.13	18.14	31.27	19.19	35.1 Tiao; Shanghai Tls., 2.7

At present this substance is extensively used by the Chinese for cleansing purposes, taking the place of soap in foreign countries. It also serves as a baking powder in the preparation of Chinese bread. As far as I have been able to ascertain, the article which is sold at Peking is nearly all derived from places outside the Great Wall. There are two different kinds—"k'ouchien," which is brought here from Kalgan, and "ksik'ouchien," which comes from the northern part of the province of Shansi, the prefecture Tat'ungfu. The former, I am told, is obtained from salt lakes, pools, or pits dug for the purpose of collecting the brine with which the soil is impregnated. It is a very superior article, almost free from impurities and largely used in the preparation of *mant'ou* and other kinds of bread. The material which furnishes the *ksik'ouchien* is found as a white efflorescence on the soil, similar to that observed in the neighbourhood of Peking. According to the account given by the Chinese, it forms layers of considerable thickness in some places, and is a good deal richer in the carbonate than what is to be got hereabout. There are several sorts of it, one of them called "*pachien*" being of an excellent quality. It is almost free from chlorides, and shows hardly a trace of sulphate, which is all the more remarkable, as it is said to be prepared by a process of crystallisation from some of the inferior sorts of *tzu-chien* already spoken of.—*Engineering and Mining Journal*.

#### CHROMIC IRON IN QUEBEC, CANADA.

There are indications that the raising of chromic iron ore may become one of the mining industries of the province of Quebec. It has long been known that chromite occurs in pockets in the Cambrian Serpentine that stretch through the province from the Vermont boundary to Gaspé, and in the past a few tons of the ore have been taken out at various times and from various points. But disappointment in the mode of occurrence of the ore, and in the price that could be obtained for the same, led to a speedy abandonment of the attempt to mine it.

So far as can be learned, the total amount of chromite mined in Canada during the past 10 years is less than 100 tons. One of the chief obstacles to chrome ore mining in Canada, common to the great majority of places where this ore is found, is the mode of occurrence. It is rarely found in beds or veins, but in detached pockets which yield from a few pounds to hundreds of tons, the larger pockets being comparatively rare.

In consequence of the mode of this mining, investors hesitate to embark in a species of mining more than usually uncertain, and having entered upon it do not feel warranted in putting up expensive machinery. Another and more serious obstacle is the present attitude of the users of chrome ore, the principal of whom are the manufacturers of bichromate of potash. These are unwilling at the present time to purchase ore carrying less than 50 per cent. of chromic sesquioxide, although it is believed that under certain conditions ore of 48 per cent. is accepted. Most, if not all, the Canadian deposits that have been tapped are below this grade. But during the present season deposits of chromite of a grade sufficiently high to meet the demands of manufacturers have been discovered and are being worked within two miles of Black Lake Station on the Quebec Central Railway, and in close proximity to the well-known Black Lake asbestos mines.

A large body of prospectors is out searching for chrome deposits, and finds are reported, but as yet only three lots are being worked. The pioneer lot in this district, and that on which most mining has been done, is the property of Mr. M. H. Lambly, of Inverness, Quebec, and associates. In this the chromite occurs in a series of pockets, extending in an east and west direction, and the series in an easterly direction into the adjoining lot. In these two lots some of the pockets are lying against a dyke of fine-grained granulite, but whether there is any relationship between the igneous rock and chromite it is impossible to say. Other pockets seen elsewhere in the vicinity are not associated with the granulite, but those in which the granulite lies

against the chromite have yielded a large amount of ore of very fine quality. From one pocket on the Lambly property nearly 500 tons have been taken out, and it is still producing. The writer selected two hand specimens of this Lambly ore as free as possible from foreign matter, and found them to yield on analysis 54 per cent. and 56.02 per cent. of chromic sesquioxide.

It is evident, of course, that a shipment of ore would not average as high as these selected hand specimens, and that careful dressing would be necessary to insure that shipments should not fall below the grade the market demands. Mr. Lambly states that a shipment of two cars tested 51 per cent. and realised 26 dols. per ton of 2,240 lb. delivered in Baltimore, which is equal to 20.50 dols. per ton f. o. b. at the mines.—*Ibid.*

#### ANTIMONY AND BISMUTH IN BOLIVIA.

The Consul-General of France at La Paz in Bolivia has recently made a special report on the mines of bismuth and antimony in that country. The only deposit of bismuth ore actually known is that of Quechisla (also known as Chorolque), though some exploration for others has been made, but without success. The returns show that the production of this mine is about 500 Spanish quintals, or 23,000 kilos., per month. This production, however, is regulated in concert with the European producers. In addition to bismuth the Quechisla mine yields some tin and a little silver.

Antimony is found in many places in the department of Potosi, generally in connection with gold and silver ores. In the province of Chayanta there are many veins of the sulphuret of antimony, which have become more accessible than formerly since the building of the Antofagasta Railroad. Owing to the present low price of the metal, however, it does not pay to work the poorer deposits. The Amayapampa Company, a recently formed Bolivian corporation, is now producing and exporting 100 metric tons a month of 65 per cent. ore. The mine is 18 miles from the railroad, over a difficult mountain trail. With better transportation the output could be largely increased. It is said, however, that all the veins so far found diminish in richness with depth. The industry is just beginning in Bolivia, and the Government has freed the producers from all direct tax and also from export duty.—*Ibid.*

#### PROPOSED GERMAN ANALYTICAL ASSOCIATION.

The German Government intend to take the initiative in the formation of a German association of analytical chemists, which will be charged with the drawing up of a code for the examination of alimentary substances and with the execution of a law relating to the adulteration of such substances. At a congress of chemists and microscopists recently held at Eisenach, and attended by Dr. Köhler, the director of the National Department of Public Health, the preliminaries of the association were discussed and agreed upon.—*Chemist and Druggist.*

#### THE CHEMICAL INDUSTRY OF BERLIN.

The following is an abstract of the report on the German chemical trade during 1893, prepared by the Berlin Chamber of Commerce.

During the year under review the German chemical trade has suffered severely from the effects of the tariff war with Russia. Although this warfare has been brought to an end, Germany will still labour under the disadvantage of having to recover trade that has been temporarily diverted to other quarters. Another drawback has been the unsettled state of the money market in the United States, as well as the tendency to withhold orders till the promulgation of the new United States Tariff Bill.

Up to the present time little advantage seems to have accrued to German manufacturers from the Chicago Exhibition, and the general consensus of opinion seems to be that the results so far have not repaid the costs involved in representation.

Almost the only products which have sustained any appreciable advance in price are the ammonia compounds. Two causes are suggested for this improvement—a decrease

in the English production of gas-water, and an increased consumption of sulphate of ammonia for agricultural purposes. The price of *ammonium sulphate* at the beginning of the year stood at 21 m. to 22 m. per 100 kilos. This gradually advanced to 30 m. per 100 kilos., and had only declined to 28 m. by the end of the year.

*Aqueous ammonia* 0.910 sp. gr. advanced from 22 m. to 35 m. per 100 kilos. *Ammonium carbonate*, unfortunately, did not share in the improvement to the same extent, and quotations did not rise above 62 m. per 100 kilos.

Technically pure *White Sal ammoniac* suffered a decrease in price out of proportion to its value, and quotations sank to 40 m. per 100 kilos.

The depressed condition of the *Potash* market has continued unchanged, 40 m. per 100 kilos. being quoted for 96 to 98 per cent.

*Oralic Acid* and *Oralates* have been unable to advance beyond last year's prices, 60 m. per 100 kilos. being the average figure for the first-named.

*Potassium Cyanide* continued in good demand, but towards the end of the year the price declined somewhat, bringing the general average to about 140 m. per 100 kilos.

For *Yellow Prussiate of Potash* the demand was so brisk that makers were emboldened to raise the price to 180—190 m. per 100 kilos.

The figure realised for *Silicate of Soda* has declined still further, although the consumption of the article has remained the same. Tariff troubles have largely conduced to this result, and the trade with the United States has practically died out.

*Soda Crystals*, which began the year at 6 m. per 100 kilos., were raised 50 pf. in consequence of an understanding with foreign producers, but as *Soda Ash* declined somewhat in the autumn, the price of crystals again fell to the first-named figure.

*Nitric Acid* underwent little change, 23 m. per 100 kilos. being the quotation for the refined 36° article.

*Sulphuric Acid*, especially of the lower qualities, underwent a considerable improvement, mainly because the fall in silver had caused many of the metallurgical works to suspend operations, and in consequence the supply of the acid was curtailed. This position of affairs naturally caused a corresponding scarcity of *Hydrochloric Acid*.

*Acetic Acid* remained at the unremunerative values of the preceding year.

*Wood Spirit* enjoyed a brisk sale at a slight improvement upon last year's prices.

In the *Tar* trade the various products remained in good demand, but sales were only effected at the cost of a continued decline in prices. There appears to be little hope for the success of the English movement to arrest this decline, as the yield from coke ovens is a continually increasing one.

The lowest *Benzol* price of the preceding year, 45 m. per 100 kilos., was soon reached, nor did the price halt here, but sank further to 40 m.

*Nylol* was in poor demand, and witnessed a decline in values, but on the other hand a brisk trade in *Toluol* sprang up, with a corresponding advance in price.

No particular change occurred in the *Anthracene* market, although large stocks were held in England, and a general disposition to withhold orders was exhibited by German consumers.

The demand for *Naphthalene* and *Phenol* continued good, but the decline in values was not arrested.

*Cresol* was well inquired for, and has realised its early promise of employment for disinfecting purposes.

*Roofing Varnish* and *Pitch* have found ready sales, but again at lower prices.

The prospects of the *Aniline Dye* industry in the beginning of the year were very favourable, but the silver troubles entirely changed the aspect of affairs. Two other causes are mentioned as contributing to the same result, the tariff war with Russia (which seems to be held responsible for a good many German misfortunes), and the unsatisfactory state of the Swiss patent laws, which permit of a wholesale piracy of German patented inventions.

The trade in non-poisonous *Chemical and Mineral Colours* has been characterised by extreme dullness, and the prices of previous years have not been maintained. This is attributed largely to the tariff troubles which were indicated in last year's report.

*Varnishes and Lacquers* have suffered from slackness in the building industry, and *Oil of Turpentine* having declined about 6 m. per 100 kilos., is again at the lowest point that has been touched. On the other hand, *Lead Compounds* have suffered little in value.

Makers of pharmaceutical chemicals who, in anticipation of a return of the cholera epidemic, had laid in considerable stocks, were heavy losers by the transaction, as no considerable demand was noticed in this direction. In consequence of the tariff difficulties, German pharmaceutical products are unable to find their way into Russia direct in anything like quantity, but as Russian buyers appreciate the German manufactures, these products have been handicapped by having to find their way to Russian consumers by more roundabout means.

An arrangement between the Stassfurt syndicate and the American producers has resulted in a greater steadiness in the *Bromine* market, and the price has risen 50 pf. per 100 kilos.

The demand for *Chloral Hydrate* has declined somewhat, in consequence of the increasing reputation of other similar products, but makers have covered this by a mutual arrangement with regard to prices.

The trade in *Citric Acid* has not come up to anticipation. Early in the year prices stood at 6d. to 7d. for 34 per cent., to 35 per cent., and 7d. to 8d. for 38 per cent., to 40 per cent. Quotations rose in February to 7d. to 8d. and 8d. to 9d., respectively, but after that declined slowly to 5½d. and 6d. to 7d., respectively.

*Glycerine* commenced the year in favourable demand, but the American crisis practically destroyed the trade with that country, and difficulties were experienced in inducing purchasers to take even their contract quantities.

The *Iodine* market has been in a disturbed state, owing to rumours of defection from the Iodine Convention. The effect of this has been to cause buyers, taught by previous experience, to withhold their orders.

Two new *Disinfectants* have made their appearance. "Formalin" is said to be an excellent disinfectant for houses and objects of all kinds, while for "Tri-cresol," that is a mixture of meta-, ortho-, and para-cresol, an equal efficiency is claimed for use in the treatment of wounds.—*Chemical Trade Journal*.

## IMPORTS OF OILS FOR MONTH ENDING 31ST AUGUST.

Articles.	Quantities.		Values.	
	1893.	1894.	1893.	1894.
			£	£
Cocoa-nut.....	Cwt. 8,715	36,844	16,066	41,105
Olive .....	Tuns 1,343	2,282	51,295	71,395
Palm .....	Cwt. 122,621	110,319	149,174	116,949
Petroleum .....	Gall. 10,909,767	13,360,521	190,631	191,429
Seed .....	Tons 2,145	2,137	53,086	45,259
Train, &c.....	Tuns 1,937	3,272	39,787	54,592
Turpentine .....	Cwt. 76,167	59,931	78,411	55,357
Other articles ..	Value £ ..	..	77,687	73,376
Total value of oils...	..	..	650,377	652,372

## IMPORTS OF RAW MATERIAL FOR NON-TEXTILE INDUSTRIES FOR MONTH ENDING 31ST AUGUST.

Articles.	Quantities.		Values.	
	1893.	1894.	1893.	1894.
			£	£
Bark, Peruvian ..	Cwt. 3,712	6,036	6,965	10,817
Bristles.....	Lb. 224,852	327,139	30,683	42,043
Caoutchouc.....	Cwt. 24,805	16,371	265,307	156,061
Gum:—				
Arabic.....	" 8,124	4,224	16,154	8,954
Lac, &c.....	" 4,844	5,796	22,855	30,862
Gutta-percha ....	" 2,858	3,749	16,095	33,021
Hides, raw:—				
Dry.....	" 31,193	33,086	75,019	80,978
Wet .....	" 58,892	74,363	120,007	153,922
Ivory .....	" 734	543	34,577	23,693
Manure:—				
Guano .....	Tons 176	2,155	1,224	11,768
Bones.....	" 1,365	5,169	5,868	23,968
Nitrate of soda...	" 10,498	3,208	92,894	28,917
Phosphate of lime	" 49,156	46,732	65,658	92,510
Paraffin.....	Cwt. 72,501	34,116	70,562	37,941
Lineu rags.....	Tons 1,145	1,853	11,297	16,535
Esparto.....	" 15,139	13,025	67,481	53,403
Pulp of wood ....	" 16,731	24,464	98,289	118,205
Rosin.....	Cwt. 292,897	145,469	62,404	38,654
Tallow and stearin	" 156,681	187,776	217,578	239,327
Tar .....	Barrels 42,890	34,423	23,196	20,835
Wood:—				
Hewn .....	Loads 316,679	270,285	639,839	515,301
Sawn .....	" 857,234	858,428	1,826,959	1,864,233
Staves .....	" 17,007	16,912	52,305	61,234
Mahogany .....	Tons 3,007	3,332	26,312	25,787
Other articles....	Value £ ..	..	932,120	823,391
Total value .....	..	..	4,781,648	4,512,360

Besides the above, drugs to the value of 63,031*l.* were imported, as against 72,504*l.* in August 1893.

IMPORTS OF CHEMICALS AND DYE-STUFFS FOR MONTH  
ENDING 31ST AUGUST.

Articles.	Quantities.		Values.	
	1893.	1894.	1893.	1894.
			£	£
Alkali..... Cwt.	9312	7919	8,103	6322
Bark (tanners', &c.) ..	36,349	17,752	13,916	19,881
Brimstone..... "	21,756	79,368	7,015	15,178
Chemicals..... Value £	..	..	119,258	93,877

## Monthly Patent List.

\* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to oppositor within two months of the said dates.

### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

#### APPLICATIONS.

- 15,366. I. Levinstein. *See Class VII.*
- 15,413. E. Fudiekar. Improvements in and relating to apparatus for heating liquids, air, and other fluids. Complete Specification. August 13.
- 15,453. B. C. Tilghman, jun. An improved method of and apparatus for detecting and measuring the presence and amount of inflammable gases or vapours mixed with air. Complete Specification. August 14.
- 15,463. A. Bassett. *See Class XVII.*
- 15,736. W. J. C. Marie, Baron de Liebhaver. New apparatus to produce vapours of chlorhydric acid and other substances. August 18.
- 15,773. J. L. Osborn. — From C. Neuhaus, Austria. Improvements in apparatus for burning liquid fuel. August 18.
- 15,881. W. Oliphant. Improvements in filtering apparatus. Complete Specification. August 21.
- 15,885. J. C. S. McLay. Improvements in non-heat-conducting materials. August 21.
- 16,043. W. Spencer. Improvements in kilns for burning or calcining lime-stone or like substances. August 23.
- 16,235. A. Crerar. — From W. R. Boon and E. A. Hancock, West Indies. An improved process of and apparatus for evaporating or concentrating saccharine and other liquids. August 25.
- 16,246. H. B. Clark. A new and improved liquid refrigerator or cooling apparatus for breweries, dairies, and the like. August 25.
- 16,278. J. Swinburne. Improvements in and connected with electrical measuring instruments, organs, electrolysis, and working aluminium. August 27.
- 16,658. J. T. Bottomley. Apparatus for evaporation, distillation, or concentration of liquids. September 1.
- 16,692. F. Besin. An improved apparatus for the continuous heating of water. September 1.
- 16,728. F. W. Crossley and J. Atkinson. Improvements in apparatus for transferring heat or refrigerating. September 3.
- 16,938. E. Herscher. An improved continuous apparatus for the sterilisation of water or other liquid by ebullition. Complete Specification. September 5.
- 16,973. J. C. Sewell. New or improved apparatus for manufacturing heat-non-conducting material. September 6.
- 17,063. J. E. Smith. Improvements in apparatus for agitating or mixing materials, whether solid, liquid, gaseous, or mixtures thereof, applicable more especially for stuff chests for paper mills and chemical agitating machines. September 7.
- 17,160. T. Morton. Improvements in apparatus for heating, switching, or incorporating liquids, semi-liquids, or the like substances. September 10.
- 17,175. J. B. Hepburn and C. R. Honiball. Improvements in machinery for producing distilled water from sea or other impure water, and for concentrating liquids. September 10.

17,212. T. Glover and J. Brock. Improvements in or connected with concentrating or evaporating vessels. September 10.

17,219. R. Altsebul. Improvements in or connected with feeding liquid fuel, such as petroleum and other oily and inflammable substances, to steam-boiler or other furnaces, and burning same therein. September 10.

17,274. T. Craney. Improvements in apparatus for drying salt and other substances. Complete Specification. September 11.

17,289. H. E. Newton. — From E. Hart, United States. *See Class VII.*

17,314. J. S. Detwiler. Improvements in apparatus for treating powdered materials. Complete Specification. September 11.

17,315. J. S. Detwiler. Improvements in apparatus for blending powdered materials. Complete Specification. September 11.

17,374. G. Fouchard. Improvements in filters. September 12.

17,593. T. T. Best, S. A. Hollingsworth, and J. Brock. Improvements in apparatus for raising or pumping corrosive or other liquids. September 15.

#### COMPLETE SPECIFICATIONS ACCEPTED.\*

1893.

16,869. J. Gamgee. Improvements in vapour condensers or evaporators. September 5.

17,736. J. W. Pickles. The challenge sulphide rectifier. September 12.

19,630. G. E. Davis. Improvements in the construction of ammonia apparatus. August 22.

19,894. R. E. Dickinson. A new or improved bung for metallic casks or drums for containing mineral and other oils or the like. August 29.

20,303. T. F. Ennis and B. B. Waller. *See Class II.*

20,331. C. Bartelt and F. Bartelt. Improvements in apparatus for impregnating liquids with gases. September 12.

20,359. J. Musgrave and G. Dixon. Improvements in means for super-heating steam. September 19.

20,797. L. H. Bristowe. Improvements in filtering apparatus. September 5.

21,876. G. Dean. Improved Hoffman's kiln. September 19.

1894.

5187. C. Long and W. H. Barkitt. An improvement in acid raisers of steam jet pumps for raising acids, alkalis, and other liquids. September 5.

7318. T. Wheeler. An improvement in metallic thermometers and barometers. September 12.

7893. J. T. Sands. Improvements in apparatus for bleaching smoke. September 5.

9210. E. Cramer. Improvements in kilns for burning cement and other minerals. August 29.

14,184. F. Kleemann. Improvements in the process of and apparatus for beating and concentrating liquids. September 12.

15,153. B. C. Tilghman, jun. An improved method of and apparatus for detecting and measuring the presence and amount of inflammable gases or vapours mixed with air. Complete Specification. September 19.

### II.—FUEL, GAS, AND LIGHT.

#### APPLICATIONS.

15,469. A. McDougall. Improvements in or relating to the treatment of coal dust, small coal, and coke to improve them or render them fit for use as fuel or for the manufacture of gas. August 14.

15,486. E. Edwards.—From The Internationale Gesellschaft für Torfverwertung, Germany. Improvements in apparatus and process for manufacturing coke and charcoal and for separating the products obtained in such manufacture. August 14.

15,878. A. W. Burgess. Improved firelighter. August 21.

16,087. G. S. Cory and C. Cory. Improvements in the manufacture of artificial fuel. August 23.

16,149. H. Drehschmidt. A process for obtaining cyanogen or its compounds from the gases resulting from the dry distillation of substances of organic origin. August 24.

16,202. J. H. Crosby and M. McInerney. Improvements in firelighters, and in apparatus therefor. August 25.

16,342. G. B. Ellis.—From T. L. Willson, United States. Improvements in the production of metallic carbides and in illuminating gas. August 27.

16,395. W. F. Browne. Improvements in the manufacture of gas and in apparatus therefor. Complete Specification. August 28.

16,491. T. Barker. Improvements applicable to gas lights and other lights. August 30.

16,700. G. S. Cory and C. Cory. An improvement in the manufacture of so-called patent fuel. September 1.

16,701. G. S. Cory and C. Cory. Improvements in the manufacture of so-called patent fuel. September 1.

16,978. A. E. Tavernier and W. L. Malcolmson. A new and improved manufacturing of briquette fuel. September 6.

17,083. I. Carr. Improvements in or connected with the manufacture of gas. September 8.

17,219. R. Altschul. See Class I.

17,484. E. Kirbis. Method of manufacturing artificial fuel. Complete Specification. September 14.

17,491. G. Rose. Improvements in apparatus for the making of hydrogen gas to be used with an admixture of air for lead burning, brazing, and other purposes. September 14.

17,555. H. R. Dinsmore. Improvements in or connected with apparatus for making gas from coal. September 15.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

19,185. S. Psaroudaki and A. Blondel. Improvements in the diffusion and distribution of light. August 29.

20,303. T. F. Ennis and B. B. Waller. An improved gas-stoking tool. August 22.

21,485. J. Gray. Improvements in or connected with retorts for distilling shale or oil-yielding minerals. September 19.

22,185. C. D. Abel.—From M. M. Rotten and Co. Improved manufacture of fire-lighters. September 5.

1894.

11,657. J. T. Westcott. Improvements in apparatus for the manufacture of water-gas. September 5.

15,323. J. Schrader. An improved process for purifying petroleum. September 19.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

#### APPLICATION.

15,945. J. Y. Johnson.—From J. E. Pellagrini, Spain. Improvements in the manufacture or production of ethylene (bi-hydrocarbon  $C_2H_4$ ). August 21.

### IV.—COLOURING MATTERS AND DYES.

#### APPLICATIONS.

15,564. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik, Germany. The manufacture and production of new azo dyes. August 15.

15,621. H. E. Newton. From The Farbenfabriken vormals F. Bayer and Co., Germany. The manufacture or production of dye-stuffs and materials therefor. August 16.

15,859. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik, Germany. The manufacture of new dyes of the rhodamine series and intermediate products and leuco-compounds related thereto. August 20.

16,083. O. Imray.—From The Farbwerke vorm. Meister, Lucius, and Brüning, Germany. Manufacture of substituted ethenylidiphenylamines and ethenylmonophenylamines. August 23.

16,530. C. D. Abel.—From The Actien-Gesellschaft für Anilin-Fabrikation, Germany. Improved manufacture of colouring matters dyeing blue with mordants. August 30.

16,559. G. W. Johnson.—From Kalle and Co., Germany. Improvements in the manufacture or production of ortho- and para-oxy-ortho-toluic acids and meta-cresol. August 30.

17,048. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning, Germany. Manufacture of a yellow basic colouring-matter. September 7.

17,049. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning, Germany. Manufacture of yellow basic dye-stuffs. September 7.

17,133. E. Straub. Improvements in the manufacture of hydrazo compounds from aromatic nitro hydrocarbons. September 8.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

15,698. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of azo colouring matters from diamidodibenzimidazols. August 22.

18,924. J. J. Johnson.—From The Badische Anilin und Soda Fabrik. Improvements relating to the manufacture of dihydroxynaphthalene sulpho acids, and of corresponding azo-dyes. August 22.

19,623. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of colouring matters and new materials therefor. August 22.

19,624. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of a trihydroxy-naphthalene mono-sulpho acid. September 19.

19,880. R. Vidal. Improvements relating to the manufacture of colouring matters. September 22.

19,962. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik. Improvements in the manufacture and production of mordant dyeing colouring matters. August 29.

20,579. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of new colouring matters. September 5.

20,580. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture of a new anidonaphthol disulpho acid and colouring matters therefrom. September 5.

21,753. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik. Improvements in the manufacture and production of new azo dyes. September 19.

22,204. H. H. Lake.—From K. Oehler. Improvements relating to the manufacture of colouring matters. August 29.

1894.

15,064. J. C. L. Durand, D. E. Huguenin, and A. J. J. d'Andiran. Manufacture of new condensation products and colouring matters for dyeing and printing. September 12.

## V.—TEXTILES, COTTON, WOOL, SILK, Etc.

### APPLICATIONS.

15,718. H. H. Leigh.—From C. B. Schneider, Holland. See Class XIX.

15,727. C. Malley, J. Brett, and W. H. Hughes. A new and improved process for cleaning and bleaching jute, jute tow, and waste, flax and flax waste, and such like fibres, and preparing the same for spinning and felting. August 18.

15,815. J. V. Eves. Improvements in apparatus for use in the wet spinning of flax. August 20.

16,137. C. H. Arnold. Improvements in the manufacture of waterproof fabrics. Complete Specification. August 24.

16,541. J. M. Webster. Improvements in machinery or apparatus for the manufacture of wood wool. August 30.

16,648. J. Foulkes, J. E. Park, and G. N. Peake. Improvements in machines for scutching the leaves and stems of fibrous plants. September 1.

16,785. G. Jacober and A. Rabourdin. Improvements in the manufacture of filamentous products from cellulose. September 3.

17,070. E. Hornung and R. Liebl. Improvements in waterproof fabrics, garments, wrappers, and coverings, and in the process and composition for manufacturing the same. Complete Specification. September 7.

17,162. D. Whiteley. Improvements in apparatus for registering or recording the length of yarn produced in spinning, doubling, twisting, winding, and like textile machinery. September 10.

17,205. A. Dickins. Improvements in the treatment of wool and other textile materials with liquids, and in apparatus therefor. September 10.

17,370. G. Riche and A. Rivret. A process and apparatus for separating burrs and other foreign matters from wool. September 12.

### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

15,945. A. F. B. Gomess. A new and improved process for the treatment of textile vegetable fibres (more especially those of the urtica family). August 29.

1894.

7907. W. Pickstone and A. Greenhalgh. Improvements in and relating to the manufacture of crinkled textile fabrics. August 29.

13,672. E. Richard-Lagerie. Improvements in apparatus for extracting suint from wool and other substances. August 22.

14,299. W. Pickstone and A. Greenhalgh. An improved thick, soft, absorbent cloth. August 29.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

### APPLICATIONS.

15,365. W. B. Hart and C. A. McKerrow. Improvements in and connected with dyeing and printing vegetable fibres and goods made therefrom. August 13.

15,433. H. Wylie and J. Morton. Improvements in dyeing certain colours on cotton yarns and fabrics. August 14.

16,128. J. A. O'Loughlin. Improvements in producing patterns on indigo-dyed cotton fabrics. August 24.

16,252. J. W. Sanderson. Improvements in or relating to the process of indigo dyeing and to apparatus employed therefor. August 25.

16,661. C. D. Leng. Improved method of producing tinted or coloured covers for periodicals and the like. September 1.

16,987. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning, Germany. Process for the production of red tints by combining on the fibre paranitraniline with mixtures of betanaphthol and its sulphonie acids. September 6.

17,172. J. Pritchard and F. A. Blair. Improvements in apparatus for dyeing yarns and slubbings or rovings, or otherwise treating the same with liquids. September 10.

### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

20,916. J. C. Walker and J. E. Stephenson. Improvements in apparatus for scouring or washing wool and other fibrous substances. September 12.

21,087. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Process for producing insoluble azo colours on fibre. September 12.

21,843. W. P. Thompson.—From T. Salzmänn. An improved process and apparatus for treating dyed cotton yarns and the like —August 29.

1894.

14,223. H. H. Lake.—From M. E. Waldstein, A. H. Peter and E. Spott. Improvements relating to the dyeing of fibre. August 29.

## VII.—ACIDS, ALKALIS, AND SALTS.

### APPLICATIONS.

15,366. I. Levinstein. Improvements in apparatus employed in the concentration of sulphuric acid and other liquids. August 13.

15,473. F. L. Slocum and C. Y. Wheeler. Improvements in and relating to a process of making green oxide of chromium. Complete Specification. August 14.

15,702. S. B. Archdeacon. A process or method of treating siliceous material chiefly intended for the production of salts of sodium and potassium, and including the recovery of the waste products. August 17.

15,886. S. A. Saddler and R. H. Wilson. Improvements in process and apparatus for the manufacture of chlorine. August 21.

15,941. J. E. Chaster. Improvements in the manufacture of cyanides. August 21.

15,942. J. E. Chaster. Improvements in the manufacture of cyanides and apparatus therefor. August 21.

16,014. R. Loewenherz. Method of producing solid persulphate of sodium. August 22.

16,067. J. Grossmann. Improvements in the preparation and manufacture of hydrosulphurous acid and hydrosulphites. Complete Specification. August 23.

16,068. J. Grossmann. Improvements in the preparation and manufacture of hydrosulphurous acid and hydrosulphites. Complete Specification. August 23.

16,119. H. Drehschmidt. See Class II.

16,227. P. R. J. Krause. A new or improved process for the production of gas-formed hydrochloric acid by gas-formed nitric acid and chlorine. August 25.

16,258. H. H. Lake.—From J. H. C. Belinke and The Chemische Fabrik in Billwärd, vorm. Hell and Stäumer, A. G., Germany. Improvements relating to the manufacture of formates and of cyanides from the same. August 25.

16,320. E. Buckse. Process and apparatus for obtaining magnesium manganate and hydrochloric acid from the double chloride of manganese and magnesium, or for utilising certain residual liquors produced in the manufacture of chlorine. August 27.

16,342. G. B. Ellis.—From T. L. Willson, United States. See Class II.

16,529. G. Kraemer. Manufacture of potassium cyanide and yellow prussiate of potash from carbazol and its alkali compounds. August 30.

16,536. R. England. Improvements in or connected with the transport of sulphuric, hydrochloric, nitric, and other corrosive acids. August 30.

16,705. T. L. Willson. Improved metallic carbides and means for producing the same. September 1.

17,112. N. McCulloch. A new or improved method for oxidising the proto-salts of iron to the per-salts. September 8.

17,274. T. Craney. See Class I.

17,275. T. Craney. Improvements in salt evaporators. Complete Specification. September 11.

17,289. H. E. Newton.—From E. Hart, United States. Improved apparatus for the condensation of nitric acid and other vapours. Complete Specification. September 11.

17,556. J. Aseough. Improvements in the manufacture of sodium bichlorate or borax. Complete Specification. September 15.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

17,639 E. Dyson. Improvements in apparatus for concentrating sulphuric and other acids. September 19.

18,139. J. Reich. Improvements relating to the manufacture of alkaline carbonates and silicates. September 12.

18,786. J. B. Murray and M. B. Baird. An improved process for recovering alkali from a waste product. September 12.

20,104. C. T. J. Vantin. An improved process and means used therein for the production of caustic alkali. September 5.

20,604. D. A. Peniakoff. See Class X.

21,356. J. M. Milnes and A. Milnes. Improvements connected with apparatus for the manufacture of bleaching powder (chloride of lime) or similar commodities. September 19.

1894.

14,228. E. W. Enequist. Improvements in the process of manufacturing carbonic acid and in the production of by-products, such as sodium sulphate and magnesium sulphate. August 29.

15,473. F. L. Slocum and C. Y. Wheeler. Improvements in and relating to a process of making green oxide of chromium. Complete Specification. August 14.

#### VIII.—GLASS, POTTERY, AND EARTHENWARE.

##### APPLICATIONS.

15,607. R. C. Baker. Improvements in or relating to the manufacture of glass. August 16.

15,792. W. L. Pilkington. Improvements in the production of corrugated sheet glass, and in apparatus employed therein. August 20.

16,073. L. Böhm. Improvements relating to the decoration of glass. August 23.

17,096. P. Shelley. Improved material for sticking edges of pottery together during firing. September 8.

17,318. R. Stanley and G. Beck. Improvements in or relating to machinery employed in the manufacture of earthenware and like sanitary pipes. September 11.

17,366. Craven, Dunnill, and Co., Limd., and T. Pitt. Improvements in apparatus for the manufacture of tiles. Complete Specification. September 12.

17,579. T. Harvey. An improvement in the manufacture of flower pots and other decorative ornaments. September 15.

##### COMPLETE SPECIFICATIONS ACCEPTED.

1894.

9546. H. J. Haddan.—From The Columbian Pottery and Brick Kiln Co. Improvements in kilns. September 12.

9860. F. W. Golby.—From M. Hoffmann. A process for producing pressed glass plates for lining walls, ceilings, and for similar purposes. September 12.

14,938. W. Grane, sen. Improvements relating to the ornamentation of porcelain, glass, and the like. September 12.

#### IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

##### APPLICATIONS.

15,460. J. Sheppard and F. Dashwood. A combined fireproof floor and ceiling. August 14.

15,755. J. Elliott. A stone composition for repairing any natural stone and refacing cement floors, steps, &c., also for making imitation stone and bricks of any colour. August 18.

15,818. F. Young. Improvements in the manufacture of fireclay, refractory, and non conducting bricks and blocks, building bricks, or the like. August 26.

15,834. H. Wood. Improvements in the manufacture of bricks. August 20.

16,152. E. T. Hughes.—From J. Seipel, United States. Improvements in fireproof floor and ceiling constructions. August 24.

16,781. R. Haddan.—From J. Beauléquin, France. Improvements in the manufacture of material similar to mosaic. September 3.

16,875. W. West and O. V. Rhodes. A machine for forming rolls of stiff or plastic clay by means of a revolving and internally grooved or rifled cutter, which may be attached or affixed to a pug-mill or other clay-mixing machine. September 5.

17,059. J. H. Amies and J. U. Robertson. Improvements in pavements. Complete Specification. September 7.

17,208. F. H. Lenders.—From C. Bertin, Belgium. An improved composition forming a substitute for stone, marble, plaster, and the like. September 10.

17,221. J. Rueben. Improvements in or relating to fire-proof ceilings. Complete Specification. September 10.

17,486. J. Matthews. A composition for preserving wood, also applicable to other uses. Filed September 14. Date applied for 28th February 1894, being date of application in United States.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

19,939. A. Mack. Improvements relating to composite boards or slabs for building purposes. September 5.

22,227. M. Williams. Improvements in the manufacture of cement mortar. September 12.

1894.

3496. L. Tebbutt. New method of covering bricks, walls, and similar surfaces with a glazed or enamelled surface. September 19.

5626. T. L. Banks. Improvements in the construction of fireproof floors. August 29.

12,233. A. J. B. Ward. Non-slippery pavements, cellar covers, stair-treads, and the like. August 22.

14,599. E. Groebe. Improvements in the preservation of wood. September 5.

20,343. J. C. Montgomerie. Improvements in and in connection with the extraction of gold and silver from ores or compounds containing the same. September 5.

20,601. D. A. Periakoff. Improvements in the manufacture of alumina and aluminous compounds and metallic aluminium or alloys of aluminium, and obtaining chlorine, hydrochloric acid, carbonate of soda, and other by-products resulting from this manufacture. August 22.

20,684. E. Commelin. An improved furnace for roasting and smelting ores and reducing them to the metallic state. September 5.

22,397. B. Mierisch. Improvements in the extraction of gold and silver from ores or matte. September 19.

1894.

3224. J. M. While. Improvements in the manufacture of steel or iron plates and apparatus therefor. September 12.

11,447. J. J. W. Carr. Improvements in furnaces for melting, heating, or annealing metals, metallic alloys, and the like. September 12.

12,582. O. Klatte. New or improved process for producing rolled bars. August 29.

12,879. E. W. McKenna. Improved process for renewing old steel rails. September 5.

14,502. J. W. Dixon and W. Skinner. An improved metallic alloy. September 5.

### X.—METALLURGY, MINING, Etc.

#### APPLICATIONS.

15,761. R. Biewend. Process for treating sulphureous zinc ores in blast furnaces by the addition of ferri-ferrous substances. Complete Specification. August 18.

15,847. H. L. Sulman. Improvements in or relating to the precipitation of precious metals contained in solutions. August 20.

15,848. A. V. Newton.—From A. Nobel, France. Improved means for increasing the tenacity of metals. August 20.

15,891. R. A. Smith. A new metallic alloy. August 21.

16,041. W. K. Greenway. Improvements in the coating or galvanising of metals. August 23.

16,071. H. R. Angel. Improvements in the extraction of lead, silver, and gold contained in sulphide of zinc. August 23.

16,173. F. L. Lesage and A. F. Breuilland. Improvements in the method of and apparatus for obtaining metallic zinc from zinc ores. August 24.

16,557. W. P. Thompson.—From Stum Bros., Germany. Improvements in the manufacture of metal ingots. August 30.

16,785. W. Roberts. Improvements in utilising the bosh cinder produced in the puddling of iron, and in puddling and mill furnaces to be employed in utilising the said bosh cinder. September 3.

17,340. G. Love. Improved treatment of molten iron or steel. September 12.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

17,623. R. I. Roman. An improved solder for use with aluminium or aluminium alloys. August 22.

19,543. R. I. Roman. An improved aluminium alloy. September 5.

20,068. H. H. Lake.—From G. F. Simonds. Improvements in metallurgical furnaces. August 29.

### XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

#### APPLICATIONS.

15,712. D. B. Morison. Improvements in what are known as dry voltaic cells or batteries. August 17.

15,920. G. H. Reid. Improvements in and connected with primary batteries. August 21.

16,002. H. A. House, H. A. House, jun., and R. R. Symon. Improvements in apparatus for refining metal by electrolysis. Complete Specification. August 22.

16,100. H. Auer and F. Hunter. Improvements in apparatus for use in the electrolysis of alkaline chlorides and other alkaline salts. August 23.

16,105. R. Heathfield and W. S. Rawson. Improvements connected with the electrical deposition of zinc and other metals. August 23.

16,145. C. Hessel. Improvements in electrolytic processes and apparatus. August 24.

16,162. M. Engel. Improvements in accumulators or secondary batteries. August 24.

16,425. D. Young.—From The Hess Storage Battery Co., United States. Improvements in electric accumulators or storage batteries. Complete Specification. August 28.

16,686. C. Vogt. Improvements in the construction of galvanic cells. September 1.

16,696. H. Le Roy Bridgman. Improvements in or relating to electro-depositing apparatus. September 1.

16,697. H. Le Roy Bridgman. Improvements in or relating to electro-depositing apparatus and to products obtained thereby. September 1.

16,774. D. G. Fitz-Gerald. Improvements in the construction and working of voltaic batteries. September 3.

16,775. D. G. Fitz-Gerald. Improvements in voltaic batteries and electrolytic cells or tanks. September 3.

17,353. S. Miller and C. J. Grist. Improvements in charging primary batteries. September 12.

17,369. L. Epstein. An improvement in secondary voltaic batteries. September 12.

17,510. H. Le Roy Bridgman. Improvements in or relating to electro-depositing apparatus. September 14.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

16,307. J. Swinburne. Improvements in and connected with electric meters, for alternating currents. September 5.

17,466. W. Wright and J. B. Hamond. Improvements in the treatment of zinc produced by electrolysis. September 19.

19,688. J. C. Richardson. Improvements in safety appliances to be used in connection with electrical decomposing apparatus. August 29.

19,791. F. Hurter, H. Auer, and E. K. Muspratt. Improvements in or connected with electrolytic cells. August 29.

24,017. E. Stouls. Improvements in or relating to processes and apparatus for obtaining and depositing metals by electrolysis, and in the treatment of the metals after leaving the electrolytic bath. September 5.

1894.

9862. W. Morison. Improvements in portable primary batteries. September 12.

15,756. C. N. Waite. Improvements in or connected with electrolytic cells, and diaphragms therefor. September 5.

13,795. W. P. Thompson.—From C. M. Barber. Improvements in the process of electro-plating, and apparatus therefor. August 22.

14,642. V. I. Feeny.—From F. Dubero and P. Mohrdieck. Electrical battery. September 19.

15,276. M. Kiliani, W. Rathenau, C. Suter, and the Electrochemische Werke Gesellschaft mit Beschränkter Haftung. Improvements in or connected with diaphragms or electrolytic purposes. September 19.

## XII.—FATS, OILS, AND SOAP MANUFACTURE.

## APPLICATIONS.

15,780. G. Steeken. Improvements in the manufacture of soap. August 18.

16,040. S. Neumann. Improvements in or connected with the manufacture of fluorescent soaps. Complete Specification. August 23.

16,416. S. Rosenblum and F. L. Bartelt. Improvements in the treatment of vegetable, animal, and fish oils, fats, or grease. August 28.

16,417. S. Rosenblum and F. L. Bartelt. Improvements in the bleaching and refining of animal, vegetable, and fish oils, fats, and grease. August 28.

17,396. M. Evans. Improvement in bar soap. September 13.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

17,309. A. J. Inston. Improvements in recovering grease from waste suds which have been used in washing wool, hair, or other fibre. September 12.

19,475. J. P. F. Field. Improvements in soaps and washing compounds. August 22.

19,732. M. Baerlein. Improvements in the manufacture of soap compositions. August 29.

19,733. M. Baerlein and C. Dreyfus. A paste or mixture for cleansing various materials and articles. August 22.

1894.

1963. A. R. Scott. Improvements in the manufacture of cleansing soap powder for washing filcons and other materials. September 19.

13,672. E. Richard-Lagorie. Improvements in apparatus for extracting suint from wool and other substances. August 22.

14,821. W. O. Robbins. A new or improved apparatus for treating substances containing fats and oils. September 12.

## XIII.—PAINTS, PIGMENTS, VARNISHES, RESINS, INDIA-RUBBER, ETC.

## APPLICATIONS.

15,676. J. Tennant and A. Tennant. An improved composition paint. Complete Specification. August 17.

15,836. B. Angel and F. W. Lack. Improvements in paints and printing inks. August 20.

15,914. A. V. Newton.—From A. Nobel, France. An improved manufacture of artificial india-rubber, gutta-percha, and leather, suitable for conversion into varnish. August 21.

15,982. D. Williams. Improvements in or appertaining to a paint. August 22.

16,381. J. McLintock. Improved quick-drying anti-fouling paint. August 28.

16,664. R. Hutchinson. Improvements in treating bulky tree gum. September 1.

17,113. N. McCulloch. A new oil improved process for making red oxide of iron pigments from hydrated peroxide of iron. September 8.

17,145. W. B. Priest. Improvements in the manufacture of lead pigments or lead compounds for use as pigmentary materials. September 8.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

15,686. C. U. King and R. V. Jellicoe. An improved material or compound adapted for use as a varnish, as a substitute for india-rubber, gutta-percha, and like substances, and for other purposes, and the process for its production. August 22.

16,638. C. H. M. Lyte. An improved process for the production of iron oxide for use as a pigment. August 29.

16,800. T. W. Elliott. A new or improved composition for coating iron and steel. September 12.

17,159. W. V. Wilson and W. B. Priest. The manufacture or production of paints. September 12.

17,711. H. Mullerson. "Terpentine," a chemical preparation for cleaning and reviving all kinds of clothing. August 22.

19,163. L. Le Brocqy. A new substitute for india-rubber and gutta-percha. August 22.

19,284. M. Gerber. Improvements in devulcanising india-rubber and other like gums. August 22.

20,253. W. M. Walters and F. R. Stone. Improved preservative coating for iron and steel. September 5.

1894.

8112. C. W. Kriens. Improvements in the manufacture of animal charcoal. September 12.

## XIV.—TANNING, LEATHER, GLUE, AND SIZE.

## APPLICATIONS.

16,611. S. H. Epstein. Improvements in the treatment of fancy leather. August 31.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

14,491. E. S. Spencer. Improvements in the manufacture of gelatine. August 1.

15,937. H. H. Lake.—From G. Sachsenroder. Improvements relating to the manufacture of a substitute for leather. August 29.

16,783. J. D. de Joseph. Improvements in or connected with tanning hides and skins. September 12.

1894.

14,697. H. Hartmann. A new or improved process for the production from skins or hides of a substitute for whalebone, horn, or the like. September 12.

## XV.—AGRICULTURE AND MANURES, Etc.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

17,235. G. F. Redfern.—From J. Hensel and F. Spiethoff. Improvement in the manufacture of mineral manure. September 12.

19,255. J. Morten. The universal weed, seed, worm, grub, and insect destroyer and fertiliser. September 19.

22,559. J. Carter. Improvements in making manure from sewage precipitate, sediment, residue after filtration, or from liquid sewage. August 22.

## XVI.—SUGARS, STARCHES, GUMS, Etc.

## APPLICATIONS.

15,772. L. Fulda. Improvements in or connected with the manufacture of confectionery. August 18.

15,777. J. Y. Johnson.—From J. E. Pellegrini, Spain. Improvements in the manufacture of production of invert sugar or syrup. August 18.

15,976. P. S. Alexander. An improved process and machine for manufacturing confectionery. August 22.

16,235. A. Crerar.—From W. R. Boon and E. A. Hancock, West Indies. An improved process of and apparatus for evaporating or concentrating saccharine and other liquids. August 25.

16,759. C. M. Lafontaine. New treatment of raw sugars by sulphurous anhydrides and their derivatives by oxygenation for decolourating, purifying, whitening, and refining the crystallised mass by means of a special turbine, their direct agglomeration in parallelopipeds, slates, or equal cubes by a new machine for agglomerating sugar. September 3.

## COMPLETE SPECIFICATION ACCEPTED.

1893.

14,086. J. Y. Johnson.—From J. E. Pellegrini. Improvements in the manufacture of sugar and in the apparatus employed therein. September 19.

## XVII.—BREWING, WINES, SPIRITS, Etc.

## APPLICATIONS.

15,463. A. Bassett. Improved method of and apparatus for measuring or checking the production of alcoholic liquids, or the flow of liquids. August 14.

15,778. J. Y. Johnson.—From J. E. Pellegrini, Spain. Improvements in the manufacture or production of alcohol. August 18.

15,833. A. W. Billings. Improvements in the manufacture of beer. August 20.

16,704. G. C. Downing.—From L. Christ, France. A new and improved process and apparatus for extracting the saccharine juice from sugar-cane and bagasse. September 1.

17,143. T. D. Lichtenstein. The manufacture and production of a new material especially intended for use in the manufacture or treatment of beers, spirits, vinegar, aerated waters, and other beverages. September 8.

17,144. T. D. Lichtenstein. Improvements in the manufacture or treatment of beers, spirits, vinegar, aerated waters and other beverages. September 8.

17,277. J. Takamine. Improvements in diastatic enzyme taka-koji, diastase taka-koji ferment, and alcoholic ferment mash for developing active ferment cells. Complete Specification. September 11.

17,309. C. W. Ramstedt. A Pasteurising apparatus with rotating, heating and cooling elements. Complete Specification. Filed September 11. Date applied for 12 February 1894, being date of application in Sweden.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

19,549. F. N. Mackay. Improvements in and relating to brewing plant. August 22.

20,960. E. W. Greening and E. O. Greening. An improved method of utilising and means for treating yeast. September 19.

## XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

## APPLICATIONS.

## A.—Chemistry of Foods.

15,558. D. A. Sutherland. An improved process and means used therein to effect the preservation of perishable substances. August 15.

15,906. I. Gilson. A new alimentary product. August 21.

16,548. R. Haddan.—From Kathreiner's Malzkaffee-fabriken mit beschränkter Haftung, Germany. An improved process for producing substitutes for coffee. August 30.

16,998. T. O. Kent. An improved coffee extract. September 6.

17,251. J. A. Wilson. Improvements in methods of treating meat in the raw condition in order to arrest or retard decay. September 11.

17,463. D. Cook. Process for treating meat, game, fish, and the like. September 14.

17,548. J. Gray. Improvements in and relating to the treating and aerating of milk. September 15.

## B.—Sanitary Chemistry.

15,620. R. A. Chesebrough. Improvements in the method of cremating garbage and other refuse. Complete Specification. August 16.

16,724. E. W. Ives. Improvements in screening and mixing chambers for precipitating tanks and the like for treating sewage and other foul or waste waters. September 3.

17,254. R. Pickup. Utilization of waste products for purpose of purification of foul waters. September 11.

17,372. W. Lawrence. Improvements in treating, purifying, and sterilizing water or contaminated liquids, and in apparatus therefor. September 12.

### C.—Disinfectants.

15,805. P. Nussbaum. A new process of making combustible capsules for medical and disinfecting purposes. August 20.

16,161. Sir W. G. M. Call, Bart. Improvements in antiseptic compounds and in the application of the same for the preservation of perishable goods. August 24.

16,414. M. S. Sharp. Improved means for disinfecting or deodorising. August 28.

16,422. R. England. Improvements in or connected with the manufacture of disinfectants. August 28.

16,448. J. Taylor. An improved manufacture of insecticide material. August 29.

### COMPLETE SPECIFICATIONS ACCEPTED.

#### A.—Chemistry of Foods.

1893.

20,027. W. P. Thompson.—From C. Artus. Improvements in the treatment and preparation of butter, butter substitutes, margarine, and alimentary fats or compounds. August 29.

20,477. T. Block. Improvements in the composition and manufacture of chocolate. September 5.

24,970. M. Watson. Improvements in cereal leguminous or other vegetable foods. August 29.

#### B.—Sanitary Chemistry.

1893.

21,024. T. Twynam. Improvements in the utilisation of sewage sludge. September 12.

21,820. T. W. Baker. Cremating and destroying obnoxious gases from dust destructors, &c. September 19.

1894.

13,777. W. J. Pughley. Improved means of purifying the effluent waters of tin-plate works and the like. August 22.

#### C.—Disinfectants.

1893.

19,622. H. E. Newton.—From the Farbenfabriken vormals F. Bayer and Co. Improvements in the manufacture of antiseptics. August 22.

### XIX.—PAPER, PASTEBOARD, Etc.

#### APPLICATIONS.

15,718. H. H. Leigh.—From C. B. Schneider, Holland. An improved process to render paper, cellulose, textile, or any other material fireproof and non-inflammable. August 17.

16,612. P. C. Peebles. An improvement in the manufacture of paper. August 31.

### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

20,036. C. D. Ekman. Improvements in obtaining useful products from the liquors resulting from the manufacture of cellulose or fibres by the sulphite process. September 12.

20,043. E. G. Law. Improvements in and relating to continuous paper for writing and copying purposes. September 19.

20,144. M. Levy, A. Rustin, and L. Boyer. Improvements relating to the manufacture of artificial whalebone, and to apparatus therefor. September 19.

20,353. J. F. H. V. Hoop. Improved decorative paper. September 5.

### XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

#### APPLICATION.

15,168. A. Sommer. Solution of sweet carbamides in oils, fats, waxes, resins, and process of making the same. Complete Specification. August 14.

### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

22,114. J. C. W. F. Tiemann. A process for converting compounds of the citral series (geranium series) into isomers having a higher specific weight and a lower boiling point than the original bodies. August 22.

12,174. The Peptine Maltine Co., Lim., and G. Bartlett. Peptonised extract of malted and other cereals. September 12.

14,138. L. R. Seammell. An improved process for the extraction and estimation of encalyptol. September 12.

1894.

15,468. A. Sommer. Solution of sweet carbamides in oils, fats, waxes, resins, and process of making the same. August 11.

### XXI.—PHOTOGRAPHIC PROCESSES AND MATERIALS.

#### APPLICATIONS.

16,693. E. de Couinck. Improvements in the manufacture of dry coloured plaques for photography. September 1.

17,362. C. D. Durnford. Improvements in effecting photographic exposures. September 12.

### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

16,354. E. Albert. Improvements in the production of photographic negatives. August 29.

19,810. A. A. Barratt and A. J. F. Hill. A new or improved process for separating photographic gelatin films from celluloid supports or bases. September 12.

## XXII.—EXPLOSIVES, MATCHES, Etc.

## APPLICATIONS.

15,887. G. J. Baechert. Explosive compounds. Complete Specification. August 21.

15,977. R. W. Anderson. Igniting matches. August 22.

17,527. W. Hope. Improvements in sporting and other ammunition. September 14.

17,577. G. Trench. Improvements in blasting cartridges. September 15.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

20,327. A. Schindler. Improvements in the manufacture of gunpowder. August 29.

23,773. H. H. Lake.—From C. Pieper. Improvements in the manufacture of explosives. August 29.

1894.

9798. J. Hauff. Employment of trinitroresorcine as smokeless driving powder. September 5.

13,714. L. Jaroljmek. Improvements in or relating to the exploding of blast charges in mines. August 22.

14,068. R. Odeyn. A new or improved combustible composition. August 29.

## XXIV.—PATENT UNCLASSIFIABLE.

## COMPLETE SPECIFICATION ACCEPTED.

1893.

15,453. F. Chaplet. Manufacture or production of substances of extreme hardness. August 22.

# THE JOURNAL

OF THE

# Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 10.—Vol. XIII.]

OCTOBER 31, 1894.

[Non-Members 30/- per annum; Members  
21/- per Set of extra or back numbers;  
Single Copies (Members only) 2/6.]

## The Society of Chemical Industry.

### Past Presidents:

Sir H. E. Rosece, M.P., LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, Bart., D.C.L., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, Ph.D., F.R.S.	1884—1885.
E. K. Muspratt	1885—1886.
David Howard	1886—1887.
Prof. James Dewar, F.R.S.	1887—1888.
Ludwig Mond, F.R.S.	1888—1889.
Sir Lowthian Bell, Bart., F.R.S.	1889—1890.
E. Rider Cook	1890—1891.
Prof. J. Emerson Reynolds, M.D., D.Sc., F.R.S.	1891—1892.
Sir John Evans, K.C.B., F.R.S.	1892—1893.
E. C. C. Stanford	1893—1894.

## COUNCIL FOR YEAR ENDING JULY, 1895.

**President:** Prof. T. E. Thorpe, F.R.S.

### Vice-Presidents:

Sir F. A. Abel, Bart., F.R.S.	Sir John Evans, K.C.B., F.R.S.
Horace T. Brown, F.R.S.	E. K. Muspratt.
H. Brunner.	Dr. W. H. Perkin, F.R.S.
John Calderwood.	John Spiller.
Chas. Dreyfus.	E. C. C. Stanford.
Dr. A. Dupré, F.R.S.	Prof. W. A. Tilden, F.R.S.

### Ordinary Members of Council:

Frank Clowes, D.Sc.	Ivan Levinstein.
Thos. Fairley.	Manning Prentice.
C. A. Fawcitt.	G. N. Stoker.
Prof. G. G. Henderson, D.Sc.	Wm. Thorp, B.Sc.
David Howard.	T. Tyrer.
Prof. A. K. Huntington.	Frank Wilson.

With the Chairmen and Secretaries of Sections.

### Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

### Honorary Foreign Secretary:

Ludwig Mond, F.R.S.

**General Secretary:** Charles G. Cresswell.

**Offices:** Palace Chambers, 9, Bridge Street, Westminster, S.W.

### Editor:

Watson Smith, 34, Upper Park Road, Haverstock Hill, N.W.

### Assisted by the following Staff of Abstractors:

L. Archbutt, F.R.S.	XII., XVIII., B.	A. R. Ling, F.R.S.	IV., XVI., XVII.
D. Bendix	III.	F. Machenhauer	III., IV., VI.
Jos. Bernays, M.I.C.E.	I.	W. G. McMillan	X., XI., XIV., XXII.
Bertram Blount	IX., XI., XII., XIII.	W. Macnab	XXII.
Arthur G. Bloxam	XIV., XV.	N. H. J. Miller, Ph.D.	XV.
E. R. Bindstone	II., III., B.A.	Herbert Morris	VII., XIII.
R. B. Brown	V., VI.	H. S. Pattinson, Ph.D.	VII., X.
J. C. Chorley	I., XIX., XXI.	H. T. Penter	XVI., XVII.
E. G. Coker, B.Sc.	I.	mann	XVI., XVII.
J. H. Collins	X.	R. B. Pollitt	I., II., XXII.
V. Cornish	VIII., IX., XIII.	J. C. Richardson	XI.
C. F. Cross	V., XII., XIX.	F. W. Renault	Patent Lists.
W. P. Dwyer	VI.	H. Schlichter, Ph.D.	V., XV., XXI.
J. T. Dunn, D.Sc.	VII., X., XI.	J. Shields, D.Sc.	Gen. Chem.
S. P. Eastick	I., III., XI., XIX.	E. Sonstadt	III., VII., X.
T. A. Glendinning	XVII.	Eustace Thomas	XI.
Prof. D. H. Jones, B.Sc.	XI.	L. T. Thorne	II., III., XVII.
W. E. Kay	VI.	H. K. Tompkins, B.Sc.	X.
J. J. Knight	VI., VII., XII., XV.	V. H. Veley, M.A.	Gen. Chem.
Chas. A. Kohn	Gen. Chem.	Prof. Jas. Walker	D.Sc., Ph.D. Gen. Chem.
L. de Koninck	XVIII., XXII.	C. Otto Weber, Ph.D.	IV., XIII.
T. A. Lawson, Ph.D.	IV., XX.	J. G. Wells	XVII., XX.
F. H. Leeds	III., XIII., XXI.	A. Wingham	X.
J. Lewkowitsch	III., XII.		

## THE JOURNAL.

### Publication Committee:

#### The President.

A. H. Allen.	C. Clarke Hutchinson.
G. H. Bailey, D.Sc., Ph.D.	Wm. Kellner, Ph.D.
Joseph Bernays, M.I.C.E.	J. Lewkowitsch, Ph.D.
Horace T. Brown, F.R.S.	W. G. McMillan.
H. Brunner.	Ludwig Mond, F.R.S.
E. Rider Cook.	B. E. R. Newlands.
W. Y. Dent.	John Pattinson.
Chas. Dreyfus, Ph.D.	W. H. Perkin, Ph.D., F.R.S.
Sir John Evans, K.C.B., F.R.S.	H. R. Procter.
Percy Gilchrist, F.R.S.	Boverton Redwood.
John Heron.	Walter F. Reid.
D. B. Hewitt, M.D.	John Spiller.
David Howard.	Wm. Thorp.
Prof. J. J. Hummel.	Thomas Tyrer.
Prof. A. K. Huntington.	Lewis T. Wright.
F. Hurter, Ph.D.	

## NOTICES.

Notice is hereby given that, in accordance with the alterations in Rule 27 sanctioned at the Annual General Meeting in Edinburgh, all new members elected after January 1st next, and also those elected after the date of this notice who do not pay subscription for 1894, will be required to pay an entrance fee of one guinea. In accordance with the same rule the Life Composition Fee will be 20/-, instead of 15/- as heretofore, after the 1st January next.

## BANKERS' ORDERS.

To the convenience of Members, the Treasurer has arranged for the Bankers of the Society that they shall collect subscriptions from Bankers in town and country; and Members, who have not already done so, are invited to fill up and sign the Banker's Order enclosed with the December number of the Journal, which should then be sent to the Honorary Treasurer, Mr. E. Rider Cook, East London Soap Works, Bow, E.

Authors of communications read before the Society, or any of its Local Sections, are requested to take notice that under Rule 41 of the bye-laws, the Society has the right of priority of publication for three months of all such papers. Infringement of this bye-law renders papers liable to be rejected by the Publication Committee, or ordered to be abstracted for the Journal, in which case no reprints can be furnished to the author.

Notice is hereby given, for the information of members and advertisers, that the advertisement columns of this Journal have been contracted for by Messrs. EYRE and SPORRISWOOD, the Society's printers and publishers, to whom all communications respecting them should be addressed.

Notice is hereby given that the next List of Members will contain the professions or business occupations of the Members of the Society. Any Member who desires to confirm or alter his description as given before election should communicate with the General Secretary.

Foreign and Colonial Members are reminded that the subscription of 25s. for 1895, payable on January 1st next, should be sent in good time to the Treasurer, in order to ensure continuity in the receipt of the Society's Journal. Any changes of address to appear in the new List of Members now in course of preparation, should reach the General Secretary not later than January 15th, 1895.

## LIST OF MEMBERS ELECTED 23rd OCTOBER 1894.

Abbott, Cecil W., 6, Chichester Terrace, Brighton, chemical student.

Abbott, Fred. L., 6, Chichester Terrace, Brighton, chemical student.

Augell, Arthur, Shirley, Southampton, analytical chemist.

Aseough, Jesse, The Grange, Laurel Road, Handsworth, Birmingham, borax manufacturer.

Bamber, H. K. G., Portland Cement Works, Dovecourt, Harwich, Essex, chemist and manager.

Biekes, Theodor, 309, Manhattan Avenue, Brooklyn, N.Y., U.S.A., chemist.

Cousins, W. J., 11 and 12, Southampton Buildings, Canncery Lane, W.C., consulting chemist and managing director.

Crossley, Atkinson, The Scarlet Ferric Oxide Co., Talywain, near Pontypool, chemist.

Crow, Henry W., Abbey Creek Wharf, West Ham, E., tar distiller.

Dawson, Jas., 27, St. Vincent Place, Glasgow, drysalter.

Glen, Chas., Glengowan Printworks, Caldercruix, via Airdrie, N.B., calico printer.

Harrison, J. Arnold, 4, Ryverdale Road, Stoke Newington, N., chemical manufacturer.

Hatfield, Jno. A., 89, Bridge Street, Wednesbury, Staffordshire, analytical chemist.

Hodge, Andrew, Dalmonach Printworks, Alexandria, N.B., chemist.

Jameson, A. H., Cleveland Linseed Oil Co., South Chicago, Ill., U.S.A., chemist.

Leslie, H. Mackenzie, c/o Mysore G.M. Co. Ltd., Oorgaum, Mysore, South India, chemical engineer.

Lloyd, Harold T., 1, Hermon Hill, Snaresbrook, N.E., analytical chemist.

Lungwitz, Theo., c/o Pfizer and Co., 81, Maiden Lane, New York City, U.S.A., superintending chemist.

Mabey, Fred. O., 193, Amhurst Road, Hackney, N.E., wine merchant.

Mackay, Geo. A. D., 1, Parliament Square, Edinburgh, sanitary inspector.

Mills, Chas., 21, St. Mary Abbots Terrace, Kensington, W., chemist (colour works).

Muir-Smith, W., Carolina Port, Dundee, manager (Dundee Oil Works).

Nason, Carleton W., 71, Beckman Street, New York City, U.S.A., mechanical engineer.

Packer, Thos. J., Bayonne, N.J., U.S.A., chemical works manager.

Paul, Dr. Benjamin H., 20, Victoria Street, Westminster, S.W., consulting and analytical chemist.

Pilling, John E., 28, Agnew Villas, Whitegate Lane, Blackpool, chemist.

Price, Raymond B., c/o Boston Woven Hose and Rubber Co., Cambridgeport, Mass., U.S.A., chemical engineer.

Proude, Jas., 13, Oak Terrace, Halifax, Yorks, soap works chemist and manager.

Ridding, Howard C., 20, Algernon Road, Birmingham, (A.R.S.M.), analytical chemist.

Robertson, Alex., Argyle Chemical Works, Oban, N.B., manufacturing chemist.

Rowe, G. Vanner, 11, The Green, Stratford, E., chemist.

Russell, Oliver F., 54, St. Germain's Road, Forest Hill, S.E., analytical chemist.

Salter, Chas. T. C., 84, St. Paul's Road, Camden Square, N.W., scientific journalist.

Sandys, Hon. Michael, Pyrford Place, Ripley, Surrey, stockbroker.

Settle, Wm., 57, Bradford Street, Haulgh, Bolton, mining engineer.

Spence, J. Napier, Heathfield, Harrow-on-the-Hill, teacher of chemistry.

Towner, Rev. Geo., Carpenters' Company's Institute, Stratford, E., head master of Organised Science School.

Walker, Dr. Jas., University College, Dundee, professor of chemistry.

Wanklyn, Jas. Alfred, New Malden, Surrey, professor of chemistry.

Wells, Pierson L., 86, Joralemon Street, Brooklyn, N.Y., U.S.A., patent lawyer, M.E.

White, Arthur J., Ariston Gold Mine, Klerksdorp, South Africa, assayer.

Willidigg, A. E., Ford Cottage, Coventry, varnish maker.

Williamson, J. Alex., c/o Millom and Askam Hematite Iron Co., Askam-in-Furness, Lancashire, analytical chemist.

## CHANGES OF ADDRESS.

Baister, Howard C., l/o Liverpool; Elmhurst, Blundell-sands, near Liverpool.

Barrett, A., l/o Alabama; Bronheulog, Glandydon, Mostyn, North Wales.

Brookes, E. A., l/o Claremont Grove; 31, Bamford Street, Didsbury, Manchester.

Buchanan, Joshua, l/o Krugersdorp; United Langlaagte G. M. Co., Box 1018, Johannesburg, S.A.R.

Caldecott, W. A., l/o Eureka City; Barberton, S.A.R.

Conrad, E. C., l/o Gravesend; 1, Sunnyhill Terrace, Lowestoft Road, Gorleston.

Croft, A., l/o West Bridgeford; 55, Beeston Road, Old Lenton, Nottingham.

Dawson, W. Haywood; Journals to 135, Herbert Road, Woolwich.

Dixon, W. Hepworth, l/o Bow; Wingfield, Waustead, E.

Doolittle, O. S., l/o Franklin Street; 130, North 5th Street, Reading, Pa., U.S.A.

Duncan, Jas., l/o Dalbeattie; 9, Mincing Lane, London, E.C.

Edwards, H. W., l/o Canada; c/o Copper Queen Consolidated Mining Co., Bisbee, Arizona, U.S.A.

Forrester, Jas., l/o Finchley; 73, Ridge Road, Stroud Green, N.

Freeman, And., l/o 111; 98, Needham Road, Edgchill, Liverpool.

Fuerst, Dr. A. F., l/o Belsize Park; c/o Wood Street Smelting Works, 30, Wood Street, London, E.C.

Fulton, R., jun., l/o Saltecoats; Ardeer Factory, Stevenston, Ayrshire, N.B.

Gamble, W., l/o St. Helens; Briars Hey, Rainhill, near Liverpool.

Green, A. G., l/o Clapton; 13, King's Drive, Heaton Moor, near Stockport.

Hendrick, Jas., l/o Young Laboratory; Agricultural Department, 60, John Street, Glasgow.

Holmes, F. G., l/o New Cross; 1, Grange Avenue, Chapeltown Road, Leeds.

Johnson, E. C., l/o Alexandra Park; 422, Stretford Road, Old Trafford, Manchester.

Joy, Douglas G., l/o Brongh; Sealcoats Oil Mill, Hull.

King, W. Grant, l/o Ithaca; The Selvay Process Co., Syracuse, N.Y., U.S.A.

Knecht, Dr. E., l/o Moss Lane East; Station Road, Crumpsall, Manchester.

Liddle, G. A., l/o Carr Bank; 313, Derby Place, Walmersley Road, Bury, Lancashire.

Louis, H., l/o London; c/o Iberian Ore Co., Ltd., El Pedroso, Seville, Spain.

Lunn, C., l/o Liverpool; Woodsome Lees, Kirkburton, near Huddersfield.

Mann, H. H., l/o Paris; 7, Minster Yard, York.

Martyn, Wm.; Journals to Afton House, Hebburn-on-Tyne.

Mellon, W. W., l/o Howden; 16, Sandymount Road, Dublin.

Moffat, Alex., l/o Linlithgow; 104, Bothwell Street, Glasgow.

Nicol, Dr. W. W. J., l/o Birmingham; 15, Blacket Place, Edinburgh.

Parker, Thos., l/o Newbridge; Manor House, Tottenhall, Wolverhampton.

Phillips, A., l/o Barnes; Heriot Watt College, Edinburgh.

Pope, Frank, l/o Pearl Street; 31, Lawrence Street, Cambridgeport, Mass., U.S.A.

Radmacher, H. A.; Journals to Goddard House, East Walpole, Mass., U.S.A.

Rindoul, Wm., l/o Greenwich; Royal Compository, Waltham Abbey, Essex.

Rowell, W. A., l/o Hedworth; retain all communications until further notice.

Soyers, Jos.; Journals to Mayville, Stevenston, Ayrshire, N.B.

Schad, J., l/o Cooper Street; York Buildings, 33, Mosley Street, Manchester.

Schlichter, H. C., l/o Leipzig; Royal Ordnance Survey Department, Bangkok, Siam.

Sindall, R. W., l/o Station Street; "Daily Chronicle" Paper Mills, Sittingbourne, Kent.

Society of Public Analysts; Journals to Dr. Sykes, 59, Friends Road, Croydon.

Starling, J. H., l/o Belvidere; 32, Craven Street, Strand, W.C.

Tweedie, G. R., l/o Sturry; 3, Granville Terrace, East Cliff, Ramsgate.

Warne, Thos., l/o Lostock Gralam; 26, Bridge Street, Wodnesbury, Staffordshire.

Waterhouse, Robt., l/o Sheffield; 101, Leadenhall Street, London, E.C.

Weed, H. T., l/o Allegheny; 298, Herkimer Street, Brooklyn, N.Y., U.S.A.

Wild, W. E., l/o Cheetham Hill; Ousel Nest Cottage, Bromley Cross, near Bolton.

Wilson, Cecil H., l/o Grimssthorpe Road; 31, Miln Road, Burngreave Road, Sheffield.

Wright, L. T., l/o Hazlitt Road; 1, Victoria Street, Westminster, S.W.

Wuth, Dr. A., l/o Wiesbaden; 3, Hohenstrasse, Stuttgart, Germany.

Wyle, J. R., l/o Prescot; Hill House, Wavertree, near Liverpool.

## Deaths.

Pinkney, Robt., 18, Bread Street Hill, E.C. Sept. 29th.

Topley, Wm., F.R.S., Geological Survey Office, 23, Jernyn Street, London, S.W.

## London Section.

THE CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE, W.

*Chairman:* B. E. R. Newlands.

*Vice-Chairman:* C. C. Hutchinson.

*Committee:*

E. J. Bevan.	S. Rideal.
W. G. Blazden.	A. Gordon Salamon.
E. Grant Herper.	A. Shearer.
T. A. Lawson.	Wm. Thorp.
R. Messel.	T. Tyrer.
H. de Meuthal.	Frank Wilson.
E. O'Neil.	

*Hon. Local Secretary:* John Heron,  
74, North Side, Clapham Common, S.W.

### SESSION 1894-95.

Monday, November 5th:—

The late Dr. C. R. Alder Wright, F.R.S. The Paper to be read by Mr. Watson Smith, F.I.C., F.C.S. "The Composition and Constitution of Certain Alloys."

Mr. F. W. Read, F.I.C., F.C.S. "Note on the Oxidation of Lensed Oil."

Monday, December 3rd:—

Dr. Kuhn of Paris. "The Sterilisation of Water."

Dr. D. H. Atfield, M.A., Ph.D. "An Investigation of the Natural Sodium Sulphate Lakes of Wyoming, U.S.A."

## Liverpool Section.

UNIVERSITY COLLEGE, BROWNLOW STREET.

*Chairman:* E. Carey.

*Vice-Chairman:* H. Brunner.

*Committee:*

J. Campbell Brown.	G. Schack-Sommer.
Jos. C. Gamble.	E. Scott.
C. L. Higgins.	A. Smetham.
C. A. Kohn.	Frank Tate.
E. K. Muspratt.	H. Tate, jun.
W. Norris Jones.	

*Hon. Treasurer:* W. P. Thompson.

*Hon. Local Secretary:*

Dr. Lewis Bailey, University College, Liverpool.

### SESSION 1894-95.

November 7th.—Chairman's Address. "The Invasion of the Inventor."

December 5th.—Mr. Eric E. Watson. "The Calculation and Composition of Blast-Furnace Charges, as applied to the Smelting of Lead and Silver Ores."

## Newcastle Section.

*Chairman:* G. T. France.

*Vice-Chairman:* Alf. Allhusen.

*Committee:*

P. P. Bedson.	B. S. Proctor.
T. W. Hogg.	W. W. Proctor.
T. W. Lovibond.	W. L. Reimoldson.
W. Martyn.	W. A. Rowell.
John Morrison.	T. W. Stuart.
John Pattison.	John Watson.

*Hon. Local Secretary and Treasurer:*

Samuel Shaw, Durham College of Science, Newcastle-on-Tyne.

### SESSION 1894-95.

Thursday, November 8th.—Dr. G. Lunze. "Practical Results of the Lunze-Rohrmann Plate-Towers for Condensing Hydrochloric Acid."

## Scottish Section.

*Chairman:* Robt. Irvine.

*Vice-Chairman:* J. Clark.

*Committee:*

G. Beilby.	J. S. Macarthur.
R. Cox.	E. Ostlere.
C. J. Ellis.	T. L. Patterson.
C. A. Fawsitt.	R. Pullar.
D. Harris.	J. B. Readman.
G. G. Henderson.	H. Rose.
R. A. Inglis.	E. C. C. Stanford.
W. I. Macadam.	D. R. Stewart.

*Hon. Secretary and Treasurer:*

J. Stanley Muir, Chemical Laboratory, University of Glasgow.

### SESSION 1894-95.

*Dates of Meetings.*

Glasgow.—Philosophical Society's Room, 267, Bath Street. November 6th; January 8th; March 5th; May 7th.

Edinburgh.—Philosophical Institution, 4, Queen Street. December 8th; February 5th; April 2nd.

November 6th.—Glasgow. Chairman's Address. "Shale Distillation and the Purification of the Products therefrom."

## New York Section.

*Chairman:* Alfred H. Mason.

*Vice-Chairman:* Arthur McGeorge.

*Committee:*

G. T. Bruckmann.	E. G. Love.
T. Lynton Briggs.	John McKesson.
H. Comer.	W. H. Nichols.
H. Endemann.	Francis J. Schleicher.
Jos. D. Geisler.	Jas. H. Stebbins, jun.
Jas. Hartford.	T. B. Stillman.

*Hon. Treasurer:* R. C. Woodcock.

*Hon. Local Secretary:*

Dr. H. Schweitzer, 159, Front Street, New York, U.S.A.

Notices of Papers and Communications for the Meetings should be sent to the Hon. Local Secretary.

## I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

*The Standard Wire Gauge.* Chem. Trade J., 15, 1894, 239.

THE following table constitutes the only legal wire gauge in the United Kingdom. A "Mil." equals the one-thousandth part of an inch. For convenience of comparison the equivalent in millimetres is also given.

No.	Mils.	M.M.	No.	Mils.	M.M.
0,000,000	500	12.70	10	128	3.25
000,000	464	11.78	11	116	2.95
00,000	432	10.97	12	104	2.64
0,000	401	10.16	13	92	2.34
000	372	9.45	14	80	2.03
00	348	8.84	15	72	1.83
0	324	8.23	16	64	1.63
1	300	7.62	17	56	1.42
2	276	7.01	18	48	1.22
3	252	6.40	19	40	1.016
4	232	5.80	20	36	.914
5	212	5.33	21	32	.813
6	192	4.88	22	28	.711
7	176	4.47	23	24	.610
8	160	4.06	24	22	.559
9	144	3.66	25	20	.508

\* Any of these specifications may be obtained by post by remitting 8d.—the price now fixed for all specifications, postage included—to Sir Henry Reader Lack, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C.

N	M	M.M.	No.	M	M.M.

### PATENTS.

*An Improved Apparatus for Use in Measuring the Pressure of Gas in Guns.* A. Castenholz, Karlsruhe, Germany. Eng. Pat. 11,991, August 1, 1893.

THE invention relates to apparatus for use in measuring the pressure of gas which in the combustion of a certain quantity of powder or other explosive material, is produced in guns. An improved apparatus is described for measuring the gas pressure for small arms and cannon, characterised by a cartridge case without a base, a sleeve having the same bore and fitted gas tight, and a pressing stamp or plug adapted to move axially therein and provided with a central firing device, which said stamp or plug forced back by the explosive gases upsets or "jumps" a cylinder, the amount of upset being proportional to the pressure. A modification of the above is also claimed.—J. C. C.

*Improvements in Filter Presses.* J. Critchlow, Stoke-on-Trent. Eng. Pat. 17,024, September 11, 1893.

THE inventor proposes to provide the supporting arms of each movable plate of a filter press with rollers, running upon the side frames of the press. Also to fit to each plate similar rollers bearing horizontally against the frames. The object of the invention is to facilitate the manipulation of the press plates.—B.

*Improvements relating to Metallic Tubes used for Heating Liquids.* H. and A. J. Goldthorpe, both of Wakefield. Eng. Pat. 20,362, October 28, 1893.

TO prevent the wearing away of the apertures made for the escape of steam, in tubes used for boiling and heating, a stout nipple is screwed into the aperture. The nipple may be straight or conical, and pierced with one or more holes for the escape of steam.—E. G. C.

*Improvements in and connected with Charging Vessels with Volatile Liquids or other Substances and Hermetically Sealing the same.* J. Macrae and J. Dickson, both of London. Eng. Pat. 20,697, November 1, 1893.

A RESERVOIR containing the volatile liquid has a tubular outlet below, furnished with a nozzle connected thereto by a flexible tube, which latter can be closed by a spring clip; a movable plug regulates the supply of air and consequently the flow of liquid from the reservoir into the receiving tubes. The narrow necks of the charged tubes, which are of glass, are afterwards made red hot by means of a blow pipe and pinched together by tongs or nippers, thereby hermetically sealing the tubes; as a further precaution the closed neck is dipped in liquid gutta-percha or shellac. A

of test-tube stand is provided for holding the tubes. To facilitate the operation of sealing the tubes, the glass of which they are formed should be soft.

*Filtering Apparatus.* L. H. Bristowe, London. Eng. Pat. 20,797, November 2, 1893.

The invention relates to filtering apparatus in which the liquid to be filtered passes through radial arms perforated along one side and radiating from a central hub or hollow shaft through which the liquid enters. In the usual arrangement before the liquid can reach the outer end of the radial arm, a good deal of the working pressure is lost through part of the liquid escaping by the perforations near the central hub, to avoid which the inventor divides the arm into two compartments by means of a central longitudinal division reaching to within a short distance of the outer end. The liquid passing outwards by the unperforated compartment, arrives at the outer end of the arm before encountering any perforations, and thence travelling towards through the perforated part, is more efficiently distributed over the filtering medium.—B.

*Improvements in Acid Raisers or Steam Jet-Pumps for Raising Acids, Alkalies, and other Liquids.* C. Long, Walsall, and W. H. Burkitt, Wednesbury. Eng. Pat. 5187, March 13, 1894.

THE main object of the invention is to construct pumping apparatus having easily removable parts, especially the steam-jet, which is liable to become worn, and, by admitting too much steam, to occasion needless dilution of the liquid.

Fig. 2.

Fig. 1.

IMPROVED ACID RAISER OR STEAM-JET PUMP.

In the drawing, Fig. 1 shows the pump, consisting of a "globe-shaped" case A, reduced at the ends, with flanges B, and two flat sides C, on one of which is a branch D for reception of the steam-jet pipe E, made square or oblong

that it may not get out of position, and having a raised boss G when made for acids; H and h are flanges. A cup or rest K is provided for the jet pipe, which is thus relieved of strain.

To renew the acid raiser, the jet pipe is taken out, and the jet hole e is filled up with suitable metal by a flame. The jet pipe is then replaced, and the delivery nozzle F is removed, and the guide bush f (Fig. 2) is inserted; then by means of a turned drill b, the drill is shouldered down d so as to drill a jet hole of the desired diameter through the tused-in metal. The jet hole is thus renewed and brought into perfect line. When the apparatus is used for alkalis, a new jet hole may be drilled as described, or a new jet may be screwed into the jet pipe.—E. S.

*Improvements in Condensing Plates.* J. W. Mackenzie, London. From Brante and Company, Lyons, France. Eng. Pat. 7229, April 11, 1894.

IN condensing sulphuric, nitric, hydrochloric, and acetic acids, or other products requiring large condensing surfaces, plates about 32 cm. long and 10 cm. in width and thickness are used. The plates are provided with projections, funnel-shaped openings, channels, and bores of various shapes, of which designs are shown; and the material is such as may resist the action of the substances to which they are exposed. It is stated that by a combination of such plates "all the conditions required from the Glover's and Gay-Lussac towers and from lead chambers are attained."—E. S.

*Improvements in and relating to Tubes employed for Heating, Vaporising, Refrigerating, and other Purposes.* A. Dumas, Brévannes, France. Eng. Pat. 8320, April 26, 1894.

WITHIN tubes used for heating, vaporising, and refrigerating, are placed flat, curved, or spiral wings for the purpose of giving more exposed surface and thereby increasing the efficiency of the tubes for the purposes for which they are employed.—E. G. C.

*Improvements in Steam Superheaters.* J. Grouvelle and H. Arquembourg, Paris. Eng. Pat. 13,586, July 13, 1894.

THIS invention relates to the coils of tubular zig-zag superheaters, disposed in two or more series, and so arranged as to expose those tubes which first receive the moist steam to the greatest heat in the flues. Part of the invention also refers to the device for connecting the tube ends to the steam-collectors, as indicated by the accompanying cross-section, in which a represents the section of the collecting

IMPROVEMENTS IN STEAM SUPERHEATERS.

vessel. Each tube-end a<sup>1</sup> is screwed into a conical plug a<sup>2</sup>, tightly driven into a corresponding hole in the collecting vessel. The plug has also a screw-thread at its inner end, admitting of the use of a tool for screwing the plug to the tube-end, and of the subsequent insertion of an auxiliary plug a<sup>3</sup>, whose centre is pierced with an opening of a size to determine the quantity of steam passing through the tube. A removable cap a<sup>4</sup> is fitted to the collecting vessel opposite each tube-end, as shown.—B.

*Improved Apparatus for Raising, Forcing, and Circulating Semi-Liquid and Liquid Substances.* J. Taylor, Wandsworth Common, Surrey. Eng. Pat. 13,709, July 16, 1894.

The apparatus is intended principally for dealing with semi-liquid substances, such as paper-pulp, sewage, and the like, for which ordinary pumping apparatus is unsuitable, and it consists of a modified form of centrifugal pump, with an axial inlet and tangential outflow. The vanes of the pump-wheel are spiral, and curved to a D shape in cross-section; and suitable scrapers are inserted through the casing, to clear the vanes from adherent matter. The apparatus is mounted upon a bed-plate, and the vane-wheel shaft, carrying fast and loose pulleys for driving, is supported upon suitable bearings.—E. G. C.

## II.—FUEL, GAS, AND LIGHT.

*Heating Power of Smoke.* R. R. Tatlock. Chem. News, 70, 1894, 51.

It appears to be generally imagined that a large percentage of fuel is lost in the smoke which issues so abundantly from most chimneys. A little consideration, however, will show that the loss of any large percentage of combustible matter, and consequently of heating power, is quite out of the question. This may be proved in two ways—(1) by calculation of the two sources of heating-power as shown by an analysis of coal or dross used for steam-raising, and (2) by actual analysis of the furnace gases for combustible solids and gases.

In the following paper are given the results of these two methods of observation, the same dross being analysed and also employed as fuel in a works furnace, from which smoky gases were given off which were tested for combustible matters.

1. The following is the analysis of the dross employed:—

	Per Cent.
Gas, tar, &c. ....	37.63
Fixed carbon.....	49.97
Sulphur.....	0.40
Ash.....	2.72
Water.....	9.28
	100.00
Heating-power (practical) due to gas, tar, &c.....	1.16
Heating-power (practical) due to fixed carbon ..	6.49
	7.65

The points to be observed are the relative proportions of heating-power (represented in the analysis by the number of pounds of water at 212° F. capable of being evaporated by 1 lb. of the fuel) given out respectively by the combustion of gas, tar, &c., and by the fixed carbon. These are calculated according to Playfair's well-known formula, which was practically tested on coals intended for the British navy, and which shows that while 1 lb. of fixed carbon is capable when burned of evaporating 13 lb. of water at 212° F. to dryness, 1 lb. of the gas, tar, &c., will only evaporate 3.1 lb. From these figures it appears that in the coal or dross the gas, tar, &c., only contribute 15 per cent. of the total heat given out during the combustion, and that the fixed carbon produces the remainder, or 85 per cent. In coals with less of the former ingredients and more of the latter, which is commonly the case, the proportion given out by the volatile constituents would be considerably reduced. It is thus perfectly clear that even though the whole of the volatile matters (which can alone be accountable for any loss of combustible material) escaped combustion, there could not possibly be a greater loss of heat than 15 per cent. of the whole, even in such an extreme case as this represents.

2. An analysis was made of the furnace gases given off during the burning of the dross, of which the results are given above, with the following results:—

	Grains per 100 Cubic Feet of Smoke.	Grains per 100 Cubic Feet of Furnace Gases.
	Per Cent. by Volume.	Per Cent. by Volume.
Carbonic acid.....	5.90	3.75
Carbonic oxide.....	None	None
Hydrocarbons.....	Trace	None
Nitrogen.....	77.9	79.9
Oxygen.....	15.1	14.9
	100.00	100.00

It has been asserted that carbonic oxide is given off in considerable quantity when much smoke is being produced, but it does not appear in this case; and Hempel, in his work on "Gas Analysis," comes to the conclusion that little or no combustible gases are present in furnace gases. In the volume referred to (page 205) Hempel says "furnace gases usually contain only carbon dioxide, oxygen, and nitrogen. All other gases are present in but very small amounts. In oft-repeated analysis the author has always found only traces of carbon monoxide, methane, and the heavy hydrocarbons."

That there is loss of combustible matter in the smoke is an undoubted fact, but the quantity seems also to be greatly magnified in certain random statements. In the experiment referred to above, the soot was also collected during one hour and a half with following results:—

	Grains per 100 Cubic Feet of Furnace Gases.
Carbonaceous matter .....	3.481
Ash or mineral matter .....	20.65
Total soot.....	24.13

It will be observed that the soot collected, consisted largely of mineral or incombustible matter. In several experiments to estimate the soot in furnace gases similar results to these were obtained, and the average would come very close to the quoted results of this special test.

To find how much carbonaceous matter was actually lost as smoke, it will be necessary to know the number of cubic feet of furnace gases given off by the combustion of, say, 1 ton of the dross. If the percentage of carbonic acid in the furnace gases is taken at 5 per cent., the total volume of these given off from 1 ton of dross would be about 940,000 cubic feet measured at the ordinary temperature and pressure, and this would contain 41 lb. of carbonaceous matter and 27 lb. of mineral matter. This would represent 1.83 per cent. of the volatile matters (gas, tar, &c.) given in the analysis of the dross; and if from this is now calculated the heating-power according to Playfair's formula, it will only come to 0.057. This figure, compared with the practical heating-power (7.65) of the dross, goes to show that the solid combustible matter of the smoke can only account for the very small percentage of 0.74 of the total heating power which can be obtained from the coal.

From the results of these experiments it is evident that the loss of combustible matters in smoke is very small indeed. In adopting methods of removing the smoke nuisance, it must therefore be borne in mind that there is little or no gain in burning smoke, and that other methods of dealing with the problem, such as Dalser's smoke absorption process, ought also to receive consideration.

*The Holden Liquid Fuel Burner.* Eng. and Mining J.  
1894, 101.

The accompanying drawings illustrate an apparatus and system for using liquid fuel which was devised by Mr. W. F. Holden, locomotive superintendent of the Great Eastern Railway, and which has been very successfully used there and elsewhere. Elevations and sections of the burner are shown and also its application to a boiler of the locomotive

type. It can, of course, be used with other types of boilers, with modifications in the arrangement which will readily suggest themselves.

By this system liquid fuel and air are introduced into the firebox above a thin layer of solid incandescent fuel by means of a special injector, and burnt in combination with the solid fuel, without any alteration of the firebox other than the insertion of one or more tubes through the casings,

HOLDEN'S LIQUID FUEL BURNER.

the boiler so fitted being equally suitable for the use of ordinary fuel. The use of this method results, it is claimed, in effectual combustion, entire absence of smoke, intense and regular heat, and great economy of fuel. Slack, inferior coal, lignite, cinders, wood, peat, or sawdust may with equally good results be used as solid fuel. As the air necessary for combustion need not be introduced through the fire, a very small amount of draught is required, and in the case of locomotives the orifice of the blast pipe may advantageously be enlarged from 50 to 60 per cent., reducing the wear and tear of the firebox, tubes, smokebox, and chimney, preventing the emission of sparks and ashes, and diminishing back pressure. The steam pressure in a boiler fitted with the apparatus can be regulated with great nicety, as the solid fuel required is only sufficient to form a base for ignition, and the steam pressure can be promptly increased or reduced by varying the quantity of liquid fuel. Where an engine is doing intermittent work, as in hoisting for instance, this is often a great advantage.

The chief novelty in Holden's injector consists in the provision of an annular ring near the nozzle from which small jets of steam or air issue. These small jets perform the following duties:—1. They introduce atmospheric air close to the streams of liquid fuel issuing from the nozzle, sufficient to insure perfect combustion and consequently

entire freedom from smoke. 2. They effectually break up the spray of liquid fuel, and secure thorough admixture of the hydrocarbon atoms with the air induced. 3. They diffuse the flames over the surface of the furnace or firebox and prevent local heating of the boiler plates. The internal cones can be readily removed for cleaning, &c., by unscrewing the large nut at the back. The central air tube provides means for clearing the nozzle without disconnecting the injector. On locomotives, two injectors are generally used where the grate is more than 2 ft. 6 in. wide. On stationary boilers the number will be determined by the size of the firebox.

Where steam is used intermittently it is believed that a considerable economy can be effected by the use of this system. It has been fitted with equally good results and worked by compressed air upon rivet furnaces, forge furnaces, &c. Where steam is required at a short notice and at a constant pressure, this system is found valuable for such purposes as central stations for electric light, factories, gasworks, &c. Long extended tests with this system show that 14 lb. of water are evaporated by 1 lb. of dead oil. On stationary boilers it is found that on an average 1 ton of oil does the same work as 1.75 tons of coal, and in many instances 1 ton of oil is equal to 2 tons of coal.

*Carburettling.* H. Bunte. *Journ. für Gasbeleuchtung*, **37**, 81.

THE author first discusses the causes which operate against the extended use of carburetted water-gas in Germany. Even in the best water-gas processes there is often a loss of

50 per cent. of the heat value of the coal. One chief source of this loss is the passage of undecomposed steam through the generator whenever the temperature is lowered. Experiments in this direction furnished the results here tabulated.

Mean Temperatures ° C.	Composition of the Water-Gas Produced.			Steam.		Speed of the Current of Gases per Second.
	H. Vol. per Cent.	CO. Vol. per Cent.	CO Vol. per Cent.	Decomposed per Cent.	Undecomposed per Cent.	
674	65.2	1.9	29.3	8.8	91.2	0.9
758	65.2	7.8	27.0	1.33	71.7	1.8

*Carburettling of Coal-Gas.*—Since benzene has been recovered from the gases of coke-ovens, it has come into the market at so low a price that our attention is naturally directed towards it as a means of carburettling coal-gas. The four million kilos. of benzene produced in this way up to the present would suffice, according to the author's previous experiments (*Journ. für Gasbeleucht.* **36**, 442—449; this *Journal*, 1893, 817—819) for the improvement of 800 million cubic metres of gas, by one Hefner light (= 0.886 "standard candle"). Since in Germany, at present, less than 10 per cent. of the coke ovens are provided with plant for the recovery of benzene, its production is capable of enormous extension, and there is little fear of a rise of price consequent on its employment for carburettling purposes.

The cheapness of benzene may allow of a further step being taken. Coal-gas has hitherto been produced in retorts rather than in large distillation chambers, chiefly because in the latter, methane, and especially benzene, may be decomposed in passing over heated layers of coke, and the illuminating power of the gas would thus be decreased. But now, considering that we have a cheap source of carburettling, and taking into account the lower cost of the large chambers, a slight diminution in the illuminating power may be neglected, and we may even use cheaper coal when the illuminating power is to be increased by carburettling with benzene.

This process would have many advantages over the use of carburetted water-gas, and very possibly the future development of the German gas industry will be in this direction.—R. B. B.

*The Manufacture of Coke.* R. de Soldenhoff. *Iron and Steel Inst. Autumn Meeting*, 1894. *The Ironmonger*, **68**, 1894, 381—384.

IN this posthumous article the author describes in a general way the three forms of coking used in Great Britain, viz.: (1) the bee-hive oven; (2) the Welsh or rectangular oven; and (3) the Coppée oven. Of the total quantity of coke annually made in Great Britain, 85 per cent. is made in the first-named oven and 10 per cent. in the Welsh oven. The quantity of coal made into coke is 35,000,000 tons, yielding approximately 21,000,000 tons of coke, and leaving 14,000,000 tons to be accounted for as follows:—3,500,000 tons of ashes, representing 4,250,000 tons of original shale or earthy matter extracted from the coal before coking by the process of washing, whilst 9,750,000 tons of volatile matters, hydrocarbons and nitrogen, represent the balance. As one ton of volatile or gaseous matter

is equal to about five tons of coal in heating energy, the above quantity represents about 50,000,000 tons of coal. In the question of utilising this matter for boiler purposes, the author shows that the value of the gases is about 6,000,000*l.*, of which 2,500,000*l.* only is utilised, the remainder being wasted. The gasworks practice of extracting tar and ammonia, acted as an example to the coke manufacturers, and also to the Scotch ironmasters in their blast-furnace working, to try and save the by-products. It is about 10 years ago, that the question of saving the by-products in the coking process, was revived.

The subject was brought to the front in England by Watson Smith in his paper read before the Iron and Steel Institute at Chester, and illustrated with every kind of oven then in existence for saving by-products (this *Journal*, 1885, 451. *J. Iron and Steel Inst.* 1884, 186). However, there are at present only about 200 ovens at work in Britain, 40 of which are of the Semet-Solvay type in use by Brunner, Mond, and Co., whereas in Westphalia there are 470, and in Silesia 705. Otto's installations are the most complete form in Germany, but they are very costly on account of the condensing plant being duplicate. The principal feature is that the gases are not drawn direct from the oven, as in general practice, but from a flue situated in the top of the wall on each side of the oven. This flue, by means of two dampers situated on each end of it, may be, at will, connected or disconnected from the flue situated inside of the side wall, so that when the two dampers are in their normal positions, the oven is working as a closed vessel and the gases are drawn to the condensing plant at first. If, however, from any cause it is necessary to turn the oven into one working in the presence of the oxidising atmosphere, the dampers are lifted and the burning gases are admitted into the side walls first, under the floor afterwards, and ultimately into the main flue.

The author omits the bee-hive oven improvements, because the by-products obtained by the same are inferior in quality to those obtained by the Simon-Carvés or Coppée-Otto class of oven. It has been found by Otto that one ton of coal gives 25.44 lb. of sulphate of ammonia and 60.84 lb. of tar. Taking this as a standard the author calculates that in Great Britain there is wasted annually 4,262,500*l.* worth of these two products. Beyond this there is the heating power of the gases after the extraction of the ammonia and tar, which is put down as 1,500,000*l.* The author admits that there is to be considered the cost of plant, which in the by-product oven is about three times that of the ordinary coking plant, and also the possibility of local difficulties. As regards the quality of the coke, he believes that made by the Coppée

is not superior to that of the bee-hive.  
It suggests the utilization of the heating power of the waste gases of coke ovens for the destructive distillation of shale, and the production and extraction therefrom of sulphate of ammonia.—A. W.

## PATENTS.

*Improvements in or connected with the Manufacture of Gas.*—J. H. R. Dunsmore, Liverpool. Eng. Pat. 5647, March 16, 1893.

According to this invention, gas of a given illuminating power is first heated, then mixed with the heated vapours of tar or oil, the resulting mixture being again heated. The temperature employed is about 1,700° F.

In a typical instance the apparatus is as follows:—To each bench or oven there are two sets of apparatus, each apparatus comprising three retorts. The lowermost retort is of rectangular section and is made of iron or steel; in it the tar or oil is vaporised. The central and the uppermost retorts have circular sections, and—holding, as they do, only vapours or gases—are of fireclay.

The three retorts are connected up in the following manner:—At the back of the bench, the mouthpieces of the top and bottom retorts are connected with that of the central retort, while in front of the bench is the inlet to the upper retort and the outlet from the central retort.

Coal-gas or water-gas, &c., entering the top retort at the front end, traverses it and enters the central retort at the other end. Similarly the heated tar or oil vapours, which distil from the contents of the lower retort, enter the central retort at one end, the mixed gases travelling through that retort, and passing out at the other end into the outlet pipe.

According to the drawings which accompany this specification, the retorts have similar capacities.

It is stated that gases so treated have their illuminating power raised, while at the same time their volume is increased.—E. R. B.

*Improvements in the Production of Illuminating Gas from Mineral Oils, and in Apparatus therefor, and for Producing Water-Gas.*—W. Young, Priorsford, Peebles, county Peebles. Eng. Pat. 12,355, June 23, 1893.

The inventor still further develops the system of decomposing mineral oils described in his and A. Bell's patent, Eng. Pat. 12,421 of 1892 (this Journal, 1893, 666).

In the production of water-gas and in the decomposition of hydrocarbons for the purpose of carburising water-gas or other gas, very generally the necessary heat has been obtained, for the most part, from an extraneous source; that is to say, it has not been obtained by the combustion of the elements of the hydrocarbons employed; yet most of these hydrocarbons, especially those of crude tarry oils of high densities, contain carbon in considerable excess of

APPARATUS FOR THE PRODUCTION OF ILLUMINATING GAS FROM MINERAL OILS.

that which can be rendered gaseous by destructive distillation. Moreover, this excess carbon is a source of much trouble, choking up, as it does, the passages and depositing on the walls of the apparatus and rendering the distillates thick and pitchy.

The main object of the inventor has been to overcome the difficulties enumerated, by effecting a partial combustion of this carbon, while utilising the heat so evolved for the decomposition of a further quantity of hydrocarbons and for the production of a certain quantity of water-gas. Fig. 1 is a partly sectional elevation, and Fig. 2 the plan of the author's typical apparatus, while Fig. 3 is a horizontal section of one of the decomposing chambers invented. The cycle of operations is as follows:—

At starting, hydrocarbon fluid is allowed to flow by gravitation from the tank K, so as to seal the condenser chests, H<sup>2</sup>, and the main seal box G<sup>1</sup>, and to overflow into cistern M. Hence, pump M<sup>1</sup> (Fig. 2) lifts a supply through pipe M<sup>2</sup> into the cistern N.

The combustion chamber and water-gas generator B (Fig. 1) is now charged with any convenient form of carbon, kindled, and air driven through the charge by opening valve E<sup>2</sup> (Fig. 2) and so admitting air to the ashpit B<sup>2</sup>, valve C<sup>1</sup> on the smoke-stack C<sup>3</sup> being opened, and all products of combustion escaping to it through the ports D<sup>1</sup> and the flues C<sup>1</sup>, C<sup>2</sup>, which lead to the stack C<sup>3</sup>. Valve E<sup>3</sup> is then opened and a second supply of air enters by the pipe E<sup>1</sup>, leading to the annular flue D, and so to the openings D<sup>2</sup>. The CO formed in B is lit through the port D<sup>3</sup>, and the two air supplies so adjusted that all CO is burnt to CO<sub>2</sub>.

As soon as the fuel in B and the firebrick linings of the decomposing chamber C have acquired a sufficiently high temperature, both air valves are closed, and steam is admitted under the firebars by opening F<sup>2</sup>, and the water-gas so produced is allowed to displace all air and products of combustion. Hydrocarbon liquid is now allowed to slowly flow through O and along the floor of the wide conduit G<sup>2</sup> (which is very hot) into C. Here it drops through the whole height of the chamber on to the highly heated coke, being exposed to very considerable radiant heat the whole way. The hydrocarbon is partly gasified, partly carbonised. As to the latter, some forms a hard coherent cake on the coke, while any flocculent carbon set free is caught and entangled in further falling drops of hydrocarbon.

As the temperature falls, less and less hydrocarbon is allowed to enter C, and finally it is turned off. Steam is then again admitted and sufficient water-gas so produced to drive out the hydrocarbon vapours. The steam is next turned off, C<sup>1</sup> opened, air admitted, the original working temperature restored, and a second cycle entered upon.

According to the inventor, during the carburetting, only sufficient water-gas to prevent the heavy hydrocarbon vapours from sinking through the fuel is to be employed; for, he states, "the presence of water-gas interferes with the decomposition of hydrocarbon vapour in various ways, particularly when the decomposition is effected by radiant heat."

The inventor's second modification of apparatus is to allow for the cases where very much carbonisation of the hydrocarbon occurs; while in his third modification, he employs two or more combustion and decomposing chambers in one producing arrangement. By this means he obtains a continuous process and also great facility in manipulating the ratio of water-gas to carburetted water-gas produced. The fourth modification very considerably modifies the decomposing chamber, and is designed to meet the cases of those hydrocarbons which, during decomposition, "sponge or swell up in foam," this peculiarity tending to close the spaces between the pieces of carbon in the combustion chamber, and so to impede its action. The modification in question is shown in Figs. 4 and 5, and will be seen to consist of a series of retort-like chambers C, slightly inclined and connected by the chambers C<sup>3</sup>. There are clearing doors C<sup>6</sup>, through which the deposited carbon may be raked down into the combustion chamber B from time to time. The hydrocarbon is allowed to slowly flow over the large bottom surface of the retorts in a very thin layer.

When the liquid hydrocarbons carry water or, as in the case of coal-tar, valuable benzene, this is readily separated in the condenser; for, as already explained, the flow of the hydrocarbons through the condenser chests is against that of the gas; and the gas entering G<sup>1</sup>, and even H<sup>2</sup>, is sufficiently hot to vaporise these substances, which are therefore condensed in and may be recovered from one of the chests further forward.—E. R. B.

*Improvements in Obtaining Combustible Gases, Ammonia, and Tar from Fuel, and in Apparatus therefor.* L. Mond, London. Eng. Pat. 12,410, June 24, 1893.

See under III., page 938.

*Improvements in Water-Gas Apparatus.* A. G. Glasgow, Westminster. Eng. Pat. 5588, May 1, 1894.

This invention relates to the construction of the valve necessary in those water-gas plants where the steam is conducted through the incandescent fuel alternately from the top or bottom of the generator.

Three forms of valve are minutely described and figured, and in each of them the construction is such that the valve lies entirely out of the way of the intensely-heated blast gases of the generator, while the operating mechanism is for the most part outside the apparatus. The conduits from the top and bottom of the generator are so arranged that the hot gases issuing from either of them never impinge on the opening of the other. As to the steam supply, the inventor prefers to connect the controlling mechanism of this with that of the gas valve in such a way that when the conduit from the bottom of the generator is open the top injector is automatically turned on, and when the valve is moved, shutting this conduit and therefore opening the other, it turns on the bottom injector.—E. R. B.

*Improvements in the Production of Illuminating Gas and Bye-Products from Liquid Hydrocarbons, and in Apparatus therefor.* W. Young, Peebles. Eng. Pat. 13,126, July 5, 1893.

This inventor brings forward a modified process and a new arrangement of existing coal-gas plant to enable such plant to be used for producing illuminating gas and benzene from hydrocarbon liquids in accordance with the principle of the previous invention of the author and A. Bell (see Patent 12,421 of 1892).

From suitably placed tanks regulated quantities of coal-tar and of "more refined tars and oils, such as natural petroleum and those distilled from shale at low temperatures," flow through siphon pipes to one or more of the retorts heated by a given oven.

In cases where some of the retorts are carbonising coal the temperature will be too high a one to which to expose the finer qualities of oil; a rapid current of the tar through the retort is therefore in the first instance maintained, and not until the internal temperature of the retort is reduced is the finer oil allowed to enter. "The presence in the retort of the vapour and gases from the tar has a conservative action upon the oil vapours, protecting them from over-decomposition even at the high heat employed." The gas so produced in the tar-decomposing retorts mixes in the hydraulic main with that from the coal-decomposing retorts, and any excess of distillates and condensable hydrocarbons is condensed with the coal-tar, and is thus used over again.

Near the ends and cooler parts of the retorts tar is liable to soak into the fireclay, and, by swelling during coking, is liable to crack the walls; to obviate this difficulty the inventor inserts a sheath or lining of iron or steel at these points.—E. R. B.

*Improvements in and Apparatus for Distilling or Cracking and Gasifying Hydrocarbon Oils and the like.* H. M. Caldwell, London, and E. Tatham and J. E. Tatham, both of Lewisham, Kent. Eng. Pat. 13,163, July 5, 1894.

The chief aim of the patentees is to accomplish the gasification of a given oil at a known suitable temperature, and to separately collect its condensable hydrocarbon by-products, so that each of these in its turn may be gasified at its proper temperature.

In the figure, A is a bench of retorts, arranged in four tiers, the retorts (*a, a, a*) of the lowest tier being maintained at the highest temperature, and those (*d, d, d*) of the

uppermost tier at the lowest temperature. The crude gas manufactured passes by *h<sup>2</sup>, n, r,* and *h* into the ascension pipe *i*, which terminates in the condenser S.

The condenser S consists of a vessel D, divided into three compartments, E, F, G, respectively. Into E dips the end of the ascension pipe *i* and the two legs of the inverted U-pipe *ll, ll*; into F dip the ends of *ll<sup>2</sup>, ll<sup>2</sup>*; into G, those of *ll<sup>3</sup>, ll<sup>3</sup>*. The connecting tubes *l, l<sup>2</sup>, l<sup>3</sup>, l<sup>4</sup>*, allow of the passage of the gas through the condenser into *l*, and thence through the meter K into X, the pipe leading to the gas-holder. The oil employed in the manufacture is contained in the tank B, and is conducted through *e* into *d, d, d*, the coolest series of retorts. As to the distillates, the

APPARATUS FOR DISTILLING OR CRACKING AND GASIFYING HYDROCARBON OILS.

heaviest of them, viz., that condensed in the descending limb of *i* and in *ll, ll*, and collected in E, is conducted through *e<sup>2</sup>* into *a, a, a*, the hottest of the retorts; the intermediate distillate, similarly collected in F, is treated in the retorts *b, b, b*; while the lightest distillate, that collected in G, flows into the still cooler retorts *c, c, c*.

C—C' are apparatus, attached to the feeding tubes, the function of which is to automatically shut off the supply of hydrocarbon to any given retort, should the outlet from such retort become choked.

Oxygen may be mixed with the products of distillation as they pass to the condenser. This gas is contained in the meter L, entering by P and leaving by Q. The oxygen meter is operated from the gas meter K by the endless chain M, which passes round the sprocket wheels N and O on the axes of the respective meters; the relative sizes of N and O are determined by the proportion of oxygen it is desired to mix with the products of distillation.—E. R. B.

*Improvements in Electric Furnaces.* F. Chaplet, Paris. Eng. Pat. 15,577, August 16, 1893.

A cavity is made on the upper side of a mass of refractory material, and fitting above this is a similar block with a

hollow on its under side, which thus forms a domed roof over the first cavity. A refractory retort, muffle, or tube projects into or across one axis of this chamber, and a pair of carbon electrodes project across an axis at right angles to the first, the ends of the electrodes passing through opposite walls of the chamber to rolling supports outside, by which the length of the arc may be regulated. Several pairs of electrodes may be used, if required, to produce higher temperatures, or for local heating. The tube contains the substance to be heated, which may be fed in at one end and run out of the other in a fused condition, into a receptacle outside, or into a well within the furnace, the tube being sloped at an angle varying with the fluidity of the fused mass. Or, the muffle may be used for cupelling or any other required purpose.—W. G. M.

*Improvements in Apparatus for Supplying Liquid Fuel to Furnaces.* J. C. Etchells, Heaton Chapel. Eng. Pat. 19,110, October 11, 1893.

For the purpose of supplying liquid fuel to furnaces in the form of a spray, provided with air-inlets around the steam-nozzle, through which a current of air enters, and, together with the steam, mixes with the fuel before reaching

the fire. The apparatus includes a nozzle and valve for the admission of steam, and at right-angles a second nozzle and valve are arranged, through which the liquid fuel enters. From the nozzle the steam enters a chamber of larger diameter, through the walls of which are a number of air-inlets, somewhat similar to those found in a Bunsen's burner. Into this chamber, a short distance nearer the furnace, the fuel enters, and meeting with the current of air and steam, is broken up into a spray, which is carried along a tube into the furnace, and striking a deflecting plate, is thrown down upon the hearth of the furnace. The quantity of fuel is regulated by a valve and hand-wheel, as is also the steam-supply. Accompanying the specification is a detail drawing of the apparatus.—S. P. E.

*Improvements in Gas Producers.* C. D. Abel, London. From the Gas Motoren Fabrik Deutz, Kolu-Deutz, Germany. Eng. Pat. 21,089, November 6, 1893.

THE inventors' producer differs from the ordinary type in that at the bottom and immediately above the grate it is enlarged, the chamber so formed being rectangular in horizontal section. This chamber has openings of its full width on opposite sides of the producer, closed by air-tight doors. To ensure further the protection of the doors from too direct heat and so to assist them in the maintenance of an air-tight closure, protective shields lined with firebrick, like the doors, are slid into the openings so as to lie about midway between the very highly heated fuel and the doors; a non-conducting layer of air therefore always existing between the shield and the door.

The structure detailed above allows of the rapid clearance of clinker and of any caked material adhering to the sides of the producer, and thus, as the inventors state, strongly slagging or caking fuel can be used for the manufacture of combustible gas with the same facility as anthracite.

A further improvement consists in the employment of several steam injectors, an arrangement which permits of a very accurate adjustment of the steam supply, according to the varying needs of the producer.—E. R. B.

*New or Improved Method of Focussing or Controlling Flame or Heat in connection with Burners, Stoves, Kilns, Melting Pots, or other Heaters provided with Combustion Chambers.* C. H. Land and H. J. Caulkins, Detroit, U.S.A. Eng. Pat. 13,106, July 6, 1894.

THIS invention relates to a method and apparatus for focussing flame and producing an intense heat (combustion being complete), in connection with burners, stoves, kilns, &c. provided with a combustion chamber, and heated with liquid or gaseous fuel. The arrangement consists in having a combustion chamber, the lower portion of which is covered by a bed with an opening in the centre. Upon this bed is placed a removable slide, also having an opening in the centre, and which further carries a removable diaphragm with as small an orifice as necessary. By means of such removable diaphragms with orifices of varying sizes the flame may be focussed. Beneath the diaphragm is placed the burner, consisting of an open pan which is fed by gravity with liquid fuel. Resting within the pan is a wire gauze screen or collar. The pan and its contents can be raised or lowered by means of a series of levers. When the surfaces above the pan are heated they radiate the heat and vaporise the fuel, which is important for obtaining the greatest efficiency; the burner being gradually lowered in proportion as the temperature rises in the combustion chamber until the maximum heat is obtained. The periphery of the opening in the movable slide forms a seating corresponding in form and size with the upper rim of the fuel pan, so that by raising the pan to the seating, the draught through the aperture at the base of the combustion chamber is completely closed, or the amount of air and flame passing through the aperture is in proportion to the height the pan or burner is raised. The air is admitted by a fine passing through the side of the burner and opening into a tubular stem that supports the burner and thence to the top of the fuel pan or point of ignition. The size of the orifice in the diaphragm used depends upon the draught

of the chimney; with a strong draught the orifice of the diaphragm should be reduced and the distance between burner and orifice proportionally decreased to obtain the proper focussing. Suitable arrangements are provided for removing any carbon that may collect upon a muffle or anything placed in the combustion chamber, also an overflow pipe from the fuel pan, and means for preventing fire outside the furnace.—S. P. E.

*A New or Improved Combustible Composition.* René Odeyn, Brussels. Eng. Pat. 11,968, July 21, 1894.

THE composition claimed by the inventor consists of 700 parts of schistous stone, crushed; 250 parts of powdered charcoal or sawdust, spent tan, or peat; and 50 parts of tar. These are well mixed together, and made into briquets.—S. P. E.

*Improvements in the Manufacture of Incombustible Burners for Liquid and Gaseous Fuel.* C. Westphal, Berlin. Eng. Pat. 11,136, July 27, 1894.

FOR the manufacture of incombustible burners for liquid and gaseous fuel, carbonate, silicate, or fluoride of calcium, clay, kaolin, tile, sand, quartz, pumice-stone, carbonate and sulphate of strontium are employed as forming the chief substance. By this invention the author claims the addition of compounds of the heavy metals, as the oxides of lead, tin, zinc, iron, manganese, &c., which is said to prevent cracking or changing in shape during the burning or drying process. For the purpose of making them porous, the inventor adds to the above mixture sulphur or some compound that volatilises when heated. The above mixture is moistened with a solution of water-glass, alum, or boric acid, and then moulded and, if necessary, burned.—S. P. E.

*Improvements in and relating to Apparatus for the Distribution and Burning of Fluid Hydrocarbons for Lighting and Heating Purposes.* J. McCownan McMurtrie, Glasgow. Eng. Pat. 16,701, September 5, 1894.

THIS apparatus is constructed for burning petroleum and other liquid hydrocarbons and water, first vaporising and then converting hydrocarbon oils and water into permanent gases, or by first vaporising the hydrocarbon or water and then superheating the vapour or steam and conducting the same to the burner. The illustration shows the general construction of the apparatus. Fig. 1 shows a side view, the lower portion being in section. Fig. 2 is a section on line  $x-x'$ , and Fig. 3 a section on line  $y'-y'$  of Fig. 2. A is the outer metal casing, which is open at the top. B is a vaporising-coil, which is connected outside with the supply-pipe  $u$  for water or hydrocarbon oil, and the inner end communicates, through a passage in the casing  $c$  and sockets  $b$  and  $d$ , with the gasifier or superheater C. This superheater communicates with the cup D of the burner by the passages  $j$  and  $i$ . An inner casing  $h$  around the coil may be employed, thus forming an annular space down which air for supporting combustion passes. The nozzle or burner is a metal cup screwed into a seating in such a way as to leave an annular chamber  $D'$ , which communicates above with the burner and below with the chamber  $k$  and supply-pipe  $n$ . The burner is connected with the stand-pipe  $m$  and pipe  $n$  by the tee-piece E, having two passages  $n'$  and  $m'$ , Fig. 2, the former leading to the chamber  $k$  and the latter to the vaporising coil. The pipes  $a$  and  $k'$  are connected to the tee-piece with coned couplings, so as to allow the burner to be inclined at any angle. The pipes  $m$  and  $n$  are connected respectively with suitable store tanks, preferably arranged one within the other, and provided with an air-pump and other necessary fittings. One tank only is required if water is obtained under pressure, in which case it is directly connected with the coil. If the apparatus is to be used for heating purposes, only a small quantity of oil is employed, and the coils B and C are allowed to get red-hot, so as to decompose the steam. Instead of water, two hydrocarbons may be employed, in which case that passing through the gasifier is converted into permanent gases, and burns with the oil at the nozzle.

The specification gives a description, accompanied by illustrations, of several modifications of the apparatus, to be employed respectively as a portable lamp, a search-light,

Fig. 1.

Fig. 2.

Fig. 3.

and an arrangement for a number of lamps supplied from a central reservoir.—S. P. E.

### III.—DESTRUCTIVE DISTILLATION, TAR, PRODUCTS, Etc.

*Action of Light on Phenol.* A. Bach. Monit. Scient. 42, 508—510.

This question as to whether this action is due to formation of hydrogen peroxide is answered by the author in the negative. According to his investigations it is shown that when phenol is subjected to the simultaneous action of light and moisture in an atmosphere of carbonic anhydride free from air, it assumes a brown colour much more readily than in air free from carbonic anhydride (see this Journal, 1893, 107, 112, 415 and 553).—D. B.

See under II., page 933.

### PATENTS

*Improvements in Obtaining Combustible Gases, Ammonia, and Tar from Fuel, and in Apparatus therefor.* L. Mond, London. Eng. Pat. 12,440, June 24, 1893.

In this invention a suitable mixture of air and steam is driven by a fan or blower through a superheater of special design until it attains a temperature of at least 150°, with a pressure usually sufficient to support 6 to 9 ins. of water. It then enters a producer of particular construction, to react with the fuel contained therein. The inventor claims both process and apparatus.

With regard to the process, he states: "I believe that I have been the first to discover that, by burning fuel with a

Fig. 1.

mixture of air and steam in proper proportions raised to a temperature of not less than 150° C., the quantity of ammonia obtained from the fuel is largely increased."

With regard to the apparatus, the inventor specially claims the superheater, "constructed of a series of pipes arranged vertically in zig-zag form, through which the hot gases from the producer pass, and which are surrounded by wider pipes, thus forming an annular space through which the mixture of air and steam is driven in a direction opposite to the producer gas, and the combination of this superheater with a gas-producer, substantially as described."

Fig. 1 is a median vertical section of the producer and of one unit of the superheater. Fig. 2 is a median vertical section of the superheater in a plane at right angles to the foregoing.

The air and steam mixture enters at *r* (Fig. 2), and traverses *s*, *s*, *s*, *s*, and so reaches (Fig. 1) the space

Fig. 2.

between *c* and *d*, the inner and outer casings of the producer, and passing between the bars *i* of the grate *j*, reaches the fuel in the body *A* of the producer.

The producer-gas manufactured leaves by *p*, *p*. The outer wrought-iron casing *d* of the producer is closed at the bottom by the water-lute *l*, and the inner wrought-iron casing *c*, which is lined with firebrick, has attached to it the inverted conical grate with wedge-shaped bars *j* open below, though closed during work by the heap of debris, as represented in Fig. 1. The cast-iron cylindrical apparatus *g* allows of feeding the producer from the charging chamber *A* without disturbance, only a minimum, therefore, of fuel dust entering the gas pipes. The lines *x x* show the upper limit of the fuel. The inventor admits that circular gas-producers, with surrounding annular spaces for heating the air, have been previously described, as have also various devices for heating this air by the waste heat of the producer; but, he states, "none of these are sufficient to attain the rise of temperature required." As to the process, he points out that hitherto, for obtaining ammonia from fuel with gas-producers, mixtures of superheated steam with cold air have been proposed—a method which would involve a greater expenditure "for extra fuel than would be compensated for by the increase in the ammonia obtained."

Previous patents of the inventor, relating to this subject, are 3923 of 1883 and 8973 of 1885; this Journal, 1884, 236, and 1886, 235.—E. R. B.

**A Paste or Mixture for Cleansing Various Materials and Articles.** M. Baerlein and C. Dreyfus, Manchester. Eng. Pat. 19,733, October 20, 1893.

THE paste is made by taking china clay, pipeclay, fuller's earth, French chalk, or other similar materials, either

separately or mixed in various proportions, and incorporating them with "benzol, toluol, xylol," solvent naphtha, "patent naphtha," petroleum naphtha, or carbontetrachloride, also either separately or mixed in various proportions. The paste or cream is intended for removing grease and other spots from cloth, wearing apparel, gloves, lace, pictures or prints, and metals. It is to be applied in a thin layer, left to dry, and then brushed or rubbed off. The inventors claim the paste, and also the method of using it. J. A.

## IV.—COLOURING MATTERS AND DYES.

*The Action of Light on Textile Dyes.* Remarks on J. J. Hummel's paper. M. Kischelt. *Färber Zeit.* 5, 1894, 165—168, 181—183. (See this Journal, 1894, 801—807.)

THESE remarks are based upon an extensive series of experiments carried out since 1891 at the Elberfeld colour works. In the year named all the colouring matters then known were dyed on cotton and wool and exposed simultaneously. In the autumn of 1892 the same series dyed on silk was similarly exposed, and since then the experiments have been followed up by a repetition with smaller groups of the dyes. Altogether the daily experiments fully confirmed the results obtained from the larger series. All the colouring matters were dyed to the same depth of shade without any consideration as to whether to this end 2 per cent. of the one and 1 per cent. of another dye were required. Hummel's method consists in dyeing 2 per cent. shades of each colouring matter upon cotton, wool, or silk, without consideration of the strength of each individual dye, in the author's opinion necessarily involves the error of finding too high a degree of fastness for the strong dyes, whilst the results for the weak dyes must, he thinks, be too low. Therefore they do not represent the fastness to light of the dyes, but rather are a product of the intensity of a dye and of its fastness to light. Even supposing, however, that all dyes be of the same intensity when dyed upon wool in the skein, the fact that in these tests the colours are dyed upon cloth may, the author thinks, lead to another serious error. The various dyes known exhibit great differences with regard to their capability of dyeing cloth evenly all through, so that of two dyes the one may be distributed with perfect evenness through the cloth, while the other will be almost entirely fixed on the surface. Under such circumstances an amount of fastness may be attributed to a dye which it does not actually possess. Hummel's plan of dividing each sample into six parts, one of which is kept for reference, whilst of the five others which are exposed, one is withdrawn after the expiration of each one-fifth of the whole time of exposure, is very useful. But mention should have been made, it is considered, of the remarkable difference thus observable between various dyes or classes of dyes from stage to stage during exposure. In the first group the dye disappears uniformly from beginning to end. In the second group a decided alteration of the shade becomes apparent after a few days' exposure, but then this slightly altered shade remains unaffected for a very considerable time. Such behaviour is very clearly exhibited in the case of indigo, light tints of which at first rapidly assume a somewhat greenish tone, which then remains permanent for a very long time. In the third group a reverse action takes place, i.e. the original tint remains for weeks unaffected, but as soon as the alteration sets in, a few days' further exposure will suffice for the destruction of the shade. This shows that to avoid errors the exposure must not be too short, and should not be interrupted until all the specimens under experiment begin to show decided signs of deterioration. Hummel exposed all his patterns to the same quantity of chemically active light, which was measured by means of "types." For the absolute necessity of gauging the length of exposure in this manner, instead of by time, Hummel has furnished interesting proof. According to the amount of deterioration the exposed patterns

arranged in groups, but within the groups the dyes are arranged by Hummel in the order of their fastness. Thus, as is to be seen, done in the experiments carried on at the Mulhouse colour works. Their first group comprises the fast dyes, whilst Hummel's first group contains the fugitive ones. In Hummel's first group appear the fast dyes, Eosine, Erythrosine, Phloxine, Bengal, Rose bengal, Cyanosine, Cyclamine, &c., which are not more stable or fugitive. Not more stable are safranines, Neutral red, Neutral violet, Neutral blue, and Roxamine. The rosindulines may be divided into two groups, the yellow brands ranging somewhere between the first and second group, whilst the blue brands are considerably faster. Titan, scarlet R and Patent atlas red, also belong to the first group of very fugitive dyes. Larger differences exist in the second group. The triphenylmethane colouring matters follow immediately in fastness after the first group, and are followed by the somewhat faster rhodamines. Between these two appears a considerable number of the azo dyes, especially some of the substantive dyes, such as the stilbene dyes and Congo red. Brilliant Congo stands rather higher. Ponceau SS extra is only little better than magenta. Fast red BF, Thionine, Cloth scarlet G and R, Coccine B (on silk), Ponceau acide, the Xylidine and Cumidine scarlets, the rhodamines, Pyrouine, Double brilliant scarlet G, Bordeaux COV, Archil substitute and Cloth red 3 B extra follow next. Hummel placed the Xylidine and Cumidine scarlets, Bordeaux COV, and Ponceau G in the third group, but they are much more sensitive to light than Cloth red 3 G extra, Bordeaux BX, and others. On the other hand, Cloth red 3 G extra, Fast red A, Bordeaux BX, and Fast red B are faster than they appear according to Hummel. Of the substantive dyes, Benzopurpurin 1 B, 4 B, and Brilliant Congo come next or nearly so to Fast red BF, the rhodamines next to Bordeaux COV. The rhodamines are faster on silk than on wool. The third group, containing moderately fast dyes, contains a great many azo dyes. But part of those mentioned by Hummel really belong, according to the author, to the second group. The Rosindulines 2 B and 3 B, and Azocarmine stand at the beginning of the third group, then follow Fast red A, E and D, Scarlet R and Ponceau GG are of about the same fastness as the fast reds. Next follow Palatine red, Cloth red 3 G extra, Azo-eosine, Croceine 3 BX, crystal Ponceau and finally Carmoisine B (Fast red C). Of the natural dyestuffs, cochineal on alumina and tin mordant stand between this and the next group. From this group should be removed, according to the author, the following dyes placed in it by Hummel: the Ponceaux, Cloth scarlet (into group II.), Buffalo ruby (into group II.), and Cloth red G extra (into group IV.). Also Carmoisine and cochineal were better assigned to the fourth group. Azocarmine, which Hummel judged too favourably, as the author thinks, should be removed to this group, whilst Cloth red 3 G extra, fast red A, B, and Bordeaux BX, which Hummel placed in the second group, the author places in the third. Of the substantive dyes, the deltapurpurins stand with the fast reds. The last members of the third group, Carmoisine B and cochineal, are perhaps better placed in the beginning of the fourth group, followed by Brilliant double scarlet 3 R, Brilliant Ponceau 4 R, Ponceau 5 R and 6 R, Biebrich scarlet 3 B, 7 B, Palatine scarlet, Cloth red G extra, and alizarin on alumina mordant, according to the author. All these show about the same degree of fastness. Ponceau S, the Azo-magentas, and the Chromotropes then immediately follow. Compared with Hummel's results the following differences appear, as the author thinks, in this group: Ponceau 2 G and Wool scarlet belong to Fast red; Coccine B (on silk) is about equal to the Xylidine scarlets, Cloth red GB and Archiline BB undoubtedly belong to the next group. On the other hand, Diamine fast red, Geranine G, and Anthracene red possess the same degree of fastness as Croceine scarlet, and therefore belong to this (the fourth) group. Amongst the very fast dyes, forming the fifth group, Hummel only classes alizarin, madder, Cochineal scarlet, and Chromotrope 2 R and 2 B. The pair of last-named dyes are no better than any of the other chromotrope dyes, and therefore the author considers they should have been placed along with Azo-magenta. Alizarin, although

the fastest dye on cotton, has, the author thinks, been overrated regarding its fastness on wool, where it proves inferior to several of the cloth red brand. The same may be said of madder and cochineal, which are not fast enough to appear in this class. This first class is exclusively composed of artificial dyes: Cloth red BX, Bordeaux G, Orselline BB, Cloth red G and B, with or without chrome mordant. The two last-named dyes, says the author, are not only the fastest of red dyes, but of dyestuffs in general. All the above-named dyes were dyed on wool, in some cases on silk. When dyed on cotton the results of the experiments come out very differently.—C. O. W.

#### *A Method of Preparing Lead Peroxide for the Aniline Industry.* W. Minor. *Der Techniker*, 1894, 16, 80.

To prepare lead peroxide free from hypochlorite, and answering to the requirements of the aniline manufacture, add to molten caustic soda, at the highest possible temperature, the required amount of lead monoxide with continual stirring, and then the amount of sodium nitrate necessary for oxidation. The reaction takes place according to the equation—

By extraction of the mass with hot water the lead peroxide is obtained—

It is purified by washing with water, and dried. By this method an almost chemically pure product may be prepared.—R. B. B.

#### *Colouring and other Principles contained in Mang-Koudou.* A. G. Perkin and J. J. Hummel. *J. Chem. Soc.* 65 and 66, 1894, 851—863.

THE dyeing material named *oungkoudou*, *jong-koutong*, &c., is the root-bark of *Morinda umbellata*. It occurs in Eastern commerce as small, reddish-brown, irregular rolls of bark, much wrinkled in appearance. Its cost is about 6d. per pound. It is largely used in Java for producing the fast reds in the native calico prints known as "baticks."

The material does not appear to be considered as of any special importance by the Hindoo dyers. The shrub from which the root-bark is obtained is met with in Ceylon and the hilly regions of Eastern, Southern and South-western India, as well as in the Malay Peninsula and Java.

*Literature.*—Philosophy of Permanent Colours (1813), Bancroft. Bulletin de la Soc. Ind. de Mulhouse (1832), Schwartz and Koechlin. L'Art de la Teinture des Laines (1849), Gonfreville. Monograph on the Dyestuffs and Tanning Matters of India, &c. (1878), T. Wardle. Watts' Dictionary of the Economic Products of India (1891), J. Murray.

*Summary of Results.*—In the general character of its constituents, mang-koudou more closely resembles madder than chay-root, although like the latter it contains but a single colouring matter. There are present, though only in small quantity, numerous yellow, crystalline substances, totally different from those found in chay-root, and, judging from their behaviour, more nearly allied to those isolated by Schunck from madder. Eleven distinct substances have been isolated.

*Morindin*, the glucoside of morindone, identical with that obtained by Thorpe, Greenall, and Smith from *Morinda citrifolia*. Substances of the formula—

$\text{C}_{10}\text{H}_{11}\text{O}_6$ ;  $\text{C}_{16}\text{H}_{10}\text{O}_5(\text{A})$ ;  $\text{C}_{16}\text{H}_{12}\text{O}_5$ ;  $\text{C}_{15}\text{H}_{10}\text{O}_4$ ;  $\text{C}_{16}\text{H}_{10}\text{O}_3(\text{B})$ ; also a substance crystallising in orange-red needles, in very small quantity. These six substances form the bulk of those present in the root. Besides these there are also present, a colourless crystalline wax of the formula  $\text{C}_{18}\text{H}_{32}\text{O}$ ; a small quantity of free morindone, Rubichloric acid and a considerable amount of a free acid (undetermined). No cane-sugar is present, which is a feature distinguishing this root from both chay-root and madder.

*Dyeing Properties.*—Gonfreville and Schwartz and Koechlin have written most on this subject. The authors found that wool and silk when boiled with a decoction of

mang-koudu with the addition of a little acetic acid, acquire rich orange and yellow colours due to *morinda*, but these are of little value, as they are at once reddened by alkalis. Applied in its ordinary condition on mordanted cotton, no useful result can be obtained with mang-koudu. The ground mang-koudu must first be washed by steeping it in ten times its weight of cold water for 2–3 hours. It is then collected and the treatment repeated two or three times. Its dyeing properties are then developed. Like madder and chay-root, however, it loses about 50 per cent. of its weight, there being removed saline matter, free acid, chlorogenin, the so-called pectic matter, and a large quantity of what are probably sugary or gummy matters.

After the foregoing treatment mang-koudu may be applied in silk, wool, and cotton dyeing, exactly in the same way as madder, it being merely desirable to add to the dye-bath 1–1.5 per cent. of sodium carbonate or chalk, in order to obtain darker or fuller colours. On stripe-printed calico containing the usual aluminium and iron mordants, it gives colours fast to soap and generally similar in appearance to those obtained by the use of madder, though somewhat inferior. Experiments are now in progress as to resistance to the action of light. It may be said that the dyeing properties of mang-koudu are practically identical with those of morinda-root, with which it is closely related both botanically and chemically.

—W. S.

#### A New Process of Indigo Preparation. *Färber Zeit.* 5, 294.

THE fermentation in the steeping vats, to which is due the formation of the blue colour, ceases, according to Schrottky, after 10–12 hours, and is then replaced by lactic acid fermentation and putrefying processes. To obviate this, he would add to the vats a certain proportion of nitrates to nourish the bacteria of the colour fermentation, and carbolic acid to prevent putrefaction. Schulte, the inventor of the new process (patented in India), declares, however, that fermentation of any kind is unnecessary, and avoids it by steeping the plants in water at 50–55° C. instead of at the ordinary temperature. He assumes that the bacteria of the ordinary process are really injurious, and that during fermentation foreign substances, such as albumin and resin, are extracted from the plants, and depreciate the quality of the product. Unfortunately he does not state whether the deposit in the heating vats is merely washed, or boiled with water before filtration.

Indigo prepared by the new process has already come into the market, and appears to be superior to ordinary Bengal indigo, being softer, lighter, and less crumbly. A medium Bengal indigo contains 54 per cent. of indigotin, Schulte's 73.8 per cent., finest Bengal (old process) 77 per cent., and finest Java 88 per cent. As the two first were prepared from plants of exactly similar growth, it would appear that the new process offers a considerable advantage.

#### PATENTS.

##### Improvements relating to the Manufacture of Colouring Matters. R. Vidal, Paris, France. Eng. Pat. 19,880, July 1, 1893. (Under International Convention.)

THE colouring matters referred to, which dye unmordanted fibres, are obtained by the action of sulphur on *o*- or *p*-dihydroxybenzenes in presence of ammonia or fatty amines at temperatures from 130°–200°. The following are the proportions given:—10 kilos. of quinone, 5 kilos. of sulphur, 4 kilos. of ammonium hydrochloride, and 6 kilos. of caustic soda are heated for five hours in a closed vessel to 160°–210°. The melt, when cold, is powdered and

used directly for dyeing purposes. The aqueous solution of the crude melt is precipitated almost completely by sulphuric acid with evolution of sulphuretted hydrogen. The precipitate so obtained is very soluble in alkaline sulphides, and this solution dyes vegetable fibre bluish grey, dark blue, and black. The acid filtrate, after neutralisation with caustic soda and oxidation with air or other oxidising agents, dyes wool bluish violet from a neutral and orchil red from an acid bath. The quinone may be replaced by naphthoquinone and pyrocatechol, and the ammonia by mono- or dimethylamine. The colouring matters obtained may be used in the crude state, but if purified by the sulphuric acid treatment they must, in order to render them suitable for dyeing, be mixed with 2–3 times their weight of sodium sulphide. —T. A. L.

##### Manufacture of Diamido-dibenzimidazols and Colouring Matters therefrom. O. Murray, London. From "The Farbwerke vormals Meister, Lucius, and Brüning," Höchst-on-the-Maine, Germany. Eng. Pat. 15,698, August 18, 1893.

THE compounds referred to in this specification are diamido derivatives of anhydroxanilide and its homologues (Hübner, *Annalen*, 209, 370). The lowest term of the series has the following constitution:

and is obtained by reducing tetra-nitro-oxanilide with tin and dilute hydrochloric acid, the proportions employed being 4 kilos. of tetranitro-oxanilide, 14 kilos. of tin, and 50 kilos. of 25 per cent. hydrochloric acid. This mixture is diluted with two or three times its bulk of water, and boiled until the whole of the tetranitro-oxanilide has dissolved, yielding a deep yellow solution. After having been freed from tin by precipitation with sulphuretted hydrogen, the filtrate is evaporated, when the easily soluble hydrochloride separates out. By dissolving it in water and adding sodium sulphate the sulphate of the base is precipitated. If the nitro compound be reduced in presence of alcohol, the sulphate may be precipitated directly by adding sulphuric acid. The base forms yellowish crystalline flakes sparingly soluble in hot water and in alcohol; it is somewhat more soluble in hot amyl alcohol, giving a solution having a green fluorescence, and is insoluble in ether, benzene, and chloroform. It separates from amyl alcohol in brilliant needles melting above 300° C. In a similar manner a diamido derivative is obtained from tetranitro-oxal-*o*-toluide. This compound is produced by the action of hot fuming nitric acid or of nitric and sulphuric acid on oxal-*o*-toluide. It is insoluble in most of the ordinary solvents, but is very sparingly soluble in hot glacial acetic acid, and melts above 300° C. In order to reduce it, 4.5 kilos. of tetranitro-oxal-*o*-toluide, 8 kilos. of tin, and 45 kilos. of 25 per cent. hydrochloric acid are heated for some time on the water-bath. After having been freed from tin the base is precipitated from the solution by sodium carbonate. The base forms a gelatinous precipitate which becomes crystalline on heating, and is sparingly soluble in water, alcohol, and amyl alcohol. The melting-point is above 300° C. The sulphate, which is rather more soluble in water, crystallises in golden needles. By the action of nitrous acid it forms a tetrazo compound which yields azo colouring matters on combination with anilines, phenols, and their derivatives. For instance, 13.2 kilos. of the diamido-dibenzimidazol are diazotised with 27 kilos. of sodium nitrite in the usual manner and run into a solution containing 25 kilos. of sodium naphthionate and 3.3 kilos. of soda. After stirring for 12 hours the formation of the colouring matter is complete. It is separated and purified in the usual manner, and dyes unmordanted cotton.

—T. A. L.

*F. M. ... and Production of New Dyes of the ...* B. Willecox, London. From "The ... Anilin and Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 18,374, September 30, 1893.

The dyestuffs referred to are obtained by the interaction of phenanthraquinone and an aromatic *o*-diamine, of which one of the amido groups is substituted by methyl, ethyl, benzyl, phenyl, t-yl, or the like. The diamine may contain other amido groups, and it has been found that such a group in the position meta to the alkylated nitrogen confers the most valuable properties on the condensation product, both as regards fastness and also brightness and purity of shades. About 15 kilos. of methyl-triamido-toluene—

20 kilos. of phenanthraquinone, and 60 kilos. of glacial acetic acid are heated together on the water-bath until no increase in the intensity of the colour is observed. About 10 kilos. of 30 per cent. hydrochloric acid are then added, and the melt is poured into 20 litres of hot water. After cooling and filtering, the dyestuff is precipitated with zinc chloride, and it is purified by repeating this treatment. It is, of course, not necessary to use separated methyl-triamido-toluene, as the solution obtained by reducing the azo-dye from a diazobenzene salt and methyl-tolylene-diamine,  $(\text{C}_6\text{H}_4\text{N}_2\text{C}_6\text{H}_4\text{NHCH}_3\text{NH}_2)_2$ , with zinc dust in acetic acid solution may also be employed. The solution thus obtained, which is kept as concentrated as possible, is poured into a mixture of glacial acetic acid and phenanthraquinone, and worked up as before. The colouring matter obtained dyes a red fast to washing. The following method is given for the preparation of a yellow dyestuff. About 17 kilos. of nitro-methyl-*p*-toluidine,  $[1,2,5]\text{H}_3\text{NO}_2\text{NHCH}_3\text{CH}_3$ , are mixed with about 170 kilos. of 30 per cent. acetic acid, and reduced with the requisite amount of zinc dust. The solution obtained is poured into hot glacial acetic acid containing 20 kilos. of phenanthraquinone. Ten kilos. of hydrochloric acid are then added, the mixture is heated for 15 minutes on the water-bath, and is allowed to cool, when the dyestuff is filtered off. It is purified by dissolving in hot water, filtering, and precipitating with hydrochloric acid. The condensation product of phenanthraquinone and amido-diphenyl-m-phenylene diamine gives a blue. About 7 kilos. of the latter base having the formula  $[1,2,4]\text{C}_6\text{H}_3\text{NH}_2\text{NHCH}_3$  are dissolved in 42 kilos. of glacial acetic acid at the ordinary temperature, 5 kilos. of phenanthraquinone are then added, and the whole is heated on the water-bath until a complete solution is obtained. The melt, which has an intense blue colour, is then poured into 20 times its weight of water, and caustic soda is added till nearly neutral, to precipitate the dye. After filtering and well washing with water, the dyestuff, which forms a resinous mass, is dried at about 70° C. It is readily soluble in alcohol and in acetone, but less soluble in water. Hydrochloric acid added to the aqueous solution precipitates the hydrochloride.—T. A. L.

*Improvements relating to the Manufacture of Dihydroxynaphthalene-sulphonic Acids and of corresponding Azo Dyes.* J. Y. Johnson, London. From "The Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 18,924, October 9, 1893.

THE sulphonic acids described are obtained by fusing with caustic soda under partial vacuum conditions, the 1,1'-amidonaphthol sulphonic acid of Eng. Pat. 9676 of 1890 (this Journal, 1891, 538) and the 1,1'-amidonaphthol disulphonic acid of Ger. Pat. 62,289. In a similar manner the azo dyestuffs corresponding to these dihydroxynaphthalene sulphonic acids are produced by heating the azo-dyestuffs from the above-mentioned amidonaphthol sulphonic acids with caustic alkalis. For the preparation of 1,1'-dihydroxynaphthalene sulphonic acid, about 30 kilos. of 1,1'-amidonaphthol sulphonic acid are heated with 20 kilos. of caustic soda in 200 litres of water in an autoclave for about 36 hours to 230° C. The melt is then made acid with hydrochloric acid and potassium chloride is added to precipitate the dihydroxynaphthalene potassium sulphonate. This salt appears to be identical with that described in Ger. Pat.

67,829. The same method can be applied to the 1,1'-amidonaphthol disulphonic acid, the same quantities being taken, and the end of the operation is determined as follows:—A sample of the melt is acidified with acetic acid and after adding sodium acetate a small quantity of diazobenzene chloride solution is run in. The dye thus formed is poured on to filter paper and spotted with soda solution. If it turns yellow, characteristic of the dihydroxynaphthalene disulphonic acid, the operation is complete, and the melt is worked up by acidifying it with hydrochloric acid and concentrating on the water-bath until a crystalline paste is obtained. After filter-pressing, the product is crystallised from 90 per cent. alcohol, from which it separates in needles. It appears to be identical with 1,1'-dihydroxynaphthalene disulphonic acid S. The strength of the caustic soda in the above examples may be increased up to 10 per cent., or a weaker solution may be employed, and similarly the temperature may be increased to 250° C., but decomposition takes place at 270° C., even with dilute lye. Regarding the production of azo derivatives of the 1,1'-dihydroxynaphthalene sulphonic acid according to this invention, the following process is given. Diazobenzene sulphonic acid from 20 kilos. of crystallised sodium sulphanilate, 30 kilos. of 30 per cent. hydrochloric acid, and 7 kilos. of sodium nitrite, is stirred into 2,400 litres of water containing 24 kilos. of 1,1'-amido-naphthol sulphonic acid. When the combination is complete the solution is raised to the boil and one-fifth the volume of brine added, when the dyestuff separates out on cooling in a crystalline form. After filter-pressing and drying it is mixed with six times its weight of 35 per cent. caustic soda lye, and heated to 120–130° C. in an open vessel or an autoclave. The conversion is complete when a test dissolves with a yellowish-red and not a bluish-red colour in water, as at the commencement of the operation. The melt is then poured into an excess of dilute sulphuric acid containing about 25 per cent. of  $\text{H}_2\text{SO}_4$ , the solution is boiled and the dyestuff precipitated with salt, after which it is filter-pressed and dried. A similar method is employed for obtaining azo dyes derived from 1,1'-dihydroxynaphthalene disulphonic acid by heating the dyestuff, obtained from a diazo salt and 1,1'-amidonaphthol disulphonic acid, with caustic soda lye as above.—T. A. L.

*The Manufacture or Production of Colouring Matters, and New Materials therefor.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 19,623, October 18, 1893.

THE present specification, which is an extension of Eng. Pat. 8898 of 1893, and of Eng. Pat. 16,780 of 1893 (this Journal, 1894, 511 and 801), describes the formation of so-called mixed 1,3-dialkyl-naphthylene diamines and their sulphonic acids, and also the production of colouring matters therefrom. By the term mixed is understood a dialkylated naphthylene diamine containing a fatty alkyl group in the one, and an aromatic alkyl group in the second amido group. The dyestuffs are obtained by condensing the *m*-dialkylated naphthylene diamines with the nitroso compounds of secondary or tertiary aromatic amines or with substances which act similarly, or else by oxidising the above-mentioned diamines with certain alkylated *p*-diamines. If necessary, the products obtained are rendered soluble by sulphonation. The production of one of the diamines referred to is described in the following example:—A mixture of 32 kilos. of 1,3,1'-naphthylamine disulphonic acid, 25 kilos. of sodium ethyl sulphate, 4.5 kilos. of soda, and 100 litres of water is heated in an autoclave for 6–8 hours at 150–170° C. The melt, after cooling, is dissolved in hot water, neutralised with sodium carbonate, filtered, and acidified with hydrochloric acid, a small quantity of salt being added. On cooling, the acid sodium salt of 1,3,1'-ethylnaphthylamine disulphonic acid separates out in colourless needles. To obtain the dialkylated naphthylene diamine sulphonic acid, 30 kilos. of the acid so formed, 90 kilos. of aniline, and 30 kilos. of aniline hydrochloride are heated for 5–6 hours at 160–170° C. Sulphur dioxide is given off during the operation, and, when cool, the melt is poured into 90 kilos. of dilute muriatic acid,

when 1,3,4'-ethylphenylnaphthylene diamine sulphonic acid separates out, and can be purified by boiling with alcohol. The following example illustrates the production of a colouring matter from this compound:—A mixture of 6.8 kilos. of 1,3,4'-ethylphenylnaphthylene diamine sulphonic acid, 9.6 kilos. of nitroso-ethylbenzyl aniline sulphonic acid, 2.7 kilos. of sodium acetate, and 20 kilos. of alcohol is heated until the nitroso compound is no longer to be detected. The melt is then poured into water, and the colouring matter salted out. A colouring matter dyeing a somewhat similar shade is obtained by substituting for the nitroso compound 12 kilos. of phenyl-azo-phenylnaphthylamine sulphonic acid (1.4) and using 40 kilos. of glacial acetic acid in place of the alcohol, and warming the mixture for four hours on the water-bath. The melt having been poured into hot water, the colouring matter is salted out. A dyestuff which gives clear bluish-red shades on wool, faster to light than similar colouring matters, is produced by heating together 8.36 kilos. of 1,3,4'-di-*p*-tolynaphthylene diamine sulphonic acid, 5.46 kilos. of azobenzene, 1.36 kilos. of sodium acetate, and 30 kilos. of glacial acetic acid at 80–110° C. until the liquid becomes red and no further increase of colour takes place. The product, which is a monosulphonic acid, is separated by pouring into water, and can be crystallised from alcohol. To convert it into a soluble dyestuff, 1 kilo. is mixed with 3–5 kilos. of fuming sulphuric acid containing 25 per cent. of anhydride, and heated at 60°–100° C. until a sample is soluble in hot water. The melt is then poured into ice water, and the sulphonic acid which separates is converted into its ammonium salt. As already mentioned in Eng. Pat. 11,892 of 1893 (this Journal, 1894, 631), certain differences are produced in the shades of these dyestuffs also, according to the solvent or diluent used in the condensation, or if the reaction be carried on at temperatures above 100° C.—T. A. L.

*Improvements in the Manufacture and Production of Mordant-dyeing Colouring Matters.* J. Y. Johnson, London. From "The Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 19,962, October 23, 1893.

THESE colouring matters are thiazine derivatives obtained from the 1,2,3', 1,2,1', and 1,2,2'-dihydroxy-naphthalene sulphonic acids or the corresponding amido-naphthol sulphonic acids by oxidising these compounds together with *p*-diamine thiosulphonic acids, and finally converting the thionated indophenol or indamine into the thionine dye either by heating with chloride of zinc, with sodium thiosulphate in dilute acetic acid, or with concentrated sulphuric acid. About 25 kilos. of amido-dimethyl-aniline thiosulphonic acid are dissolved in 600 litres of water, together with sufficient dilute ammonia to neutralise the acid, and the solution is diluted with 1,800 litres of water and 200 kilos. of 30 per cent. acetic acid. A saturated solution of 24 kilos. of 1,2,3'-dihydroxy-naphthalene sulphonic acid is added, and with constant agitation a concentrated solution of 15 kilos. of potassium bichromate, the temperature being kept at 12°–15° C. After standing some time, salt, together with a little sodium acetate, is added to precipitate the indophenol thiosulphonate. To convert this product into the colouring matter, 10 kilos. of it are boiled with 100 kilos. of a 50 per cent. zinc chloride solution. The whole is gradually evaporated until a homogeneous green mass is obtained which on pouring into water deposits the colouring matter as a violet flocculent precipitate. The dihydroxy-naphthalene sulphonic acid or the corresponding amido-naphthol sulphonic acid may be replaced by a nitroso-naphthol sulphonic acid for which the quantities are as follows:—About 12.5 kilos. of amido-dimethyl-aniline thiosulphonic acid and 14 kilos. of 1,2,3'-nitroso-naphthol sulphonic acid (the nitroso-derivative of Schäffer's acid), are dissolved in 400 litres of water, together with 9 kilos. of 20 per cent. ammonia. The solution is then acidified with 80 kilos. of 30 per cent. acetic acid, and boiled until the yellowish colour of the solution has been replaced by a dirty violet coloration. This may then be precipitated

with salt and sodium acetate as above, or the solution directly may be heated with 25 kilos. of sodium thiosulphate in 60 litres of water. After a short time the colouring matters separate out in bronzy crystals, and after filtering off is dried or used in the form of paste.—T. A. L.

*The Manufacture or Production of New Colouring Matters.* H. E. Newton, London. From "The Farbendabrike Verwalt. F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 20,579, October 31, 1894.

THE 1,1',4,4'-amidonaphtholdisulphonic acid obtained from 1,3,4'-naphthalene trisulphonic acid by nitrating, reducing, and subsequently fusing with alkalis, combines readily with benzidine, its analogues and homologues, to form symmetrical or mixed tetra- colouring matters. These colouring matters dye uncoloured cotton in shades from greenish-blue or blue to violet and brown, and can be further diazotised and combined on the fibre, giving shades very fast to washing and fading.—T. A. L.

*The Manufacture of a New Amidonaphtholdisulphonic Acid and Colouring Matters therefrom.* H. E. Newton, London. From "The Farbendabrike Verwalt. F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 20,580, October 31, 1893.

ACCORDING to the researches of Armstrong and Wynne (Proc. Chem. Soc. 1890, 1293), when 2,4'-naphthylamine sulphonic acid is treated at a low temperature with fuming sulphuric acid it is converted into two isomeric  $\beta$ -naphthylamine disulphonic acids having the constitutions—

By the further action of fuming sulphuric acid at a higher temperature it has now been found that a  $\beta$ -naphthylamine trisulphonic acid is produced having the formula—

When fused with alkalis the sulphonic acid group in the position 4' is replaced by the hydroxyl group. By heating with dilute mineral acids the sulphonic acid group in the position 1 is removed, and there results 2,2',1'-naphthylamine disulphonic acid. The new amidonaphtholdisulphonic acid is to be employed for the production of dyestuffs of the benzidine series, either to give symmetrical or mixed derivatives, and the colouring matters obtained may be further diazotised and combined on the fibre. The usual methods are given for obtaining the dyestuffs, and the following quantities are employed for the production of the new raw product:—50 kilos. of the acid sodium salt of one of the above-mentioned  $\beta$ -naphthylamine disulphonic acids, or of a mixture of the two, are mixed with 150–200 kilos. of fuming sulphuric acid containing 40 per cent. of anhydride, keeping the temperature low. The melt is then gradually warmed on the water-bath until a test when diazotised and combined with K salt gives a readily soluble orange-red dyestuff. The melt, after careful dilution, is then worked up by the usual methods into the sodium salt of the new  $\beta$ -naphthylamine trisulphonic acid. In order to convert this into the amidonaphthol disulphonic acid, 50 kilos. of the sodium  $\beta$ -naphthylamine trisulphonate, 100 kilos. of caustic soda, and 50 litres of water are heated in an autoclave to 160°–220° C. until no further increase in the amount of dyestuff occurs on testing with a diazo compound. The melt, after cooling, is then acidulated with hydrochloric acid, and the acid sodium salt of the new amidonaphthol disulphonic acid separates out in matted needles. Dilute solutions of this salt show a violet-blue fluorescence, which turns blue on the addition of alkalis. Ferric chloride added to the same solution produces a green, whilst chloride of lime gives a yellow colour. The diazo compound is orange-yellow and can be salted out: it turns violet-red with alkalis.—T. A. L.

*Improvements relating to the Manufacture of Colouring Matters.* H. H. Lake, London. From K. Ochler, Offenbach-on-the-Maine, Germany. Eng. Pat. 22,204, November 20, 1893.

BRUSHING colouring matters for unmordanted cotton are produced according to this patent by combining one molecular proportion of tetrazo-diphenyl or -ditolyl with one molecular proportion of 1,1',3,3'-amido-naphthol disulphonic acid and one molecular proportion of 2,3-dihydroxynaphthalene. The tetrazo solution from 11 kilos. of tellurine or 9.2 kilos. of benzidine, 75 kilos. of 12.5 per cent. hydrochloric acid, 500 litres of water, and 7 kilos. of sodium nitrite is run into a solution containing 18 kilos. of the acid potassium salt of the above-mentioned amido-naphthol disulphonic acid and 8 kilos. of caustic soda. After a short time a solution of 8 kilos. of 2,3-dihydroxy-naphthalene and 1 kilos. of caustic soda in 100 litres of water is run in, and having stood 24 hours the mixture is heated and the dyestuff precipitated with salt, filter-pressed, and dried. The colouring matter forms a blackish-brown powder soluble in water with a violet and in concentrated sulphuric acid with a blue colour.—T. A. L.

## V.—TEXTILES: COTTON, WOOL, SILK, Etc.

"*Antibenzene-pyrine.*" R. Kissling. Chem. Zeit. 18, 1894, 330.

ANTIBENZENE-PYRINE, which is recommended as a means for preventing the electric excitation of the benzene (petroleum spirit) commonly used in the dry-cleaning of wearing apparel (this Journal, 1894, 385), is a yellow turbid liquid of sp. gr. 0.716. It begins to boil at 50° C., 63 per cent. distilling over at 180° C. The residue is a brownish jelly which on ignition leaves an ash, 90 per cent. of which consists of magnesia. This residue contains about 40 per cent. of fatty acids and 60 per cent. of unsaponifiable hydrocarbons boiling at from 240 to 280°. Accordingly antibenzene-pyrine consists of from 60 to 65 per cent. of benzene of sp. gr. 0.700, from 20 to 25 per cent. of hydrocarbons of specific gravity from 0.825 to 0.830, and from 10 to 12 per cent. of magnesia soap.—C. O. W.

*The Waterproofing of Materials.* A. Foerster. Färb. Zeit. 5, 287–288.

ONE method of waterproofing consists in precipitating some insoluble compound within the pores of the fabric. If, for example, the material be first steeped in the solution of a compound in which the oxide of aluminium, zinc, tin, antimony, or lead plays the part of an acid, and then be immersed in the solution of a salt of one of those metals, a precipitate of a hydroxide or hydroxides results: e.g., from potassium aluminate and zinc acetate are formed hydroxides of zinc and aluminium. Or, the first bath may contain a soluble silicate, and the second a salt of some metal which forms an insoluble silicate. All these precipitates, however, act in some way injuriously upon the fabrics, generally rendering them stiff and harsh. On the other hand, if fatty substances, such as stearin, are employed, the materials are oily and greasy to the touch.

A combination of metallic salts and fats gives a better result. Two baths are prepared: the first contains an emulsion of soap with potassium aluminate and sodium silicate; the second is a concentrated solution of aluminium acetate. By successive steeping in these baths the material is waterproofed, the precipitate consisting of aluminium silicate together with the aluminium compound of a fatty acid. Squeezing between rollers and washing complete the process. The proportions in the first bath should be 90 grms. of fatty acid and 60 grms. of silicic acid for 100 kilos. of water. The amount of aluminium acetate must be twice or thrice the quantity theoretically necessary.

Materials thus waterproofed exclude rain, but allow air to penetrate, and preserve their essential properties, unimpaired.

An interesting process is that patented by Dr. J. Hoffert, of Berlin, who makes use of the fact that gum and gelatin suffer a change under the influence of formaldehyde, losing their adhesive property and becoming completely insoluble in water. The fabric is steeped in a solution of gum or gelatin and is then subjected to the action of gaseous formaldehyde or its solution in water. Most probably this renders the fabric air- as well as waterproof, and, if so, although useful for many purposes, it is quite unsuitable for clothing. The patent specification states that fabrics so prepared are specially useful for medical bandages, owing to the well-known antiseptic properties of formaldehyde.—R. B. B.

## PATENTS.

*Improvements in Scouring, Degreasing, and Cleaning Wool and in Apparatus therefor.* Frederick N. Turney, Nottingham. Eng. Pat. 8179, April 22, 1893.

THE material to be degreased is enclosed in perforated wire-gauze boxes or trays and conveyed into suitable vapour-tight chambers, containing a series of tanks arranged stepwise, through which some volatile solvent is constantly flowing. The trays containing wool travel in a direction contrary to that of the solvent, and are regularly dipped into the tanks and withdrawn; previous to drying, the cages, if made collapsible, may pass through squeezing rollers to remove excess of solvent. The wool is then conveyed into a suitable heater and dried; the vapour given off is condensed, so as to be used over again in addition to that recovered from the tanks. Special provision is made to prevent loss of vapour, both when the wool enters and when it leaves the degreasing chamber. The above process, although specially applied to the degreasing of wool, may also be used for cotton waste, leather scraps, &c.—W. R.

*A New and Improved Process for the Treatment of Textile Vegetable Fibres, more especially those of the Urtica Family.* A. F. B. Gomess, South Kensington. Eng. Pat. 15,945, August 23, 1893.

THE cementing matter in the epidermis is mostly removed by boiling in alkalis. The epidermis is rendered brittle by boiling in a strong solution of some efflorescent salt, e.g., neutral sulphate of soda, drying; the epidermis and cementing matter are then subsequently removed by rotating the same in a suitable drum or otherwise. The fibre may then be bleached by any known means.—W. R.

*A Chemical Preparation for Cleaning and Reviving all Kinds of Clothing.* H. Mällerson, London. Eng. Pat. 17,711, September 20, 1893.

THE preparation described is a mixture of turpentine, 26½ parts; ammonia solution, 19 parts; methylated spirit, 25 parts; ether, 2½ parts; acetic ether, 2½ parts; and water, 25 parts; all by weight. The claim is "a compound for use in cleaning and reviving all kinds of clothing."—L. A.

*New or Improved Process and Machinery for Imparting a Silky Appearance to Cotton and other Yarns.* H. Jacob, Argenteuil, France. Eng. Pat. 19,095, October 11, 1893.

THE cotton or other yarn is first prepared by passing through a liquid obtained by distilling together methyl alcohol and β-naphthol disulphonate of sodium. The threads are then separated from each other by passing through thread guides and thread plates, and then through a first series of dressing boxes containing very fluid collodion, and dried by passage through a series of drying chests. The alcohol and ether given off from the collodion are suitably condensed and used for preparing further quantities of collodion. The dressing and drying is repeated a second time, using collodion of

greater viscosity; and again a third time, the collodion being still thicker. The drying chests are connected by dressing boxes, which are formed of a central tube communicating with one of the collodion distributors. To the ends of this tube are connected by union joints other tubes of the same diameter, and opening into the interior of the drying chests. These tubes only communicate with each other by small orifices, which are of the same diameter as the threads to be dressed. The collodion is forced through the tube by a piston plate resting on the collodion in the receiver, and is weighted.

The capillary tube has inlet and outlet orifices provided for the passage of the thread at the same time the collodion is forced on to it, the excess of collodion being squeezed off previous to drying.

The threads finally pass through glazing rollers which have a rotatory, also an alternating rectilinear movement, so that the whole of the thread surface is submitted to the glazing action.

The collodion may or may not be coloured by aniline dyes.—W. R.

*A Paste or Mixture for Cleansing Various Materials and Articles.* M. Baerlein and C. Dreyfus, Manchester. Eng. Pat. 19,733, October 20, 1893.

See under III., page 939.

*Improvements in Machines for Washing Fibres.* J. Lazarus and M. Jefferson, Bradford. Eng. Pat. 20,197, October 26, 1893.

THE invention consists, firstly, of an improved construction, arrangement, and combination of levers designed to ensure a relatively increased efficiency, and a powerful weighting or "nip" of the squeezing rollers.

A second improvement has reference to the propulsion of the fibre in the washing-machine. In the washing-machine a grid or tray is placed in the sud-bowl; it has a rising and falling motion, and also a frame with a corrugated or ribbed under-surface inside the grid or tray, having a reciprocating to-and-fro motion; the fibre is carried forward between the grid or tray and frame, and is passed on to the squeezing rollers.—W. R.

*Improvements in the Mode of and in Apparatus for Removing Fibre from Cotton-Seed.* R. Silcock, Poulton-le-Fylde. Eng. Pat. 24,546, December 20, 1893.

THE cotton-seed is fed into a revolving cylinder, whilst hot sulphuric acid of about 120° T. is being sprayed upon it. The cylinder is perforated so that the seeds with the larger fibrous covering upon them are retained in contact with the acid a longer time; when the external fibrous matter is destroyed, the seed is mixed with phosphate powder (preferably mineral) to neutralise the excess of acid employed. The mixture is then introduced into a second revolving cylinder, also perforated, containing emery wheels fixed on the axis and revolving at a high speed; emery blocks are also attached to the cylinder in the spaces between the wheels. The fibrous portion of the seeds becomes rubbed off and falls through the perforations. The dust formed is drawn off by an exhaust fan; it forms a valuable fertiliser.

The cotton seed, if necessary, is washed in a bean-washer, dried, and crushed.—W. R.

*Improvements in or relating to the Carbonisation of Rags, Wool, or the like.* Gebrüder Schüll, Düren. Eng. Pat. 12,047, June 21, 1894.

THE rags, wool, or the like, to be carbonised, are contained in a perforated or wire lattice-work covered drum, enclosed in a chamber. In the walls of the chamber is a system of hot-air passages for the purpose of heating the drum referred to. Acid fumes are conveyed into the chamber and penetrate into the interior of the perforated cage, which is continually rotating; the rags, &c., thus constantly present fresh surfaces to the action of the fumes. The

cotton dust is shaken out by the motion of the drum, and regularly removed from the chamber by a convenient opening. Since atmospheric air has no access to the chamber, any chance of an explosion is thus avoided.

—W. R.

## VI.—DYEING, CALICO PRINTING, PAPER-STAINING, AND BLEACHING.

*The Influence of the Structure of Fibril Fibres on their Attraction for Colouring Matters.* G. von Georgievics. Chem. Zeit. Rep. 18, 1894, 170.

THE author has endeavoured experimentally to answer the question as to whether, besides the chemical character of the substance of the textile fibre and of the colouring matter employed, also the structure of the material to be dyed plays any part in the absorption and fixation of the dye. Comparative dye-trials were carefully made with cotton and precipitated cellulose, using Benzopurpurin 4 B, also with the same materials and Benzo-azurine G and Methylene blue. The same textile materials were also tested as to their behaviour with tannin solutions. Dye-trials were further made with mercerised cotton, and similar ones with precipitated cellulose, using Benzopurpurin 1 B and Benzopurpurin G as the typical dyestuffs. The influence of structure was also tested on the absorption of dyestuff in the cases both of wool and asbestos. From these tests the conclusion is drawn that the structure of the fibre does exert an influence on the absorption of the dyestuffs employed. The fibrous nature of the material and the structure of the same not only influence the absorption of the dyestuff, but also influence the fixation of the latter on the material. These conclusions were especially confirmed through the results obtained with wool and asbestos. Both materials in a finely pulverised form, to which they had been reduced by purely chemical means, the question of chemical change of the substance being thus excluded, showed a far less capacity in such form of powder to absorb colouring matters than in that of the original fibre.—R. B. B.

*Substantive Azo Colouring Matters from 1,4-Naphthylamine Sulphonic Acid.* M. D. Bona. Farb. Zeit. 5, 335.

THIS is a study of the connection between the fastness of colouring matters and their constitution. The conclusions are: (1) That the presence of 1,4-naphthionic acid, influences favourably the fastness to alkalis; (2) It is unfavourable to fastness to acids; (3) It influences the shade of the dyestuff in the direction of red; (4) The naphthionic acid dyestuffs are inferior in fastness to light to those containing salicylic acid.—R. B. B.

*Sodium Polysulphide, a New Material for Domestic and Industrial Scouring, Bleaching, and Cleansing Purposes.* A. Dankelman. Chem. Zeit. 18, 1894, 332.

SODIUM monosulphide is largely used for the unhairing of skins, but its domestic use was prevented by reason of its corrosive nature. By treating the polysulphides of calcium with sodium carbonate, solutions of sodium polysulphide free from monosulphide are obtained, which are mixed with sodium carbonate and sold under the name of "Polysulfine." This preparation possesses a mild alkaline action and dissolves or emulsifies fatty matters adhering to the textile fibres. Especially in wool-scouring it was found that polysulfine very readily dissolves all the suint without in the least affecting the fibre.—C. O. W.

Stains. W. Cloth caused by Ammonio-Cupric  
(O. Walter. *Färb. Zeit.* 5, 1894, 164.

THE bottoms of milling and washing machines are frequently lined with brass or copper, and these metals often cause stains, especially when ammoniacal liquors are used in them, as is frequently the case. This was found to be due to the formation of ammonio-cupric oxide, which subsequently acting upon the cloth, causes an alteration of the colour-absorbing capacities of the wool, especially increasing its affinity for indigo. By providing glass bottoms in such machines this objection is avoided.—C. O. W.

*Progress in the Industry of Fast Woollen Dyeing.*  
Oesterr. Wollen- u. Leinen-Ind. 1894, 14, 220.

ALIZARIN colours are more and more gaining ground in this industry, especially blue alizarin dyestuffs, which have been much favoured during the past year by the fashions; as have also alizarin-cyanines, which latter have come to the front in producing the blues having a greenish shade with carded yarns, serges, and chevrons, they being used in conjunction with the fluochrome mordant. In certain factories aniline black is much used for loose wool, and, moreover, not with the old single bath process, but with wool previously mordanted with potassium bichromate and cream of tartar. This method permits also of the combination of alizarin black and logwood, which has been tried for the new grey mantle cloths of the German army. The Austrian Government has recently made the use of alizarin red compulsory for dyeing the breeches worn by the cavalry; further investigations are in progress on the use of alizarin colours for dyeing mantle cloths artillery brown and grey. Of the smaller States, Roumania was the first to use aniline black as a substitute for logwood.

In Germany experiments are being conducted by the Badische Anilin- und Soda-fabrik on the use of Anthracene blue in conjunction with Mordant yellow of that firm, both for grey and hunter's green. Mordant yellow has superseded the older Wool-yellow, which was less fast than fustic, as has also Cassella's Anthracene yellow, which covers better than Mordant yellow.

As in the dyeing of loose wool, so also in piece-dyeing, the use of alizarin dyestuffs is increasing, although in many factories they are being kept back by bad ingrain dyes.

The writer acknowledges the indifferent ingrain tinctorial power of the alizarin dyes, and ascribes it to the rapid formation of lakes. It may be, however, that the recently patented process, whereby the alizarin dye is first applied in an acid bath and subsequently fixed by means of chromium salts, will give a better result. It is still an open question whether in the process of mordanting with "fluochrome," which has advantages over potassium chromate, it is possible to protect the copper vessels by the introduction of strips of zinc. The writer has obtained satisfactory results on a small scale.

Among the substitutes for alizarin colours the following has been introduced:—Diamine fast red, Anthracite black, and Diamond black. The first has been used for loose wool, whereas the latter are employed principally for yarns, especially Anthracite black, which is used for dark blue and black. For navy blue, Galloeyanine is much used in spite of its fugitiveness towards light. Of new colouring matters which withstand the milling process, Chloramine yellow and the sulphocyanines are worthy of mention.

The writer finally discusses the subject of dyeing loose wool with indigo dyes; it appears that the new "hyposulphite vat" is now generally in use for bright shades, whereas for deep shades the old wood vat has advantages.

—A. R. L.

*Canaigre.* S. Kapff. *Färb. Zeit.* 5, 290—291.

In *Färb. Zeit.* 1, Nos. 18 and 19, the author published the results of his research on the tannin-containing canaigre root of New Mexico and Arizona, and concluded that the extract of the root might possibly serve to replace sumach extract. He has since made experiments in America on the large scale with unfavourable results.

A quantity of the undried root was sent from Arizona to New York and made into an extract at 30° B. This gave a clear reddish solution and worked favourably, as on the small scale. There is no objection to its use, except that of the cost, but this appears insurmountable, and is entirely due to the freight expenses. Even when the percentage of water is reduced by drying in the sun, from 58 to 25 per cent., the cost of transport still renders the price too high for competition with sumach, although the price of land is almost nothing, no cultivation is necessary, and the negro labour for collecting the roots is cheap. No one has yet shown sufficient enterprise to set up extraction plant on the spot. There is thus no possibility of the extended use of canaigre until present sources of tannin are exhausted.—R. B. B.

*The Effect of Certain Metallic Salts in the Direct Development of Insoluble Azo Colouring Matters on the Fibre.*  
Gaberti and Pecc. *Färb. Zeit.* 5, 333—335.

EXPERIMENTS were made with Paranitraniline red, Amido-azo-benzene red,  $\alpha$ -Naphthylamine grenate, Benzidine puce, and Nitrosamine (B. A. S. F.). The metallic compounds employed were various salts of iron, copper, zinc, manganese, chromium, lead, and nickel; also vanadium chloride, calcium, magnesium, and aluminium acetates, potassium ferro- and ferri-cyanide, and alkaline solutions of iron, chromium, zinc, and aluminium (e.g. sodium aluminate).

Moderately concentrated solutions of the metallic salts were added in various proportions to the printing colour prepared in the ordinary manner, which was then printed on cotton previously prepared with sodium- $\beta$ -naphthol; the fabric being subsequently dried, passed once through a Mather and Platt's steaming apparatus, and soaped.

Salts of copper exercise a remarkable effect on the shade; the printing colour containing amido-azo-benzene, paranitraniline, or nitrosamine, together with a copper salt, gave, on printing, eutech-browns, of greater or less intensity according to the quantity of copper. These shades are fast to light, soap, and acids, especially those from Cassella's paranitraniline. An example of the process of preparing the printing colour is here given: 62 grms. Paranitraniline C (Cassella) are dissolved in 200 cc. HCl at 21° B. and 155 cc. boiling water. Now add 309 cc. cold water and 300 grms. ice. Add gradually 272 cc. sodium nitrite solution (145 grms. per litre), leave for 20 minutes with occasional agitation, filter, and pour the filtered solution into a mixture of 2,200 grms. of gum tragacanth (75 grms. per litre), with 250 grms. of sodium acetate, and 186 grms. of copper nitrate (17° B.).

The browns from amido-azo-benzene and nitrosamine lose much of their brilliancy in the passage through the "Mather and Platt."  $\alpha$ -Naphthylamine grenate is rendered duller by copper salts, and benzidine puce becomes yellower.

If, instead of adding the copper compound to the printing colour, it is mixed with the sodium- $\beta$ -naphthol solution in the form of a copper soap, prepared with glycerol and ammonia, very red shades of eutech-brown are yielded with  $\alpha$ -naphthylamine, not differing greatly from brazil wood browns. With paranitraniline, &c., the shades are the same as when the copper salt is mixed with the printing colour, but the preparation with sodium- $\beta$ -naphthol and a copper soap does not answer well in practice, for the fabric thus prepared quickly becomes brown, and clear whites cannot be obtained. The printing colours containing copper salts, with the exception of the nitrosamine copper chloride mixture, remain undecomposed for a sufficient time to permit of their practical application.

Zinc chloride decomposes all azo colours, and if mixed with the printing colour a considerable evolution of gas results, with such quantities of foam that even printing tests on the small scale are impossible. A similar effect results from the use of potassium ferrocyanide.

Iron salts, especially ferrous sulphate, serve as resists for the red and grenate, but do not give clear whites; in this respect they are surpassed by potassium ferrocyanide, which when applied in concentrated solution, thickened with dextrin, forms an excellent resist for Paranitraniline red.

Other metallic compounds, salts of chromium, manganese, zinc, nickel, or vanadium, merely tend to impart to the shade a more bluish tone. Alkaline chromium solutions destroy the colour. Salts of aluminium and the alkaline earths influence the shade towards yellow. Sodium zincate and aluminate destroy the colour. Potassium ferrieyanide has no apparent action.—R. B. B.

*Dyeing with Lead Chromate from the Hygienic Standpoint.* Cazeneuve. *Rev. d'Hygiène*, 1894, **16**, 382.

See under XVIII. B., page 970.

*An Improved Form of Hard Glass Beakers for Dyeing Tests.* R. Lepetit. *Färber Zeit.* **5**, 1894, 183.

See under XXIII., page 978.

## PATENTS.

*Improvements relating to the Dyeing of Dyed Cotton Yarns and the like.* W. P. Thompson, Liverpool, Manchester, and London. From T. Salzmann, Dornbirn, Austria. Eng. Pat. 21,843, November 15, 1893.

This invention is an improvement in the method of drying, which follows the dyeing process for cotton yarn, slivers, or roving, described in Eng. Pat. 17,872 of 1890 (this Journal, 1891, 918), and consists in the use of a peculiarly-constructed reel or spool. The reel consists of a wire spiral and a number of longitudinal bars of wood or other material, each bar being made in two parts, which are grooved to receive the spiral, and screwed or otherwise fastened together. On this skeleton reel the yarn is wound after dyeing, and dried preparatory to further treatment, the drying being quickly accomplished owing to the air having free access to the material from both the interior and exterior of the reel.—R. B. B.

*Machine for Loosening and Drying Yarns and Threads after Sarching, Dyeing, and like Operations.* J. T. Blass, Seiffhennersdorf, Saxony. Eng. Pat. 10,993, June 6, 1894.

The yarn is clamped between two rollers attached to a revolving arm, and, while the arm is in rotary motion, strikes an anvil block. This block consists preferably of a wooden roller mounted on an adjustable axle, the use of a cylindrical block obviating injury to the yarn by contact with sharp edges. By means of springs one of each pair of rollers can be turned and held in an upright position, to admit of the introduction and removal of the yarn.—R. B. B.

*Improvements relating to the Dyeing of Fibre.* H. H. Lake, London. From M. E. Waldstein and A. H. Peter, New York, and E. Spott, Brooklyn, U.S.A. Eng. Pat. 14,223, July 24, 1894.

Stannic acid is fixed on the fibre in the form of an insoluble stannate. After mordanting with a stannic salt in the ordinary manner, the fibre is passed through a bath containing, for example, lead acetate or an ammoniacal solution of a barium salt. The insoluble stannate thus formed has no injurious action on the fibre, whereas stannic acid tends to render it brittle and rotten.—R. B. B.

## VII.—ACIDS, ALKALIS, AND SALTS.

*The Occurrence of Perchlorate in Potassium Nitrate.* C. Haussermann. *Chem. Zeit.* 1894, **18**, 1206-1207. (See page 979.)

The author confirms the observation of Hellich that the "pure" nitre intended for gunpowder manufacture has been found invariably to contain perchlorate. The samples were almost free from chloride. The fact that no chlorate was present was ascertained by heating the solution with a copper-zinc couple and testing the resulting liquid with silver nitrate. No greater turbidity than that due to the trace of chloride originally present was produced. Further, the nitric acid distilling over on heating this nitre with excess of sulphuric acid at 100° C., was nearly free from chlorine that could be recognised by means of silver nitrate. Even the acid coming over at a temperature above 100° C. gave only a slight reaction for chlorine, but towards the end of the distillation an acid was obtained which contained a noteworthy amount of chlorine. Perchlorates are only attacked by sulphuric acid above 100° C., whereas chlorates are decomposed before 100° C. is reached.

It may be admitted that Hellich's statement that the chlorine compound constantly present in nitre is a perchlorate is correct, but it does not appear that any danger can arise from this impurity in nitre used for making gunpowder, as samples thus contaminated have been successfully employed for years. The removal of the perchlorate on a manufacturing scale could be effected by keeping the salt fused in a cast-iron vessel until no increase in the reaction for chlorine in a test-portion withdrawn from the mass from time to time, was obtained. In the event of this plan being adopted special care would have to be taken to avoid the presence of nitrite in the finished recrystallised product. The origin of the perchlorate is to be traced to the sodium nitrate used in preparing the potassium salt by double decomposition. That the perchlorate actually exists in Chili saltpetre containing 0.5-1.5 per cent. of sodium chloride, is indicated by the circumstance that the nitric acid prepared from nitrate of this description is richest in chlorine towards the end of the distillation, the amount coming over being large at the beginning of the process (decomposition of chloride) and at the end (decomposition of perchlorate), and least in the middle fraction. Perchlorate probably exists ready formed in caliche, which is known to contain iodate. In the analysis of Chili saltpetre the probable presence of perchlorate should be considered, and the return of the nitrate by difference should, the author thinks, not be regarded as adequate.—B. B.

## PATENTS.

*Improvements in the Manufacture of Alumina and Aluminous Compounds and Metallic Aluminium or Alloys of Aluminium, and obtaining Chlorine, Hydrochloric Acid, Carbonate of Soda, and other By-Products resulting from this Manufacture.* D. A. Peniakoff, Paris. Eng. Pat. 20,604, April 5 (under International Convention), 1893.

Pure alumina is obtained by melting bauxite with sodium carbonate, and precipitating the cleared solution by carbonic acid. But the alkaline aluminate is obtained more economically by heating bauxite with sodium sulphate, a process which yields also sulphur dioxide and oxygen, according to

the equation:  $\text{Al}_2\text{O}_3 + \text{Na}_2\text{SO}_4 = 2\text{NaAlO}_2 + \text{SO}_2 + \text{O}$ . The effluent gases are mixed with "a proportionate quantity of hot air," and passed over previously calcined bay salt heated to about 500° C. to form sodium sulphate, chlorine being evolved mixed with the excess of nitrogen. If steam is used hydrochloric acid is obtained instead of chlorine. The sodium aluminate is decomposed, as in the first process, by carbonic acid, to obtain alumina and recover sodium carbonate. When using sodium sulphate it is preferred to add sodium sulphide in the proportion indicated by the equation,  $4\text{Al}_2\text{O}_3 + \text{Na}_2\text{S} + 3\text{Na}_2\text{SO}_4 = 8\text{NaAlO}_2 + 4\text{SO}_2$ , and pyrites may replace the sodium sulphate; in which case the sulphur dioxide may be burned into sulphuric acid. But if it is preferred to pass the gas over sodium chloride, some oxidising material capable of easy regeneration, such as barium peroxide, calcium manganite or plumbite, or cupric sulphate, is added.

Aluminium sulphide for application in obtaining aluminium is produced by passing carbon bisulphide over aluminium sulphate heated to "nasecent red," thus—

and the carbon bisulphide is regenerated by passing the sulphur vapour over incandescent carbon. The process is modified by heating aluminium sulphate with a sulphide, as sodium sulphide, in vapour of sulphur, the final products being aluminium sulphide, sodium sulphide, and sulphur dioxide. Another method consists in heating a mixture of alumina and calcium sulphide in sulphur vapour to obtain aluminium sulphide and sulphur dioxide, with recovery of the alkali sulphide. It is stated that the function of the sulphide consists in transferring the sulphur in vapour to the alumina, at the same time depriving the latter of its oxygen, so that "an extremely small quantity of sulphuret is sufficient to sulphurate considerable quantities of alumina or of sulphate of alumina."

Lead or iron may be used for reducing aluminium sulphide to obtain aluminium. It is stated that lead does not form alloys with aluminium; but that when iron is used as reducing agent, the aluminium may be obtained pure or alloyed with iron. In regenerating the lead or iron sulphide, the sulphur dioxide evolved may be utilised in obtaining sulphuric acid. Sodium may replace lead or iron in reducing aluminium sulphide. It is pointed out that aluminium sulphide being much richer in metal than the chloride or fluoride, it is better suited for electrolytic reduction, and it is stated that when fused it dissolves alumina easily, and that the mixture may be electrolysed as readily as the pure sulphide.—E. S.

*Improvements in the Construction of Ammonia Apparatus.* G. E. Davis, Salford. Eng. Pat. 19,630, October 18, 1893.

HEXAGONAL caps, steadied by wings, are placed on the division plates of the ammonia apparatus, covering a number of small apertures, instead of the central aperture covered by a cap, described in Patent 16,349, 1888 (this Journal, 1889, 884). A bent dip-pipe is used to convey the liquor from the division of the apparatus immediately above the liming chamber to a point above the liquor level, in order to prevent the entrance of lime to the upper portion of the apparatus. A perforated tray with hexagonal caps is placed at a spot above where the liquor enters the apparatus, so that the caps, when luted by steam condensed upon them, may act as washers to arrest mechanically-carried particles.—E. S.

*Improvements in the Manufacture of Cement from Chance or Ammonia-Soda Alkali Waste or the like.* B. K. Rigby, Ditton, F. A. R. Neill, St. Helens, and A. C. Carr, Rainhill. Eng. Pat. 19,705 (amended), October 19, 1893.

THE inventors have found that the waste from the ammonia-soda process, and from the Chance sulphur-recovery process, may be utilised in making cement, if first washed in a prescribed manner, and then incorporated with so much lime or other alkaline earth as will reduce to 3½ per cent., or preferably to 3 per cent., the proportion of injurious matter retained by the waste. The proportion of lime to

be added is determined by analysis of the mud, and the constituents named as injurious are calcium chloride and sulphate, sodium chloride and sulphate, iron sulphide, and free sulphur.

For washing the waste, a double tank, or one having more than two compartments, is used, into the upper part of which the waste, mixed with water, is run through a pipe having as many valved branches as there are compartments. The tank is first supplied with water to about three-fourths its height from a water pipe. The finely-divided waste gradually settles to the bottom in a washed state. The supernatant liquid is removed by pipes placed at suitable heights. The washed waste is emptied out through a mud cock by aid of a hose, or through the manhole door.

The amendment consists in the substitution of the word "Ammonia-soda waste" for "Le Blanc alkali waste," as formerly used.—E. S.

*Improvements in Acid Raisers or Steam-Jet Pumps for Raising Acids, Alkalis, and other Liquids.* C. Long, Walsall, and W. H. Burkitt, Wednesbury. Eng. Pat. 5187, March 13, 1894.

See under I., page 930.

*Improvements in Condensing Plates.* J. W. Mackenzie, London. From Brante and Co., Lyons, France. Eng. Pat. 7229, April 11, 1894.

See under I., page 930.

*Improvements in the Process of Manufacturing Carbonic Acid, and in the Production of By-Products, such as Sodium Sulphate and Magnesium Sulphate.* E. W. Enequist, New York, U.S.A. Eng. Pat. 14,228, July 24, 1894.

NITRE-CAKE (acid sodium sulphate) containing about 25 per cent. available acid, is dissolved in about twice its weight of hot water, and is brought into contact with magnesite in excess under conditions admitting of the collection of the carbonic acid evolved. The solution, containing sodium and magnesium sulphates, is drawn off into tanks, in which Glauber's salt crystallises out. The solution containing now sodium-magnesium sulphate, is concentrated to 42°–45° B., when the double salt crystallises. If it is desired to obtain a larger proportion of sodium sulphate, sodium chloride is added, either in the first stage of the process or later. The sodium-magnesium sulphate may be decomposed by an alkaline hydrate or carbonate, to obtain magnesium hydroxide or carbonate and an alkaline sulphate; or the double salt may be decomposed by an alkaline earth hydrate.—E. S.

## VIII.—GLASS, POTTERY, AND ENAMELS.

### PATENTS.

*Improvements in Moulds for Moulding Terra Cotta Blocks and like Articles.* H. L. Doulton and J. M. Carr, Lambeth. Eng. Pat. 19,445, October 16, 1893.

TERRA cotta blocks are moulded in plaster of Paris moulds, and hitherto the massive and cumbersome outer case of the mould has been made likewise of plaster of Paris; a large amount of plaster is needed for them, and when the mould is no longer required the material of which the case is made is useless. In the present invention the outer case is made of a fibrous asphalt which is readily worked when hot, and

sets firmly when cold. The material can be used over again by melting the material. The composition preferred is pitch, 1 cwt., old plaster moulds, ground, 56 to 75 lb.; cocoa fibre, 4 to 8 lb.—V. C.

*Improvements in the Manufacture of Tubes and Vessels of Covered Glass.* N. Browne, Cheapside. From G. Kastner, Dresden. Eng. Pat. 10,159, May 25, 1894.

These are improvements in tubes and receptacles, consisting of a glass-core and a protecting covering of paper or fabric surrounding it.

Glass tubes and vessels covered in the customary manner with layers of impregnated paper or other material are apt to break from shock, and if they do so break or splinter, portions of glass are liable to be carried by a liquid flowing through the tubes to parts such as stop-cock valves, whereby they are liable to do damage.

In the present invention the glass tube is separated from its envelope of paper or the like by a layer of viscous asphalt, preferably that known as "Goudron Mineral," with 3 to 5 per cent. mineral oil added. Elastic rings separate the tube from its paper envelope at the two ends. By this arrangement the liability to fracture is much diminished, and if breakage does occur the fragments of glass adhere to the viscous asphalt.—V. C.

*Process of Decorating Pottery, Glass, or similar Goods.* Percy Shelley, Longton, Staffordshire. Eng. Pat. 13,047, July 5, 1894.

The design is taken from the engraving in the usual manner, printers' oil being used either alone or mixed with non-metallic colouring matter, and the design is at once transferred to the article. The paper is then pulled off and the design (in oil) is dusted over with the colours. By this process decorative effects are obtained which have hitherto only been produced by painting, filling in, or laying on the colours by pencil or similar implement. A further advantage is that a design can be printed in various colours in which each colour can be produced in any part of the design without being superimposed upon the colour in which the design has been transferred.—V. C.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

*Effect of Frost on Building Construction.* Zeits. Oesterr. Ingenieur- und Architektenvereins, 1894, 7.

VARIOUS experimental walls were constructed in Vienna in the winter of 1890, and the behaviour of different cementitious materials was thus ascertained. The walls were 1 m. in length, 2 m. in height, and had a thickness of 0.3 m. They were built with common mortar, Roman cement, Portland cement, and slag cement, the water used being in some cases at the prevailing winter temperature, and in others at a temperature of 25° C. Water containing 7 per cent. of common salt was also used for some of the tests with Roman and Portland cement. The external temperature ranged from -3° C. to -16° C. The results of the experiments may be summarised as follows: Portland cement (to which no common lime had been added) gave good results, the remaining materials being inferior thereto. In the case of Roman and Portland cement the addition of salt appears to be useful.—B. B.

*Quick-Setting Cement.* H. Geyer. Thonind. Zeit. 1894, 18, 280.

CERTAIN hydraulic cements set almost instantaneously. The author found that reburning such cements at a high temperature had no influence on their rapidity of setting, but

on preparing mixtures with a varying ratio of alumina to silica, he arrived at the result (already well known) that a high content of alumina is favourable to rapid setting. He points out that it is not sufficient to know the ratio of alumina to the total silica in the raw materials, as the latter may be present as coarse quartz, and be more or less inert, thus disturbing the calculated ratio which assumes that both silica and alumina are completely combined as silicates and aluminates.—B. B.

*Improvements in Testing Hydraulic Cement.* C. Prussing. Thonind. Zeit. 1894, 18, 251.

The author submits the following propositions for consideration:—

(1.) The standard test for the constancy of volume ("soundness") of hydraulic cement can no longer be considered adequate.

(2.) Cement can be considered faultless in respect of constancy of volume when two test-pats, after 27 days' hardening, the one in cold water, the other in water at 90° C., remain hard and perfectly free from buckling or cracking.

(3.) It is desirable to insert in the standard rules for testing, a rapid test for constancy of volume, consisting in allowing test-pats to harden for 24 hours in the air, then for two hours under cold water, and finally for 22 hours under water at 90° C.

(4.) Cements, to be designated "slow-setting," should remain at least two hours after gauging without showing signs of incipient setting.

(5.) A slow-setting cement should not be considered faulty because its setting is accompanied by a notable rise of temperature. Many slow-setting cements of excellent quality begin to set after five or six hours, and then set completely in one hour, giving a rise of temperature of 5°—7° C. Provided such cements stand the pat-test, they are generally better than such as begin to set after half an hour to one hour, and finish the setting process after about seven hours, as in this gradual setting the evolution of heat is so distributed that no perceptible rise of temperature takes place.

(6.) It is not correct to judge the quality of cement merely from the 28 day cold test on tension specimens. Compression tests and hot tests after 7, 14, and 28 days should also be used.—B. B.

## PATENTS.

*Improvements in the Manufacture of Cement from Chance or Ammonia Soda, Alkali Waste, or the like.* B. K. Rigby, Ditton, F. A. R. Neill, St. Helens, and A. C. Carr, Rainhill. Eng. Pat. 19,705, October 19, 1893.

See under VII., page 948.

*Improvements in the Preservation of Wood.* E. Groebe, Koenigsstein, Germany. Eng. Pat. 14,599, July 30, 1894.

Dry wood is placed in a close vessel from which the air is exhausted: a solution of "tribasic or tetrabasic phosphate of lime in sulphurous acid" is then admitted, and the charge is submitted to a pressure of from six to eight atmospheres for about two hours. The wood thus impregnated is dried, preferably in a heated enclosed space, to admit recovery of the escaping sulphurous acid.—E. S.

# X.—METALLURGY.

*The Cyanide Process.* Walter H. Virgoe. Eng. and Mining J. 57, 1894, 533—534.

In the matter of gold-bearing ores, concentrates and tailings, only such material is adapted to the process as is, First: Low-grade, because the higher the grade of the material the stronger the solution of cyanide must be, and the greater the resulting loss of cyanide. An extraction of 80 per cent. on a 25 dollar ore, means a loss in the tailings of 5 dols. per ton. Similar extraction on 100 dollar ore means a loss per ton of 20 dols., besides a heavier loss in cyanide, owing to the necessity of using a more powerful solution. Second: The gold in the ore and concentrates must be in a fine state of division, as potassium cyanide, like chlorine, exerts a very slow solvent action on coarse particles of gold. Third: The material must be entirely free from deleterious compounds capable of absorbing the cyanide, such as copper-bearing minerals and the easily decomposable products of the oxidation of pyrites, such as ferrous and ferric sulphates and basic sulphates, &c. Fourth: The material must, above all things, possess good leaching properties at the size of mesh required for economical extraction.

Again, the manner in which the gold is mechanically carried in the material is of paramount importance. If it is contained in crystals of sphalerite or galena it cannot be extracted, and this is very frequently the case where the gold is contained in mispickel—arsenical pyrites. Some tellurium ores offer considerable difficulty, yet in certain cases, as at Cripple Creek, high percentages have been saved at a small cost of cyanide.

At the Mercuer gold mine, Fairfield, Utah, the ore is a siliceous limestone, containing magnetic oxide of iron, traces of cinnabar and gold. The latter occurs in a very fine state of division, coating the particles of magnetic oxide, and giving the ore a value of about 15·22 dols. per ton. The cost of treatment, extracting 73 per cent. by bullion returns from the refinery works, is about 2·40 dols. per ton, exclusive of royalty, superintendence, and office expenses, thus set forth:—

	Dollars.
Potassium cyanide, 1·27 lb. per ton .....	0·66
Zinc, 0·55 lb. per ton.....	0·05
Labour (7 shifts per 24 hours, 6 day and 1 night) ..	1·12
Supplies, repairs, fuel, freight.....	0·57
	<hr/> 2·40

This expense has been lowered by an increase being made in the capacity of the plant. The ore is a typical one for the process.

The process is far better adapted to the treatment of auriferous than argentiferous material. In fact, it must be admitted that the cyanide process is, comparatively speaking, unsuitable for the treatment of silver ores, and notably because argentiferous ores leach with more difficulty than gold ores in the raw state.

Again, because cyanogen has a greater affinity for gold than for silver, consequently silver ores require long treatment with strong solutions. Silver-bearing minerals are much more complex in their nature than those containing gold, and require finer crushing and agitation, and consume a larger amount of cyanide. Lastly, such silver ores as can be treated successfully by lixiviation methods can usually be more economically handled by some process in which cheaper chemicals are used, and on which no royalties or other charges have to be paid, such as the Van Patera process. However, without discussing the merits of the cyanide process as compared with others, it may be stated that the chlorides and bromides of silver are easily reduced, and extractions of over 80 per cent. have been made on antimonial silver ores, the value of which does not exceed 30 dols. to 40 dols. per ton. Difficulty has always been encountered in treating silver sulphide ores. Those in which the value is contained in galena crystals cannot be handled.

Regarding the qualities in an ore essential for successful treatment, it can be at once seen that large percentages of

extraction may be achieved at a heavy cost of cyanide, and the leaching qualities at the mesh requisite for economical extraction may be such as to render the process worse than useless owing to the length of time required to draw off the cyanide solution and succeeding wash waters. In this latter difficulty is the keynote of many of the failures in cyanide plants. Filter presses have been tried in South Africa, but without satisfactory results, owing to their cost and the power required to work them. No mechanical means have as yet been devised for the satisfactory separation of pulp and solution in the case of poor leaching ores. Such an invention would revolutionize the metallurgical world as far as the wet reduction of ore is concerned.

The cyanide process is very far from being a simple one. Many of its difficulties are mechanical, but there are also many chemical problems in connection with it that must be thoroughly understood, in order that a factory may be run with intelligence and economy.

The value of the alkali cyanides in the MacArthur-Forrest process of extracting gold and silver from their ores depends upon the fact that such cyanides possess the property of forming soluble double salts with these metals, viz.:—

I.

II.

It is possible that hydrogen is evolved during these reactions, as thus shown:—

III.

Since potassium cyanide costs 50 cents per pound, delivered in cases of 100 lb., the primary aim in treating all ores is to insure a maximum amount of extraction, with a minimum consumption of cyanide, consequently all sources of waste should be investigated, and, where possible, averted.

That such sources of waste may be investigated it is necessary to examine closely the reactions due to atmospheric influence liable to occur in the storage tanks; reactions occurring in the leaching vats in treating different classes of ore, also reactions occurring in the zinc precipitation boxes. Considering, first, the following sources of waste liable to occur in the supply tanks:—

1. Sources of waste due to the exposure of the solution to the effects of light and air.
2. Sources of waste due to impurities in the factory water used.

It is well known that cyanide of potassium, when exposed to the air, deliquesces and evolves hydrocyanic acid—

The presence of the hydrocyanic acid gas in large quantities in the atmosphere surrounding the tanks in cyanide factories is always a very noticeable feature.

The evolution of this gas may be brought about in another manner, where the surface of the solution is exposed to the air and is liable to absorb carbonic acid gas. Thus:—

Again, potassium cyanide is a very easily oxidizable compound and when in solution in contact with the atmosphere, is liable to be converted to some extent into potassium cyanate, and this again into the bicarbonate:—

Instances are known where impurities in the factory water used, have decomposed the potassium cyanide to a very marked extent. It will be seen that water holding much carbonic acid gas in solution, or water containing soluble metallic sulphates will decompose a cyanide solution. Hence, water as pure as possible should always be used in factory solutions.

The determination of the sources of waste due to reactions in the leaching vats is a complex and difficult matter. The sources of waste in the leaching vats are similar to those in the storage tanks. There are also the losses due to consumption of cyanide by base metals in the ore treated. In regard to hematite and limonite ores the consumption of cyanide is usually low. This is also the case with sulphide of iron ores, provided the latter be free from all oxidation. The manganese gold ores of California consume a little more cyanide than the corresponding ferruginous ores. Galena and zinc blende are unattacked. Great difficulty has always been experienced in treating copper ores containing more than 2 per cent. or 3 per cent. of copper, owing to the very heavy consumption of cyanide. A quarter of one per cent. solution is invariably the best to be adopted, if ores containing copper must be treated by this process.

Pyritiferous ores are liable to contain, especially when mined above the permanent water-level, soluble salts of iron and small amounts of free sulphuric acid. It is necessary, therefore, in treating ores of this description, to first leach them with water, in order to dissolve the ferrous and ferric sulphates out, and afterward to decompose the insoluble basic sulphates with a solution of soda-lye or lime water.

In the zinc precipitation boxes not only does an amount of zinc enter into solution proportionate to the amount of gold and silver and base metals precipitated, such as Cu, Sb, As, &c., thus:—

but far more, and the excess is proportionate to the decomposition of the potassium cyanide. Looking at the reactions occurring in an ordinary zinc box, reactions in part purely chemical, in part electro-chemical, involving a waste of cyanide, it is seen that as soon as the gold is deposited on the zinc shavings, galvanic action is at once established between the electro-negative gold and the electro-positive zinc, hydrogen is vigorously evolved at the negative pole and the zinc converted into hydrate, which in turn is immediately attacked by the excess of potassium cyanide, forming zinc potassium cyanide and potash:—

As this reaction is incessantly occurring the solution becomes very strongly alkaline in the lower compartments of the zinc boxes. This galvanic action is a source of a large loss of cyanide, not only by causing the formation of the double salt of zinc and potassium cyanide, but undoubtedly by causing the oxidation of a certain quantity of potassium cyanide to cyanate.

In the majority of factories the mistake is made of not discarding screens made of fine iron wire in the compartments of the precipitation boxes, because there is a strong galvanic action established immediately between the zinc and the iron so soon as the cyanide solution flows through them, hindering the deposition of gold and silver and augmenting to a marked degree the loss of cyanide through solution of the zinc, besides largely increasing the zinc slimes in the product and making them more difficult to handle. Commercial zinc is only slightly soluble in potassium cyanide, but in contact with iron it is readily dissolved, especially in the lower compartments of the precipitation boxes, where the solution is most strongly alkaline. This reaction is thus expressed—

Again, the majority of boxes in use are far too long. There is no advantage to be gained in using boxes 20, 30, and 40 ft. in length.

Precipitation takes place mainly in the upper compartments, after which the solution is unnecessarily exposed to the action of the zinc.

It is best to observe the rule that a larger number of smaller boxes is preferable in economic practice to a small number of very long boxes such as those referred to in the last paragraph.

The cyanide process has a very serious competitor, in the treatment of many classes of ore, in chlorination, "a process

involving the payment of no royalties, and which can be worked far more cheaply than formerly owing to the great reduction in the price of chemicals used."

*The Cyanide Process in the Transvaal Mines.* W. R. Feldmann. Eng. and Mining J. 58, 1894, 102-103.

There are now (about 50) plants, of an aggregate treating capacity of some 230,000 to 240,000 tons per month, at present in use for the treatment of tailings and concentrates on the Witwatersrand are of great variety, both in size and design, the general principle in all of them being, of course, the same. The objects which they have to fulfil consist briefly in: 1. Leaching of the ore, tailings, or concentrates with weak solution of cyanide of potassium for the purpose of dissolving the gold. 2. Treatment of the solution to precipitate the dissolved gold in the metallic form. In all plants we have the three main features: 1. Leaching or filter vats. 2. Launderers, for precipitation—"zinc boxes." 3. Storage vats for solutions.

In considering the treatment required for any particular ore or tailings three points are to be taken into account: the condition of the gold, whether coarse or fine; the material, whether acid or neutral; and what metals with a strong affinity for cyanogen are contained in the material.

The condition of the gold, that is its coarseness or fineness, determines the length of time required in contact with the cyanide solution to effect its dissolution. On the Witwatersrand, generally speaking, the gold is very fine, and a period of 12 hours' standing under a strong solution is usually sufficient with tailings to dissolve as much of the gold as it is commercially profitable to extract. Further treatment with weak solutions is chiefly in the nature of washing to remove the already dissolved gold. In the treatment of pyritic concentrates a very much longer contact with the solvent is required.

By an acid ore—a familiar phrase in the district—is understood the presence of the products of the partial decomposition of pyrites, usually free sulphuric acid, soluble salts, such as ferrous sulphate, or insoluble basic iron salts. All of these substances are destructive to cyanide, forming with it compounds useless in the extraction of gold.

As to other metals found in the ore, certain copper compounds are the most troublesome. It has been found, however, that in many cases this difficulty may be overcome by the use of weak solutions.

The treatment of acid ore, or rather tailings rendered acid by the partial oxidation of the crushed pyritous ore, offers more difficulty than in the case of the free-milling ore. In order to overcome the cyanide-destroying qualities of the acid or iron salts present it is necessary to have recourse to neutralisation by means of an alkali or alkaline earth, caustic soda or lime, with or without a preliminary water washing to remove such soluble "cyanicides" as may be present. If the quantity of cyanide present is large, and, by testing, a considerable proportion of it is found to be soluble in water, a preliminary water wash is generally applied. It has hitherto frequently been the custom to water wash in the same tank in which the subsequent treatment with cyanide is effected, the water wash being run to waste. In the writer's opinion this is a practice which cannot be too strongly condemned, as accounting largely for the so-called "mysterious" discrepancy between the expected yield of gold as estimated from assays made before and after the treatment and the actual return. When a water wash charged with acid out of the ore comes in contact with residual quantities of cyanide solution lying in the bottom and adhering to the sides of the tank, a certain quantity of hydrocyanic acid gas is liberated, which, diffusing through the whole tank, is capable of dissolving a not inconsiderable amount of gold from the ore. Such dissolved gold is not precipitated, even if passed through zinc, and is consequently run to waste with the water wash. If, in order to economise caustic soda and lime, water washing be adopted, it should be done in tanks which are reserved for the special purpose, and the ore should then be transferred to the cyanide treatment vats. This means a little extra cost for handling, but it

will, in most cases, amount to less than the loss of gold incurred by the other method. In order to neutralise the remaining acid, a quantity of a solution of caustic soda, of which the amount necessary must be approximately determined by the experimental test, is run on, allowed to stand for an hour or so, and then drained off into an "alkali" sump, there to be made up to strength for the next lot. Where practicable it is a good plan to mix powdered lime with the ore, as this not only saves caustic soda, but also keeps the cyanide solutions freer from suspended ferric hydrate, which, in the case of using caustic soda alone, makes them very turbid, and fouds the zinc.

The preliminary treatment having been finished, cyanide solutions are applied. The strength of the first solution may vary from 0.25 per cent. to 0.5 per cent. The number and strength of subsequent solutions and washes and the time of contact required depend entirely on the quality and nature of the ore.

The average extraction from acid ore, say from 5 or 6 dwt. stuff, may be put down at 70 per cent. Concentrates of 3 oz. value will give an extraction from 90 up to 98 per cent. in three or four weeks' treatment. With regard to the treatment in the presence of metals with an affinity for cyanogen, the principle usually adopted is to apply the weakest possible solution which has been approved by experience.

Having obtained the gold in solution, precipitation in the zinc boxes is, as a rule, a simple matter. Roughly speaking, it may be said that if solutions leaving the boxes assay more than 2 dwt. per ton the precipitation is not as it should be. This may be owing to the paucity of zinc in the boxes, which should be rectified at once, or too great speed in the flow of the solution, or in a few cases to insufficient cyanide in the solution.

Having reconverted the gold into the metallic form by passage of the solutions through the zinc shavings it is obtained as a sludgy looking precipitate, commonly known as "slimes," and the next step is to get it into marketable shape. This is done by separating from the zinc, drying, roasting, and smelting. The clean up, which takes place once or twice a month, is conducted as follows:—A small amount of clean water is run through the boxes to remove the cyanide solution, which might otherwise be injurious to the workmen. The zinc shavings are taken out after being twisted and scrubbed in the water to remove as far as possible the gold adhering to them. In some cases there is quite a thick plating on the zinc which cannot well be removed by scrubbing, but this is usually ignored, as the shavings are returned to the boxes in any case, and this plating will go into the precipitate of the next clean-up. Having removed nearly all the coarse zinc, the precipitate contained in the water is allowed to settle; an addition of a little alum will considerably assist this process. Most of the clear water is then siphoned or pumped off, and the precipitate together with the remaining small quantity of water is drawn off into a calico or linen filter or a filter press. After drying sufficiently to handle with a scoop the precipitate may be further dried in iron pots and is then ready for roasting and smelting.

The object of the roasting is to oxidise the greater portion of the zinc, which has, in the form of small chips and shavings, fallen through the zinc-box trays, so as to cause it to combine in the subsequent smelting with the fluxes, and leave the bullion fairly fine. Oxidation by the aid of the atmospheric air is sufficient, but a certain amount of the zinc oxide subsequently becomes reduced by the carbon of the plumbago melting pots and re-enters the bullion. A good method of roasting has been found to be the addition of a little nitre, say about 3 to 10 per cent. to the precipitate. It is best applied as a strong solution before drying the precipitate, so that it gets equally mixed with the whole mass.

The precipitate having been sufficiently roasted, the next step is to mix it with suitable quantities of flux, and smelt the mixture in plumbago pots. The fluxes commonly used are bicarbonate of soda, borax, and sand.

One of the great bugbears of the cyanide men on the Witwatersrand has been the treatment of slimes, by which

is meant the very fine, or in the case of free-milling ores, the clayey portion of the tailings. Many suggestions have been made for the treatment of these, but the only really practicable scheme so far appears to be to allow them to dry thoroughly, and by screening or otherwise to reduce them to a fine powder. This powder is thoroughly mixed with sandy tailings, and the mixture will usually allow of percolation fairly well. The trouble is that if these slimes go into the vats in half-dried lumps they will absorb liquid and pass away as slime. There is no chemical difficulty in the way. Another solution suggested is dry crushing and direct treatment of the powdered ore with cyanide.

An important discussion now going on relates to the question of removing the pyrites from tailings by concentration before treating the latter by cyanide.

The cost of treating tailings by the cyanide process is necessarily determined in large part by local conditions, the nature of the ore treated, and the special facilities for handling the ore. The biggest item of cost is generally for the cyanide of potassium, which probably averages on the Witwatersrand about 48 cents per ton of ore treated.

#### *The Cyanide Process.* W. R. Feldtmann. Eng. and Mining J. 53, 1894, 218—219.

MR. VIRGOE, in describing the nature of the material suitable for treatment by the cyanide process, names four points as essential:

1. He says that the ores to be treated "must be low-grade because the higher the grade of the material the stronger the solution of cyanide must be, and the greater the loss of cyanide," and points out that 20 per cent. left in a 25 dols. ore means less loss of gold than 20 per cent. left in a 100 dols. ore. While granting that the treatment of high-grade ore, concentrates, or tailings entails the use of comparatively strong solutions, and consequently increased loss of cyanide, the author would suggest that higher grade material will generally bear a greater working cost. Farther, experience on the Witwatersrand is that whereas 80 per cent. is a good extraction from low-grade tailings of say 5 dols. or so, we can treat concentrates running 60 dols. and upward to obtain a 90 per cent. to 95 per cent. extraction. As regards cost, it is mentioned that the Crown Reef Gold Mining Company is treating its concentrates (from blankets) by cyanide at a cost of about 5.50 dols. per ton.

Coming to the question of the various sources of loss of cyanide, the author states that the amount of the chemical wasted in the zinc boxes is probably not so great as Mr. Virgoe seems to think. From some experiments tried in the laboratories of the African Gold Recovery Company, it appears that, by means of pure zinc-potassium cyanide (without admixture of free potassium cyanide) gold is dissolved from ores.

Mr. Virgoe can satisfy himself, the author considers, that all the cyanogen in the zinc-potassium cyanide can be combined with an alkali, and can be determined by the silver nitrate test by simply rendering a solution of the double salt fairly, strongly alkaline, by addition of sodium or potassium hydrate.

In actual practice it is found that addition of alkali to working solutions which have become somewhat weak in alkali brings up the strength by regenerating, *i.e.*, decomposing the zinc cyanide. Potassium iodide being used as an indicator, this is not a fallacious result effected by the misleading action of free alkali on the silver nitrate test. So that, as a matter of fact, when the solutions are pretty strongly alkaline they contain no zinc as cyanide, but only as hydrate dissolved in alkali (zincate of potash, &c.). In consequence, the author would prefer to err on the side of somewhat excessively long boxes and thorough precipitation rather than too limited a precipitating surface, and consequent pumping back into the tailings or ore of solutions assaying high in gold.

*Sweep Smelting and Refining of Gold, Silver, and Platinum Metals.* Bettel. Johannesburg Chem. and Met. Soc., July 28, 1894.

THE processes in outline are as follows:—The material for smelting was mixed with Derbyshire lead slag and fluorspar, and melted in a furnace containing molten lead and leady copper matte. The material having been melted down, the copper being received into the matte together with some gold and silver, the remainder, with the exception of a small quantity passing into the slag, was retained in the molten lead. During melting, it may be remarked, a certain proportion of the lead and silver passed away in fume. The remainder of the processes consisted in extracting the gold, silver, copper, lead, platinum, palladium, and iridium from each other.

*Notes and Queries on Cyanide Works.* Caldecott. Johannesburg Chem. and Met. Soc., July 28, 1894.

IN the re-treatment of a mass of residues by the African Gold Recovery Company, from which on the average 70 per cent. of the original gold had been already extracted, the extraordinary fact was discovered that their value was no longer 15 dwts., but 9 dwts. only. Explanations as to the reason of this discrepancy were sought for in vain, until, when all the residues had been re-treated, the site they had occupied was sampled, with the result that the top 3 ins. were found to assay 38 dwts. fine gold per ton, evidently derived from the soluble gold, produced by the cyanide solution, contained in the residues, continuing to act after discharge, and being gradually washed downward by the rain. The Barrett Gold Mining Company at Kaapsche Hoop, some 30 miles west of Barberton, is probably unique, in that much of its ore is treated by cyanide, and very good extractions obtained, without preliminary crushing in a battery or other machine. The ore is of an earthy nature, containing much ferric hydrate, and is so soft that it does not require blasting for extraction, but is dug out with pick and shovel. By sifting through trommels worked by hand, the finer portion, after mixing with tailings to assist filtration, is fitted for cyanide treatment. These trommels, or cylindrical rotary screens, are also very useful in separating coarse tailings from lumps of slimes. They may be seen in operation at the Caledonia Works of the African Gold Recovery Company, near the Meyer and Charlton battery. For this purpose they possess the following advantages over the incline sieves generally used:—

1. Greater capacity: a sieve 8 ft. long and 3 ft. in diameter has a capacity of 50 tons per day, and requires six Kadlirs to work it.
2. Cleaner product: sieving of three or even four holes to the linear inch may be used.
3. Perfect mixing of lime with tailings, when this is required.
4. Delivery of lumps into trucks without further handling.

It will be generally admitted that the weight of a cubic foot of tailings depends upon, at least, the following factors, all liable to variation from time to time:—

- (1.) Nature of material, *e.g.*, whether weathered or pyritic.
- (2.) Degree of fineness; other things being equal, the finer the material the lighter it is.
- (3.) Whether or not closely packed, as in a settling pit or lower portion of a deep vat, or much tossed about, as by the operation of sifting.
- (4.) Percentage of moisture contained.

It is mentioned in Mr. W. R. Feldtmann's valuable article on gold extraction by means of cyanide (see page 952) that solutions, after leaving the zinc boxes, should not contain more than 2 dwts. per ton of fine gold. Assuming that this amount is present, it is asked if this would not account for the soluble gold in the residues, which is sometimes considered mysterious? Every ton of water introduced into the works, as moisture in the tailings charged, obviously necessitates a ton of dilute cyanide solution discharged as moisture in the residues. When a final water washing is

used, this dilute solution is, of course, contained in the lower portions of the residues only. Here we would seem to have the reason for the lower portion of the residues being richer than the upper, simply because it is moistened with gold-bearing solution instead of water, and theories as to the cyanide solution carrying rich gold slimes downwards through the charge, and depositing them near the bottom, would appear needless. As some 20,000 tons of dilute solution (8 per cent. on the total tonnage of tailings treated) is discharged monthly on the Rand as moisture in the residues, the loss involved, assuming it to contain only the dwts. per ton, would amount to 50,000 lb. per annum, and the necessity for constant watchfulness to ensure proper precipitation in the zinc-boxes by using solution of sufficient strength, sufficient zinc, and an equable slow rate of flow is obvious.

*Ore Roasting with a Blast.* L. Klotz. Chem. Zeit. 1894, 18, 953—954.

FREQUENTLY complete roasting is not required, as, for instance, with silver-bearing copper pyrites, which, in order to obtain a good matte, should contain from 10 to 12 per cent. of sulphur after roasting. It is often stated that ores should be dead roasted, and the required proportion of sulphur made up by adding raw ore. Practical men, however, know that this is not correct. The O'Hara furnace, which has lately been much used, has a production of from 24 to 36 tons in 24 hours. Its first cost and up-keep are, however, more than many mines can afford. Brückner cylinders are theoretically good, yet they have only been used in a few districts, for partially roasting easily treated ores, or for chlorinizing. For more perfect roasting, or where high temperatures are necessary, they are not suitable. A new roasting furnace has lately been designed by Bartlett, originally for making zinc white, but it is also applicable for roasting pyrites. It is rectangular in shape and has a bed of perforated cast-iron plates, through which a low pressure blast is introduced; from the upper part of the furnace a flue leads to the dust chambers.

Live coal, or burning wood, is spread over the bed, and covered with a uniform layer of a mixture of roughly broken ore and fuel, and the blast turned on. The roasting is completed in about an hour, when the roasted product, which is in the form of porous slabs, is withdrawn. After a few shovelful of coal have been thrown on the bed the furnace is ready for re-charging. The consumption of fuel, which may be coal slack, or fine coke or charcoal, is about 10 or 12 per cent. of the weight of ore roasted. Ore of all percentages of sulphur, from medium to high, can be roasted; it is not suitable for lead ores, however, as a considerable loss of lead takes place, although no loss of silver has been observed. A blast has also been tried with other forms of roasting furnaces. In applying it to the Brückner cylinder, the refractory lining was removed, and six iron ribs attached to the inside of the outer cylinder. To these a second cylinder of perforated iron was fixed. The ribs divide the space between the two cylinders into six compartments. From each of these an iron tube leads to a central distributing valve, so arranged that it only admits the blast to those compartments over which the ore lies as the cylinder rotates. In the "Pearce" furnace the stirring arms and shaft are made hollow, and the former are perforated so as to admit the blast into the midst of the mass which is being roasted.—R. B. P.

*The Manufacture of Steel in the Open Hearth.* J. A. Lencavech. Iron and Steel Institute. Autumn Meeting, 1894. The Ironmonger, 68, 1894, 366—368.

AFTER dealing with the advantages of the open hearth process, the author describes a furnace with stationary hearth erected at Aazin to produce steel of extra welding quality for tube manufacture. The bricks for the burners and roof are made of magnesite, and special precautions are taken to prevent the accumulation of dust in the chequer work by having straight passages without any projections. The chief point of the process is the injection of cold air through the sides or roof as well as the usual blast into the

from 5 to the extent of 5 to 15 per cent. of the weight of the air necessary for the complete combustion of the gas. The air jets are directed on to the metal bath, by the use of thin lined tuyeres, to lay bare the metal and to remove the glassy layer of slag or cinder from its surface so as to facilitate oxidation. The air jets likewise cause an intimate mixture of the hot air and gas as they enter the hearth, and by so doing raise the temperature of the flame and direct it on to the surface of the metallic bath. The final result of the combustion is only slightly modified by them.

At first sight a cooling effect might be expected, but the result is otherwise, as the air-jet uncovers the metal and stimulates the oxidation with the consequent combustion of the liberated carbon monoxide. Without the use of the sloping tuyere, this gas mostly escapes combustion "as it is separated from the zone of hot air by a layer of the products of combustion which only contain a very little free oxygen." Under these circumstances it only burns in the regenerators, where it is less effective than in the hearth. In the pig and scrap process the relative proportion of pig has been increased, the charge now consisting of two-fifths of hematite iron and three-fifths of old iron, scrap, &c., for the production of extra-weldable steel with 25 to 30 per cent. elongation. Previously the furnaces produced only 30 to 32 tons of steel per 24 hours, but owing to the prevention of stoppages by the use of the dust-catchers, &c., the minimum out-turn is 1,000 tons of ingots per month of 25 effective working days, or on an average, 40 tons per day. The coal consumption in the producers has at the same time been reduced from 748 lb. to 605 lb. per ton of steel made. As the object of blowing in air is to refine as much pig-iron as possible by the air as well as to increase the out-turn there should ensue less costly conditions owing to the smaller quantity of slag, and to its removal at a relatively low temperature.

The author announces his intention of making further trials with the blast at higher pressures and also with the ore process, and gives the following as the probable mode of procedure. The metal is fused at a relatively low temperature in a slightly oxidising flame to obtain the desulphurisation by the manganese contained in the pig-iron or added in the form of ferro manganese. The temperature is then raised by blowing to oxidise silicon and phosphorus. Lime is added to neutralise the last traces of phosphoric acid. Combined with the blowing it will be possible to oxidise by successive additions of hematite or other ores, which should be as pure as possible and possess calcareous gangues. It will be advantageous to reduce the use of these oxides to a minimum especially when they are difficult to obtain. The elimination of sulphur, phosphorus, and silicon is effected at temperatures lower than that at which decarburisation commences, or, in other words, at which carbonic oxide is generated. At these relatively low temperatures the basic walls do not suffer. Decarburisation can be performed with a very small minimum of ore, or the ore may be entirely omitted, for the main points for consideration are the shortening of the operation as well as obtaining economical results. The smaller the quantity of ore the less will be the amount of slag, the shorter will be the time required for repairs, and the lower will be the cost of converting the iron into steel.

In the discussion, Mr. James Riley stated that the author had given them the credit side for the hastening of the process, but he had not given the debit side for loss and expense of blowing, &c. He could not understand why they should try to accomplish in the open hearth furnace inefficiently that which could be so well done in the Bessemer converter. Mr. G. J. Snell said that in the ore process if the metal was to be oxidised by air they would not recover the metal from the oxide put in. The great advantage of the open hearth ore process was that by the reduction of the added ore as much steel was obtained from the furnace as there was pig-iron put in, which meant that they got the steel from the added ore for practically the price of the ore. This advantage would be sacrificed by the plan proposed. On the other side the process is put forward as of advantage in cases where good ore is not obtainable. —A. W.

*The Use of Caustic Lime in the Blast Furnace.* Sir Lowthian Bell, Iron and Steel Inst. Autumn Meeting, 1894. The Ironmonger, 68, 1894, 346—351.

It has been found that a preliminary calcination of limestone results in a considerable advantage in blast furnaces of about 50 ft. in height, but in the case of the modern furnaces of 80 ft. high the saving in fuel does not repay the cost incurred in calcining in the lime-kiln. The author infers from experiments that the carbon dioxide is not expelled from calcium carbonate until the temperature is reached in its descent in the furnace where the dioxide is reduced to carbon monoxide by the heated coke. If this be correct, then in the loftier furnaces the carbon dioxide from the fuel is probably absorbed by the calcined limestone in the higher and cooler portions, only to be decomposed again lower down, as in the case of the uncalcined limestone. Experiment showed that a moderate elevation of temperature greatly expedited the union of carbon dioxide with caustic lime, so that the above combination might take place extensively in the warm reducing zone.

It is found that the use of raw limestone entails an absorption of about 4,200 calories for the expulsion of carbon dioxide, and a further 4,300 calories in decomposing the liberated carbon dioxide, or 8,500 calories in all. This is much reduced by a preliminary treatment in the limekiln, although the calcination in the latter is very imperfect. The author gives a large number of figures showing the variations in calories used, &c., in different furnaces, using raw and calcined limestone. The temperature of the furnace gases, when the latter is employed, is higher than with the raw limestone by between 100° and 200° F. This results firstly from the greater weight of the raw limestone, and secondly, because the union of carbon dioxide with lime should such take place, is a source of heat.

The conditions under which heat is applied in the blast furnace are more favourable to economy than most other modes of raising the temperature of bodies. On the other hand, the action of the lime-kiln is very defective. It is not surprising, therefore, that whereas one unit of coke burnt as it is in a blast furnace only affords about 4,200 calories, one unit of coal burnt in a lime-kiln gives off nearly double this amount. The loss in the latter case by the ignition of the coal near the upper surface of the kiln is such that nearly 16,000 calories are evolved to effect that which is accomplished with about 5,000 calories in the blast furnace. As a matter, therefore, of commercial difference there is not much to choose between the coke in the furnace and coal in the kiln. The small coal used in the kiln is only half the price of coke, but of the former double the weight is required.

The author discusses the question of heat distribution and appropriation irrespective of the question of lime. An increase of 300° F. (from 1,100° to 1,400°) in the temperature of the blast by the change of stoves is shown to have very little effect on the temperature of the escaping gases—a rise of 40° only. But the temperature of combustion must rise in some proportion or another, and whether it does so to any appreciable or dangerous extent or not is an important question. From the character of the slag there does not appear to be much inconvenience as a result of the change in the temperature of the blast.

The opinion that furnaces heated with superheated air have a disposition to "hang" is generally accepted as correct. The author does not say that with a temperature of blast under 1,000° F. this difficulty is entirely overcome, but he has little doubt "that it has increased many hundred fold in the few years that fire-brick stoves have been in use at the Clarence works." Moreover, the tendency complained of "seems to increase with the age of the furnace," whilst again, with the higher temperature of blast there is greater irregularity in the quality of the iron and consequently in the consumption of coke. These irregularities are largely due to the want of uniformity in the blast temperature, which latter seems inseparable from the nature of brick stoves.

In the discussion, Mr. Chas. Woods said that for years he had economically used calcined limestone, with the result that there was a saving in coal, and that the furnace gases were better and hotter for generating steam. He, however, calcined the limestone and ironstone together in about equal

proportions. Mr. C. Cochrane, in a written criticism, takes exception to the statement that it is impossible to discriminate between the carbon dioxide due to reduction and that liberated from the limestone in the furnace, and says that it is quite easy to do so. He calculates the ratio of carbon dioxide to monoxide in a perfect working furnace and from any deviation from this works out his result. He regrets that Sir Lowthian Bell should continue to use the "fictitious standard" of "heat afforded per unit of coke," and thinks the unit of carbon should be employed.—A. W.

*The Influence of Aluminium upon the Carbon in Ferro-Carbon Alloys.* T. W. Hogg. Iron and Steel Inst. Autumn Meeting, 1894. The Ironmonger, 63, 1894, 355—358.

THE author gives the results of his experiments with a series of alloys containing aluminium in different proportions, with as little as possible of both silicon and manganese. Two kinds of pure Swedish pig-iron were used, one grey and the other white. The alloys were prepared by pouring the molten iron into the molten aluminium, and then pouring the mixture backwards and forwards twice. The metal was cast in two moulds, one of iron to cool rapidly, and the other of green sand to cool slowly. Alloys containing 1, 2, 4, 8, and 12 per cent. of aluminium were prepared and analyses of each were made with a view of ascertaining the effect on the carbon.

As a result, the most effectual primary change is obtained by the addition of 1 per cent., and each addition after this causes more and more of the carbon to pass into the combined state until practically the whole of it is in this condition in the 12 per cent. alloy. In all cases the rapidly-cooled alloys show a remarkable excess of graphitic carbon over that contained by the slowly-cooled alloys, and the author suggests the explanation that the aluminium may cause a precipitation of carbon in the molten alloy, and the more slowly cooled portions partially take up the carbon again by cementation. It is also observed that the percentage of total carbon in the white pig alloys is not diminished more than that produced by the addition of the aluminium, whereas in the grey-pig high-percentage alloy there is a decided loss. The addition of 12 per cent. of aluminium to the iron containing 4.33 per cent. of carbon should reduce this element to 3.80 per cent. However, only 3.44 per cent. could be found by analysis. The following curves show the results:—

DIAGRAMS ILLUSTRATING THE ALTERATIONS IN THE PROPORTION OF GRAPHITE IN PURE SWEDISH PIG-IRON AFTER ALLOYING WITH ALUMINIUM.

WHITE PIG.

GREY PIG.

Dotted lines = Total carbon.  
Thick lines = Graphite in rapidly cooled alloy.  
Thin lines = Graphite in slowly cooled alloy.  
O = Original pig.  
R = After remelting without aluminium.

It is to be observed that all tendency for carbon to be retained in the combined state is prevented in the most decided manner by the addition of 1 per cent. of aluminium, and that every increase upon this quantity tends to reverse this effect, until with a large proportion, the carbon in white pig-iron is retained in its original condition, and the graphitic carbon present in grey pig is entirely changed to the combined state.

In the case of the high-percentage alloy, there was an evolution of large quantities of gas on solidification, the alloys in this respect resembling the high-silicon alloys. The holes in the top portions of the ingots were completely filled with glistening graphite, not actually separated from the alloy, but due to decomposition of the issuing carbonic oxide gas. There is a great difference between ferro-aluminium and ferro-silicon in respect to the total carbon which they can take up, the saturation point for the latter is probably about 1.5 per cent. for an alloy containing 18 per cent. of silicon, whilst a corresponding ferro-aluminium was found by experiment to hold more than 10 per cent. (3.15 per cent.) of carbon. The effect of remelting ferro-aluminium was then tried, with the result that there was a considerable loss of aluminium with a slight increase of silicon. The addition of manganese retards the loss of aluminium, but with a great increase in the proportion of silicon. The influence of aluminium upon a high-silicon alloy does not appear to give any important results beyond showing a great change in the grain of the alloy.—A. W.

*The Alloys of Iron and Nickel.* M. H. Wedding. Moniteur Scient. 8, 1894 (Sept.), 666—674.

THE "Société d'Encouragement à l'Industrie" having decided to undertake a complete study of the alloys of iron with nickel, aluminium, and chromium, has commenced it with the preparation of a memoir detailing all the recent researches on nickel, and alloys of nickel and iron. M. Wedding, the president of this commission, finds that the chief differences between the old and modern results on nickel are due to impurities in that metal.

After tabulating the properties of nickel compared with iron, manganese, and cobalt, the author quotes largely from the researches of Riley on nickel steels (this Journal, 1889, 547 and 596).

In conclusion the commission have decided with regard to nickel steels "That despite all the energy devoted of late years to the study of nickel-iron alloys and of the good results obtained, which seem to justify the adoption of nickel steel for armour-plating, absolutely reliable results are still wanting." "We know nothing precisely as to what is the percentage of nickel and of carbon, at which we must stop to obtain a metal perfect, either from the point of view of ductility or from that of resistance. We are still less sure of the conditions which are most favourable for the melting, the casting and the working of the ingot. The researches of Riley are far from satisfying us, and the earlier work is useless."—A. W.

*The Employment of Aluminium in the Refining of certain Metals.* Moniteur Scient. 8, 1894 (Sept.), 661—665.

At present half the aluminium manufactured is used up in the iron industry. The remainder is largely used in refining nickel and copper. When added to these metals the reduction of the last traces of oxide is completed, the metals become more perfectly fluid and after cooling can be worked easily. Any alumina formed in this action is completely insoluble in the nickel or copper, and rises to the surface and thus eliminates itself. The question of how the aluminium acts in the case of steel is then reviewed. Rammelsberg found that all the aluminium was used up in deoxidising, no trace being found in the ingot obtained. At first it was thought that aluminium lowered the melting point of steel 200° to 300° C., and that its presence caused the great fluidity of the steel. Now the ingots are shown to contain no aluminium. The oxide of iron dissolved in steel renders it less fluid and more brittle, and this causes it to give off carbon dioxide, hydrogen, and nitrogen. By the use of aluminium no

in flux) is given off, but only hydrogen and nitrogen. On account of the removal of the oxide of iron with the formation of alumina. Arnold states that the carbon dioxide is decomposed by the aluminium and the carbon is again taken up by the iron, but it is difficult to see why the quantities of hydrogen and nitrogen should be at the same time reduced.

The quantity of aluminium to be added and the method of using it is then discussed. The proportion depends on the metal, and the amount of oxide of iron therein. Iron or steel with little carbon requires more than high carbon steels, and Bessemer steel more than Siemens-Martin. In practice the addition rarely exceeds 0.1 per cent. An excess causes white excrecences of alumina. So long as the quantity does not exceed 0.75 per cent. the metal will remain homogeneous and capable of hammering hot. Ingots containing too much aluminium are characterised after forging and rolling by a slight separation of aluminium as such, and of carbon as graphite, thus damaging the quality of the metal. Another objection is the considerable contraction of the ingots on cooling. It is preferable therefore to employ a little less aluminium, and to run the risk of a few gas bubbles being in the casting. It is not necessary to employ aluminium purer than 92—98 per cent., if the impurities are only silicon and iron.

Aluminium cannot replace manganese entirely, as some contend, as it cannot affect the sulphur, phosphorus, and silicon. The chief advantages of aluminium in steel are:—(1.) It dissolves much more quickly in the bath and mixes more completely. (2.) Such small quantities are required that its introduction does not lower the temperature; and (3.) Since its reduction in price it can compete with ferromanganese and ferro-silicon, provided it is employed judiciously. It favours the alloying of nickel with iron.

In refining copper the amount varies from 0.25 to 1 per cent. The aluminium diffuses itself almost instantaneously, and is a more powerful reducer than phosphorus, silicon, or manganese. It increases the resisting power of the metal without affecting sensibly its electrical conductivity. An excess has no bad effect on the quality of the final product.

Aluminium is also now employed to replace the higher priced magnesium in the refining of nickel, and the quantity used should theoretically be less than the quantity of magnesium, but this point has not yet been attained practically. In America aluminium is used in galvanising iron plates, 12 grammes to the ton of zinc being added; it renders more perfect the adherence of the zinc to the iron and gives a finer surface polish.—A. W.

*Colour Gauges for Carbon Testing.* W. G. McMillan.  
Iron and Steel Inst. Autumn Meeting. 1894.

See under XXIII., page 978.

## PATENTS.

*Improvements in the Manufacture of Alumina and Aluminous Compounds and Metallic Aluminium or Alloys of Aluminium, and obtaining Chlorine, Hydrochloric Acid, Carbonate of Soda, and other By-products resulting from this Manufacture.* D. A. Peniakoff, Paris.  
Eng. Pat. 20,604, April 5, 1893.

See under VII., page 947.

*Manufacture or Production of Substances of Extreme Hardness.* F. Chaplet, Paris. Eng. Pat. 15,453, August 14, 1893.

Dry mixtures of the required components are placed within a crucible and subjected to the heat of an electric furnace so as to produce hard crystals or amorphous masses (a) by the direct and simple union of the mixed materials; (b) by their union in the presence of an excess of metal which is subsequently removed by means of an acid; or (c) by

reduction of an oxide or salt of one of the constituents, and dissolving the resulting substance in a metal, from which it is subsequently obtained by removal of the metal.

The substances so produced consist of silicides, borides, silico-carbides, silico borides, &c., of titanium and other metals and metalloids, and are capable of scratching or cutting chrome steel, the ruby and the diamond. As an example the preparation of silicide of titanium may be referred to. Eighty-two parts of rutile in coarse powder are mixed with about 60 parts of sand or crushed quartz and about 48 parts of powdered coke or carbon. These form the materials. By the fusion, as above described, a grey mass is obtained, with a bright fracture, of great hardness, and a density of about 4.8. It contains, besides titanium and silicon, about 20—25 per cent. of carbon and varying amounts of nitrogen.—J. H. C.

*An Improved Solder for Use with Aluminium or Aluminium Alloys.* B. I. Roman, London. Eng. Pat. 17,623, September 19, 1893.

The solder consists of silver, nickel, aluminium, tin, and zinc, in the proportions as follow:—

	Per Cent
Silver.....	2
Nickel.....	5
Aluminium.....	9
Tin.....	34
Zinc.....	50

No flux is necessary, and any soldering iron or tool may be used, though one of aluminium is preferable.—J. H. C.

*An Improved Aluminium Alloy.* R. I. Roman, London.  
Eng. Pat. 19,543, October 17, 1893.

The alloy consists of copper, tungsten, aluminium, tin, and antimony, for either of the two latter manganese or nickel being at times substituted. The proportions preferred are somewhat as follows:—

	Parts.
Copper.....	0.375
Tin.....	0.105
Antimony.....	1.442
Tungsten.....	0.038
Aluminium.....	98.049
	100.000

Tungstic acid and cryolite are melted together, equal proportions being employed. When the temperature reaches 1,200° C. aluminium is added so as to produce a 10 per cent. compound of aluminium and tungsten. A second alloy is made containing equal proportions of aluminium and copper. These two alloys are then melted together with pure aluminium in the proper proportions to form the alloy required as above: tin, antimony, or their substitutes being added in the necessary proportions; or they may be left out altogether when the copper and tungstic acid originally employed are chemically pure.—J. H. C.

*Improvements in and in connection with the Extraction of Gold and Silver from Ores or Compounds containing the same.* J. C. Moutgomerie, Ayr. Eng. Pat. 20,343, October 27, 1893.

The pulverized ores are mixed with sodium or other alkaline dioxide and then treated with a solution of potassium or other cyanide, nitrate of soda or other nitrate or nitrite being added when necessary. The reactions are made to take place in closed vessels, air, oxygenated air or oxygen being supplied under pressure. The solutions so obtained are filtered through charcoal filters, which are regenerated from time to time by means of heat, superheated steam, air, or other suitable gas without removing the retained precious metals, so that the same body of charcoal may be used for filtering successive charges of solution.—J. H. C.

*Improved Means of Purifying the Effluent Waste Waters of Tin Plate Works and the like.* W. J. Pughley, Briton Ferry, Glamorganshire. Eng. Pat. 13,777, July 17, 1894.

THE "mother liquors," "scouring water," or other waste waters are passed through a series of connected filters, of which the first contains calcined limestone in pieces not more than 3 in. diameter; the second, burnt oyster or cockle shells; and the third, stick charcoal. The filters may be of any suitable material or construction, and connected by earthenware piping, or may be contiguous with perforated partitions between. It is preferred that the effluent waste water from "black pickle" should, before filtration, be deprived of part of its iron and acid by concentration and crystallisation.—E. S.

*An Improved Process of Treating Refractory Ores, and Apparatus to be Used therein.* E. A. Ashcroft, Broken Hill, New South Wales. Eng. Pat. 13,850, July 18, 1894.

THE ores are first oxidised when necessary by roasting or calcining, they are then leached, and the solutions so obtained are electrolysed. The roasting may be effected in any kind of furnace that may be preferred; the leaching is effected by the ferric-chloride process in the case of ores high in zinc and low in lead, or by the ferric-sulphate process combined with smelting for ores high in lead and low in zinc. The required solutions are obtained by an electrolytic "re-generative" at subsequent stages of the work. The electrolysis is carried on, first, in vats, using iron anodes (whereby ferrous sulphate or chloride is imparted to the solution in small quantities in place of the zinc sulphate or chloride decomposed), and then in other vats having insoluble anodes (whereby the ferrous salts previously formed are raised to the ferric state). The solutions so produced are then heated and used for the treatment of new proportions of oxidised ores. Many modifications of the process are described, with additional manipulations necessary when silver, lead, or sulphur are to be recovered.—J. H. C.

*An Improved Metallic Alloy.* J. W. Dixon and Wm. Skinner, Sheffield. Eng. Pat. 14,502, July 28, 1894.

THE alloy consists of aluminium, silver, and copper, preferably in the following proportions or approximately so:—Aluminium, 96.25; silver, 3.50; copper, 0.25 per cent. = 100.00.—J. H. C.

## XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

*The Effects of Mechanical Stress on the Electrical Properties of Metals.* J. H. Gray and J. B. Henderson. Proc. Royal Soc. 55, 283–300.

THE first part of the paper deals with the changes of density observed. The density of a well-annealed copper wire of 98 per cent. conductivity, decreased about  $\frac{1}{2}$  per cent. for a stretching of 25 or 26 per cent. A lead wire also decreased about  $\frac{1}{2}$  per cent. just before breaking.

A copper wire drawn through 12 holes of a drawplate increased in density more than 1 per cent. A manganese-copper wire (10 per cent. of manganese) increased in density about 1 per cent. when drawn down to half its former diameter.

Twisting caused copper to increase about  $\frac{1}{2}$  per cent. for 2.3 turns per cm.

Heating the wires treated above caused no appreciable alteration.

Hammering a copper wire increased its density about 0.2 per cent.

The authors deal in the second part of their paper with the corresponding alterations of resistance, and support at some length the "Weight specific resistance," against the "Volume specific resistance." The formula used is:—

Resistance = wt. sp. res.  $\times$  length per unit wt.  $\div$  length.

Their arguments are founded, firstly, upon the fact that length per unit wt. is more easily determined accurately than the area of cross section required by the usual formula; and secondly, upon the fact first mentioned by Lord Kelvin and borne out by these experiments that wt. sp. res. varies less with mechanical treatment than vol. sp. res.

The resistance of a wire under tension was always greater than that of the same wire unloaded; the maximum increase recorded, of 1.6 per cent., being shown by a steel wire. When, however, the load was removed the resistance returned very nearly to its original value. In the latter respect copper showed much more change than either iron or steel, changing 0.7 per cent., when stretched 16 per cent., while steel did not alter more than 0.07 per cent., nor soft iron more than 0.19 per cent. This permanent alteration was found in the case of copper to be nearly proportional to the stretching, and a wire once well stretched was found to experience no further permanent alteration on being reloaded, though the temporary alteration was proportional to the load applied.

The authors conclude from their experiments that "no mechanical treatment, such as stretching, drawing . . . twisting, hammering, or combinations of these, all of which were tried, had any appreciable effect on the electrical properties of copper, iron, or steel."—E. T.

*Note on the Action of Copper Sulphate and Sulphuric Acid on Metallic Copper.* A. Schuster. Proc. Royal Soc. 55, 84.

IT is known that copper sheets experience a diminution in weight when left immersed for some time in sulphuric acid or copper sulphate, the surface of which is exposed to the air. It seemed possible that this effect was due to dissolved oxygen. To test this, rolls of copper gauze were placed in tubes containing a 20 per cent. solution of copper sulphate, 5 per cent. of sulphuric acid being added to two and 10 per cent. to the rest. The tubes were exhausted and sealed and the copper gauze remained immersed in two cases for seven days, in the rest for 14. The diminution in wt. was insignificant compared with that commonly found, and might be due either to a small quantity of oxygen remaining in the liquid, or, as suggested by Mr. Hoskyns Abrahall, to the formation of copper sulphide, in accordance with the formula:— $4\text{Cu} + \text{SO}_3 = \text{Cu}_2\text{S} + 3\text{CuO}$ . In support of the latter view traces of sulphuretted hydrogen were found when the copper was heated in hydrogen.—E. T.

*Copper Electrolysis in Vacuo.* W. Gannon. Proc. Royal Soc. 55, 1894, 66–83.

SCHUSTER and Crossley have shown (Proc. Royal Soc. 50, 344), that a heavier deposit of silver is obtained by a given quantity of electricity *in vacuo* than in air. Schuster's experiments (an account of which is given in the preceding abstract) suggested that a similar result might be found for copper. The author's experiments bear this out.

Two similar voltmeters containing equal cathode areas were placed in series so that the same current might pass through both. When fresh neutral solutions were used the excess of the deposit *in vacuo* over that in air was distinctly marked, though very variable in amount.

Gray had, however, pointed out (Phil. Mag., vols. 22 and 25) that copper deposits from neutral solutions showed just such variability.

With acid solutions the difference was clear and certain.

With a current density of 0.0027 amp. per sq. cm. 0.16 per cent. more copper was deposited *in vacuo* than in air. This excess appeared to diminish with greater current densities till with 0.01 amp. per sq. cm. (9.3 amps. per sq. ft.), or more, no practical difference could be observed. It was still found, however, that less copper *proportionately* was deposited for feeble current densities than for the stronger ones, as had been previously pointed out by Gray.

A neutral solution which had been used, did not behave, on the addition of acid, like one freshly prepared and to which acid had been added immediately. Moreover, a deposit from a neutral solution *in vacuo* was, like that obtained in air, very sandy and loose at the edges.

The acid solutions contained 1 per cent. of free acid, and a specific gravity between about 1.032 and 1.180.—E. T.

### PATENTS.

*Improvements in the Electrolytic Decomposition of Chlorides and Mixtures thereof, and in Apparatus for the purpose.* F. M. Lyte, London. Eng. Pat. 7594, April 13, 1893.

THIS invention relates to cells and anodes for use in electrolytic (fusion) processes, especially the electrolytic decomposition of fused lead chlorides into metallic lead and chlorine. Electrolysis is effected within a bell-like chamber having an outlet for gas in the crown, the mouth being sealed by dipping into molten metal, corresponding to the base of the chloride treated, which is run off as it accumulates. Electrodes are of hollow, tubular carbon, closed at bottom, open at top, having a core of metal (lead, tin), or alloy, fusible at or below the temperature at which electrolytic decomposition is to be effected. Terminal connection is made to the fusible core by an infusible conductor (iron, copper) dipping therein. Connection may be also made to the same form of hollow electrode by a longitudinally-split tube fitting spring-tight therein, the fusible metal being dispensed with.—J. C. R.

*Improvements in Plating Metallic Surfaces and also Prepared Surfaces of Non-conducting Substances by Electro-Chemical Deposition.* P. Marino, Paris. Eng. Pat. 15,264, August 10, 1893.

A MOVABLE and adjustable jacket filled with the electrolyte and containing the anode plates, is pressed against the surface to be plated in such a way that that surface forms one side of the jacket. A siphon and stop-cock for supplying or withdrawing the electrolyte are provided, and the vessel may, if preferred, be filled with an absorbent, such as felt or "sponge-piline." By using a suitable flexible joint and an elastic material for the edges of the jacket, the whole apparatus may be shifted from one part of an object to another, regardless of any variation in curve. Corners or surfaces of very variable form may be coated by means of a rolling cylinder of porous material saturated with the electrolyte, and having a metallic spindle which acts as anode.—W. G. M.

*Improvements in Electric Furnaces.* F. Chaplet, Paris. Eng. Pat. 15,577, August 16, 1893.

See under II., page 936.

*Improvements in Apparatus for the Electrolysis of Chlorides and other Salts.* J. Hargreaves, Farnworth-in-Widnes, and T. Bird, Crossington, Liverpool. Eng. Pat. 18,173, September 27, 1893.

THIS invention relates to apparatus for use in decomposing chlorides, iodides, bromides, nitrates, and other salts, adapted to operate on the principle claimed in Eng. Pat. 18,871, 1892 (this Journal, 1894, 250), the primary object being to render such apparatus less expensive, more convenient to manipulate, and more compact. Apparatus is shown having numerous vertical compartments containing the electrolyte, and a corresponding number of compartments or collecting chambers, wherein the product is obtained from parallel exposed or bare electrodes. The collecting chambers are arranged alternately with the compartments containing the electrolyte, and the anode collecting chambers alternately with the cathode collecting chambers.—J. C. R.

*Improvements in Safety Appliances to be used in Connection with Electrical Decomposing Apparatus.* J. C. Richardson, London. Eng. Pat. 19,688, October 19, 1893.

IN order to avoid the danger resulting from accumulations of explosive gas mixtures produced by deranged working of apparatus during electrolysis, either a small Bunsen gas-flame, an induction coil spark, an electrically incandescent wire, or a small quantity of spongy platinum, is placed in an apparatus connected with the electrolytic cell, with a view to induce the combination of the gases as they are evolved, and before they collect in dangerous quantities.—W. G. M.

*Improvements in or connected with Electrolytic Cells.* F. Hurter and H. Auer, Widnes, and E. K. Muspratt, Liverpool. Eng. Pat. 19,791, October 20, 1893.

THESE improvements relate to cells to be employed in the electrolysis of solutions of common salt or other chlorides. A metallic containing vessel is employed, the sides of which act as the cathode. The anode is contained in an inverted trough or bell-jar, and a plate or plates of non-conducting material is placed at a distance below the edge of the trough, and projecting on all sides beyond this edge, to prevent the hydrogen liberated at the bottom of the metallic cell from entering the anode compartment.—J. C. R.

*An Improved Process and Means used therein for the Production of Caustic Alkali.* C. T. J. Vantin, London. Eng. Pat. 20,404, October 28, 1893.

THIS process relates to electrolytic (fusion) methods of obtaining hydrates of sodium or potassium from their chlorides, molten lead being the cathode. The hydrates are obtained by treating the cathode alloys, continuously or at intervals, with steam or water vapour in a separate heated vessel, or discharging the alloy into or under water.

—J. C. R.

*Improvements in or relating to Processes and Apparatus for Obtaining and Depositing Metals by Electrolysis, and in the Treatment of the metals after leaving the Electrolytic Bath.* E. Stouls, Paris. Eng. Pat. 24,017, December 13, 1893.

FOR the production of thick electrolytic deposits, rotated copper mandrels filled with wood, and supported by *lignum vite* journals mounted in glass bearings, are used as cathodes. The mandrels are rotated in the bath on parallel axes by means of bronze or copper cranks, stayed with copper tubes, and having bronze journals working in cast-iron or *lignum vite* bearings. The mandrels are coated evenly by painting and rubbing their surfaces with a mixture of plumbago and milk, which is found preferable to the present system of applying the black-lead. The electrolyte must be free from impurities, and is therefore allowed to deposit suspended matter in wide, shallow troughs heated to from 40° to 60° C., which answer better than deep settling tanks. For the purification of the liquid air may be blown through at the temperature named. After leaving the bath the deposited metal is worked under the hammer, by drawing, or otherwise, whether treated by the Elmore process of deposition or not.—W. G. M.

*Manufacture of Coated Metallic Powders.* O. Imray, London. From J. Sachs, New York. Eng. Pat. 12,381. June 26, 1894.

THIS is a process for coating powders or fine particles of one conducting material with an electrolytic deposit of another metal. The powders are fed on to the upper end of a sloping cathode plate, resting at an angle across the bath containing the electrolyte; at some distance above the cathode, and parallel to it, is a perforated anode plate supported on a dialytic diaphragm, which may be of baked clay. Between the electrodes work a series of rotating brushes with horizontal axes, which serve at once to sweep the powders along the cathode and to press them into close

contact with it. In this manner each particle receives a sheath of electro-deposited metal, and the coated powder is discharged at the lower end of the slope through a narrow outlet, together with a little of the solution which is pumped back into the trough. By using suitable electrolyte and electrodes, graphite, iron or zinc may be given the appearance of brass, or metals may be coated with gold, silver, or other material.—W. G. M.

*Improvements in or connected with Electrolytic Cells, and Diaphragms therefor.* C. N. Waite, Rumford Falls, U.S.A. Eng. Pat. 13,756, July 17, 1894.

THE inventor describes an electrolytic cell for the decomposition of alkaline chlorides which, in general character, is fully explained in Eng. Pat. 5983, 1891 (this Journal, 1891, 707), granted to E. A. Le Sueur. The improvements consist in placing against diaphragms a layer of sand or equivalent comminuted material. In the drawing it is represented as placed on the anode side and resting on a diaphragm (asbestos) which, in turn, rests on a cathode of "wire cloth." "Serious explosions have resulted in cases where the injury to the diaphragm has escaped notice, and gas generated at the negative electrode has been permitted to leak through the diaphragm" (into the anode compartment), "passing into the collecting chambers." The layer of sand operates to prevent the passage of hydrogen gas into the anode compartment, and protects the diaphragm against the corrosive action of the products set free in that compartment, which in practice has made frequent renewals necessary.—J. C. R.

*Improvement in the Process of Electro-plating, and Apparatus therefor.* W. P. Thompson, Liverpool. From C. M. Barber, Cleveland, Ohio, U.S.A. Eng. Pat. 13,795, July 17, 1894.

THIS is an arrangement by which the process of electro-plating is rendered automatic; it is intended primarily for the treatment of electric light carbons. A long endless belt provided externally with a series of clips placed close together, is rotated by and around sprocket wheels, one of which is in a sliding frame in order that the slack of the belt may be taken up if necessary. Near one end of the belt, a drum with longitudinal grooves is so rotated that the carbons, which fall into the grooves successively from a hopper, are brought in front of the clips and are pressed into them, each to each, by a cam action. The belt carries them forwards and, with the aid of guide wheels, dips them successively into a cleansing vat, and a series of plating and washing vats, and then carries them through a chamber, wherein they are dried by a current of air, heated or otherwise, and thence to a releasing arrangement in which they are automatically removed from the clips. The plating vats are of metal with anodes on either side, and carry above a bar of copper, connected with the negative pole of the generator, with which the metallic clips containing the carbons make sliding contact as they are conveyed past the vats. The guide-wheels are placed with horizontal axes, one between each pair of vats, in such a way that the belt, in passing over them, lifts the carbons over the sides of the vats.—W. G. M.

cleaning of the mill after each operation is most troublesome, especially in cases in which many samples have to be examined. The crushing mill described (see Fig.) is of such a size that after the grinding operation it may be readily inserted into the Soxhlet extractor and very small quantities of the seeds are therefore sufficient for an analysis. The mill consists of a strong tinned iron cylinder *a, a*, into which is inserted the perforated cone *b, b*,

held in position by the hinged lid *c*, which is also provided with the bayonet joint *g*. In the cone *b* rests a corresponding grooved cone *d*, the shaft of which is provided with the lid *i*, and the spiral spring *e*. The lid *i* is secured upon the cylinder by means of the bayonet joint *h*, and to the end of the shaft *f* the handle *K* is fitted. In using this mill a weighed quantity (about 5 grams.) of the seed is placed in the apparatus, lid *i* is closed and the handle attached to the shaft. By now slightly raising the grinding cone the seeds fall between the surfaces of *b* and *d*, and are thoroughly crushed by turning the handle *K*. The crushed seeds fall through the perforated cone into the lower part of the cylinder. The crushing being finished, lid and handle are removed, and, by giving the bottom lid a slight turn, perforations in it are made to correspond with perforations of the cylinder, providing openings for the solution of the oil to flow from the cylinder during extraction. The mill is then wrapped in filter paper, the top remaining uncovered, and the whole inserted into a Soxhlet apparatus for extraction. After extraction the mill is ready for another operation, the dry dust from the seeds having been removed by a brush.

—C. O. W.

*Report on Castor Oils from the Indian Section of the Imperial Institute.* W. H. Deering and Boverton Redwood. (Carried out for the Research Department of the Imperial Institute, September 18, 1894.)

FROM the collection of 78 castor oils in the Imperial Institute, we selected 23 for examination, viz.: the five grades of Pirpainti oil (as representing the inland products), the same of Kotapatam oil (from coast seeds), a No. 1 and No. 2, and five No. 3 grades of inland oil other than Pirpainti, and six "good second" inland and coast oils (other than Pirpainti and Kotapatam).

These oils have been examined as to their colour, specific gravity, viscosity, rotation of plane-polarised light, the amount of potash required to neutralise the free acid present in them and for their complete saponification, the amount of bromine which would combine with them, and their solubility in alcohol. The results are given in the subjoined table.

*Viscosity.*—This was determined by means of a Redwood viscosimeter.

*Rotation of Plane-polarised Light.*—A Hofmann-Laurent polarimeter was employed. D light, and 200 mm. of oil.

## XII.—FATS, OILS, AND SOAP MANUFACTURE.

*Extraction Mill.* N. Lehmann. Chem. Zeit. 18, 1894, 412.

FOR the estimation of the percentage of oil in seeds by means of extraction it is necessary to have the seeds well crushed. This has been done by grinding them in variously constructed mills, but is in every case accompanied by the loss of a certain quantity of the oil, and the necessary

**Bromine Absorption.**—A solution of bromine in dry bisulphide of carbon was used, the oil being also dissolved in bisulphide of carbon. This was preferred to Von Hübl's iodine absorption method, in which a mixed reagent (iodine and mercuric chloride) and a mixed diluent (alcohol and chloroform) are used, and chlorido-products are formed; while in the bromine bisulphide of carbon method a more definite reagent is used, with formation of bromine addition-products only.

**Solubility in Alcohol.**—One volume of oil was shaken up with three volumes of alcohol of sp. gr. 0.830 (at 60° F.). All 23 oils were wholly soluble in the alcohol; they gave clear solutions, which remained clear after standing for a couple of days.

The specific gravity, time of efflux (viscosity), amount of potash required for saponification, amount of bromine absorbed (also refractive index as indicated by the oleo-refractometer reading), point to practical identity of composition of the oils examined. Triricinolein (the glyceride of which castor oil almost wholly consists) requires by calculation from the accepted formula 18.07 per cent. potash and 51.47 per cent. bromine; the calculated amounts required by triolein, tristearin, tripalmitin (frequent constituents of oils and fats) are shown below and on next page.

	Potash required for Saponification.	Bromine required to form Saturated Compound.
	Per Cent. KHO.	Per Cent. Br.
Triricinolein, $(C_{18}H_{34}O_2)_3.C_3H_5$ ..	18.07	51.47
Tristearin, $(C_{18}H_{36}O_2)_3.C_3H_5$ .....	18.92	0
Triolein, $(C_{18}H_{34}O_2)_3.C_3H_5$ .....	19.05	54.26
Tripalmitin, $(C_{16}H_{32}O_2)_3.C_3H_5$ ..	20.89	0

The estimation of the amount of bromine absorbed tends to be rather too high. The oils, as was to be expected, contain appreciable and varying amounts of free acid; the percentage of "potash required for free acid"  $\times 5$  gives the amount of free acid. The lower grades of oil contain more free acid than the higher ones; thus the No. 1 oils contain about 0.6 per cent. to 0.8 per cent., most of the "good second" oils about 2 per cent., most of the No. 3 oils about 5 per cent. of free acid. The Kotapatam oils (except the No. 1) contain less free acid than the Pirpainti oils.

As lubricants the oils examined should be equally good, judged by their viscosity (as indicated by times of efflux) alone; but the lower grades of oil would be likely to cause considerably greater corrosion of metal bearings on account of their greater acidity.

The depth of colour increases in proceeding from the higher to the lower grades of oil; colour has probably to a great extent been relied on in grading the oils.

The rotation of the plane of polarisation by castor oil is of scientific interest. The recorded observations are conflicting; thus, Flickiger and Hanbury ("Pharmacographia," p. 513) state that they found some samples of castor oil to be right-, others left-rotating. Allen observed no rotation. Popp found specific rotatory power of castor oil  $(a) = +12.15$ , but this was deduced from the rotation of 10 per cent. solutions of castor oil in alcohol, in which case errors of observation would be greatly multiplied up. Schädler gives the rotation of castor oil (apparently for 198 mm.) as  $+9.78$ , but gives 0.9163 at 15° C. as the specific gravity of the oil; which, although probably a misprint, lessens confidence in the statement. The rotation caused by 200 mm. of castor oil under before-mentioned conditions was pretty nearly the same in all 23 oils: a dextro-rotation of about  $8.5$ . The comparatively slight variations observed with so considerable a number of castor oils of varying origin justify the belief that rotatory power is a property of the glyceride ricinolein, and not of impurities or unknown constituents of the oil; the

amount of the latter must be small (castor oil gives about 96 per cent. of total fatty acids), and would need have a most unusually high rotatory power to produce the observed effect. The power (scarcely possessed at all by other natural glyceride oils) is probably connected with the fact that ricinoleic acid is an oxy-acid.

**Turkey-Red Oil.**—Castor oil, as is well known, finds important application in Turkey-red dyeing, being converted into Turkey-red oil by the action of strong sulphuric acid and subsequent neutralisation with alkali. From the general similarity in chemical composition of the oils examined, much difference in their behaviour with sulphuric acid was not anticipated; accordingly three oils, Nos. 1,549, 2,527, 1,564 (a first, second, and third grade oil respectively) only were experimented with. The rise of temperature on stirring 50 grms. of oil with 10 cc. pure strong sulphuric acid (sp. gr. 1.844 at 15° C.) was practically the same with the three oils—about 62° C.; 63°, 61°, 60.5° C. respectively.

100 grms. of each of the three oils were treated with 33 grms. of sulphuric acid, added in drops with constant stirring, the oil being cooled externally; the rise of temperature did not in any case exceed 17° C., and the evolution of sulphurous acid was very slight. The three products were left for a couple of days; they were then greenish-brown in colour, of treacly consistence, without appreciable difference in either respect. Each was then treated with 170 grms. of water at 40° C.; after separation of the water, the washed products were of light greenish-brown colour (No. 1,549 lightest coloured, No. 2,527 next lightest, No. 1,564 darkest), and of the consistence of castor oil. They were neutralised with caustic soda solution to the extent of four-fifths of the acidity present and then solution of ammonia added in moderate excess. All three gave clear liquids; No. 1,549 was of golden-yellow colour, No. 2,527 slightly browner, No. 1,564 was the brownest—a brownish-yellow, or light yellowish-brown.

**Purgative Principle.**—The purgative principle of castor oil has not yet been identified; Tison's "ricinine" is stated by himself to be non-purgative. The greater part of the active principle appears to be left in the pressed seeds; its isolation and examination, and the estimation of the amount present in the oil and the press-cake, would be desirable.

#### Meal of Sunflower Cake. R. Theodor. Chem. Zeit. 18, 531.

SUNFLOWER cake has been found, especially in Russia, one of the best auxiliary cattle-foods. As early as the year 1856 about 100,000 centners of sunflower oil (oil of the seeds of *Helianthus annuus*) were manufactured in Russia, and its amount has increased year by year, it being esteemed as a very palatable alimentary oil. The oil was formerly obtained by hydraulic means; the residual cake is harder than any other variety of oil-cake, and for this reason apparently it has not found a wider application. Denmark and the northern countries import large quantities annually, as do also the eastern provinces of Germany, and the problem of its disintegration has been successfully solved by several manufacturers there. It is still unknown in Southern and Western Germany; now, however, that it is put on the market in the form of meal, it will doubtless soon find general application, suited, as it is, both on account of its composition and pleasant taste, for fattening cattle. The percentage of proteid varies between about 30–44 per cent., the fat between about 9–18 per cent. It is possible to prepare two qualities, one rich in proteid and poor in fat, and the other rich in fat and poor in proteid. When, for example, the somewhat finely ground meal is sifted, employing a mesh of 1 mm., that which passes through is much richer in proteid and poorer in fat than the original, whilst the reverse is true of that which remains in the sieve.—A. R. L.

*Process for the Estimation of Small Quantities of Chlorine in Fats.* R. Bandedikt and H. Zikes. *Chem. Zeit.* 18, 649.

See under XXIII., page 981.

#### PATENTS.

*Improvements in Soap and Washing Compounds.* John Penfold Friend Field, London. Eng. Pat. 19,475, October 17, 1893.

This specification describes (1) a soap which will cleanse linen "without the need of rubbing"; (2) a washing powder; (3) a paste for cleaning silver, metals, paint, &c. The laundry soap is a mixture of ordinary soap, soda crystals, pipeclay, and benzine, with or without indigo or ultramarine blue. The washing powder is the same as the soap, minus the benzine, and reduced to a dry powder. The paste contains caustic soda in addition to the other ingredients, but no benzine or blue. There are four claims. The first is for the employment of the above-named materials, in about the proportions stated in the specification, in the manufacture of soap; the other three are for the particular combinations needed to produce each article.—L. A.

*Improvements in the Manufacture of Soap Compositions.* M. Baerlein, Salford, Lancashire. Eng. Pat. 19,732, October 20, 1893.

The inventor claims the manufacture, use, and application of an improved soap composition, "having very much greater cleansing and detergent properties than ordinary soaps," and produced by the mixture of soap with "benzol, toluol, xylol," solvent naphtha, "patent naphtha," or mixtures of the same.—L. A.

*Improvements in or applicable to Soap in Tablets, Cakes, or Bars.* Feodor Heilbronn, Kilbarn, London. Eng. Pat. 13,104, July 6, 1894.

The improvements consist in coating the soap with a thin and preferably transparent film of gelatin, wax, spermaceti, ozokerite, or other suitable material, in order to preserve the odour, appearance, colour, &c., of the soap for an indefinite period. The coating may also be made thick, if desired, as for exhibiting soap in shop windows.—L. A.

*Improvements in Apparatus for extracting Suint from Wool and other Substances.* Emile Richard-Lagerie, Roubaix. Eng. Pat. 13,672, July 16, 1894.

IMPROVEMENTS upon Pat. 12,433, 1893 (this Journal, 1893, 1044), whereby the distribution of the liquors according to the graduated concentration of the extracts, into the different compartments of the tank or their equivalents, and the discharge of the said compartments upon the wool in the required succession, are effected automatically, instead of requiring the intervention of a workman as hitherto.

The distribution and discharge of the liquors are brought about either by utilising the change of level of the liquors by means of floats during filling and emptying, which actuate mechanism to effect same, or by making use of the rise and fall of the hydrometer according to the concentration of the liquors.

The improved apparatus is applicable for extraction and concentration of other substances besides suint; for instance, sugar from sugar cane or beet, &c.—W. R.

### XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, Etc.

#### (A.)—PIGMENTS, PAINTS.

##### PATENTS.

*An Improved Process for the Production of Iron Oxide for Use as a Pigment.* C. H. M. Lyte, London. Eng. Pat. 16,638, September 4, 1893.

An ore of iron, such as burnt pyrites or the "purple ore" from the wet copper extraction process, is heated with caustic potash or soda until the mixture becomes converted into a ferrite or ferrate. It is then decomposed by boiling with water, and the red oxide washed and ground, the alkali being used again. Insoluble matter may be removed by treating the ferrate with cold water and filtering before decomposition.—F. H. L.

*A New or Improved Binding Medium for Size Colours, and Method of Manufacturing the same.* J. Clasen, Hamburg. Eng. Pat. 13,004, July 4, 1894.

HERETOFORE ordinary size has been rendered fit for distemper work by the addition of an extract of Carrageen moss, which, however, deteriorates the binding and keeping qualities of the size. The improved size is made as follows:—Ordinary size or glue, selected so as to be as rich in fat as possible, is soaked for about 14 hours in cold water so that it may become soft, and is then transferred to a boiler, where it is heated until the whole contents become a thick viscid liquid; about 2 parts of water to 1 part of size should be used. The liquid size is then tested to ascertain its richness in fat by leaving it for about 30 minutes at 90° C., whereupon the fat will have risen to the surface. Cocoa-nut oil or stearine oil is then added in a quantity inversely proportional to the content of fat in the size, namely, from 3 parts by weight of oil to 300 parts of size, for a size rich in fat, to six parts of oil to 300 parts of size, for one poor in fat. When the whole has been thoroughly mixed and cooled to about 50° C., 60 to 70 parts by weight of sago meal or potato meal are added by degrees with constant stirring; this addition supplies the acnelaginous matter to replace the Carrageen moss. The liquid mass is poured into moulds and allowed to set; a short drying serves to render the tablets ready for sale. In using the tablets they are soaked and boiled with water, and the solution added to the colour mixed with water. The surface to be painted does not require the usual preliminary soaping.—A. G. B.

#### (B.)—RESINS, VARNISHES.

##### PATENTS.

*An Improved Material or Compound adapted for Use as a Varnish, as a Substitute for India-Rubber, Gutta-Percha, and like Substances, and for other Purposes, and the Process for its Production.* C. V. King, and R. V. Jellicoe, London. Eng. Pat. 15,686, August 18, 1893.

This material consists of collodion cotton made in the usual manner, and the solvent is prepared by dehydrating methylated spirit by quick-lime or potassium carbonate, mixing it, after distillation, with 10 to 50 per cent. of methylated ether or hydrocarbon, such as benzene. The addition of castor oil and gum copal to increase flexibility, and of pigments or dyes to alter the colour, is also claimed.

—F. H. L.

*A New or Improved Composition for Coating Iron and Steel.* T. W. Elliott, Newcastle-on-Tyne. Eng. Pat. 16,800, September 7, 1893.

"VULCAN cement" is mixed with raw or boiled linseed oil, or preferably "patent boiled oil," with or without the addition of turpentine or benzoline (petroleum spirit).

—F. H. L.

*Improved Preservative Coating for Iron and Steel.*  
W. M. Walters and F. R. Stone, Liverpool. Eng. Pat.  
20,253, October 27, 1893.

A SOLUTION of tannic acid in water of about 10 per cent. strength is mixed with a 5 per cent. solution of gum arabic or dextrin, and the metal painted; ordinary paints or varnishes being afterwards applied as desired.—F. H. L.

### (C.)—INDIA-RUBBER, &c.

*The Analysis of India-Rubber Articles.* C. A. Lobry de Bruyn and F. H. van Leent. Chem. Zeit. **18**, 1894, 309.

THE determination of the specific gravity of india-rubber articles is of very little use, although it may be said that india-rubber which will float on water is free from mineral admixtures. Fatty oils and paraffin wax may be estimated in india-rubber articles by extracting them with turpentine, carbon bisulphide, or benzine (petroleum spirit), as suggested by Heinzerling, but the results are liable to be

vitiated by the presence of native resins in the india-rubber. Donath estimates in india-rubber articles only the specific gravity, ash, and percentage of sulphur. His opinion, that the value of an india-rubber article mainly depends on the quantity of india-rubber and the proportion of sulphur of vulcanisation present, altogether neglects the influence of different qualities of india-rubber, as well as the fact that articles manufactured from the same india-rubber may contain 3, or as much as 6, per cent. of sulphur without showing any difference in quality. Henriques' method for the analysis of india-rubber articles is too detailed and and elaborate for ordinary purposes, although it may be very useful in special cases. For ordinary purposes, the estimation of the mineral matters by ignition, and the estimation of the constituents soluble in alcoholic soda are sufficient, but it is useful to submit the samples, in addition to these chemical tests, to a dry-heat test for two hours at 135° C., and to a moist-heat test for four hours at 170° C., observing the general behaviour of the samples in these tests as well as their loss of weight. In this manner the following samples were examined:—

No.	Description of Sample.	Ash.	Per Cent. soluble in 6 per Cent. Alcoholic Soda.	Calculated upon Substance free from Ash.	Heated to 135° C. for		
					One Hour.	Two Hours.	Three Hours.
		Per Cent.			Loss of Weight, 0.1	Loss of Weight, ..	Loss of Weight, 0.25
1	Para rubber vulcanised with 6.4 per cent. S.	..	..	5.0	..	..	..
2	Mozambique rubber vulcanised with 5.5 per cent. S.	..	..	6.5	0.2	..	1.3
3	Borneo rubber vulcanised with 8.3 per cent. S.	..	..	36.0	1.7	..	3.6
4	Sheet .....	3-4	..	33.4	1.4	..	3.1
5	" .....	3-4	..	20.4	1.4	..	3.5
7	" .....	3-4	..	30.2	1.4	..	3.1
11	Sheet, 15 years old, 5.5 per cent. S.	..	..	..	1.7	3.1	..
13	Red sheet .....	..	..	5.8	..	1.2	..
15	Black ring .....	6.5	..	0.7	1.1	2.5	..

18	Ring .....	15.5	19.7	23.3	..	3.0	..
21	Ordnance break ring .....	19.5	2.6	3.3	0.11	..	0.4
24	Sheet, 15 years old, 3.7 per cent. S.	33.0	12.9	19.2	0.1	..	0.7
25	Floor mat .....	41.0	28.0	50.0	..	..	0.4
47	Sheet (sample) .....	57.0	4.1	9.0	..	1.7	..
53	Hose .....	63.5	1.3	1.0	..	1.2	..

Pure vulcanised Para and Mozambique rubber stands the heat tests very well, losing only from 0.15 to 0.25 per cent. in weight, while most of the other samples show much greater losses. Sample No. 21, which contains 20 per cent. of zinc-white, stood many years' wear very well. It is probably made of Para rubber, but yields no extract to alcoholic soda. White and brown rubber substitutes, on being heated for two hours to 135° C., lose from 2 to 2.5 per cent. in weight, but neither do they melt nor are they otherwise impaired in their quality. In the wet test they melt, become discoloured, and decompose. Rubber articles containing rubber substitute do not stand the moist-heat test. The quantity of resinous matters contained in india-rubber is without perceptible influence upon the result of the heat tests, but it seems that in this respect age has a detrimental effect upon india-rubber articles. The percentage of resin in an india-rubber seems to be without influence upon the durability of the articles manufactured from it.

## PATENTS.

*A New Substat for India-Rubber and Gutta-Percha.* L. Le Brocquy, Dublin. Eng. Pat. 19,163, October 12, 1893. This consists of the substance known as printers' "roller composition"—consisting of glue, glycerin, and sugar—encased in a covering of ordinary india-rubber, to protect it from damp and mechanical injury. Into the composition may be introduced various substances such as tannic or chromic acid to raise its melting point, salicylic acid as a preservative, ground cork, china clay, and barium sulphate, and mica to increase its insulating capacity.—F. H. L.

*Improvements in Decolourising India-Rubber.* M. Gerber, Clermont-Ferrand, France. Eng. Pat. 19,284, October 13, 1893.

THE vulcanised rubber, containing from 5 to 8 per cent. of sulphur is heated under a pressure of three or four atmospheres with constant agitation in the presence of three and a half times its weight of toluene and one-fourth of tin. Instead of the tin, any metal or mixture of metals combining with sulphur may be employed, and the toluene may be replaced by any other indifferent solvent. The heating is continued for eight hours, when the mixture is poured off and allowed to settle.—F. H. L.

## XIV.—TANNING, LEATHER, GLUE, AND SIZE.

*The Action of Tannin on Hides.* J. Pässler. Chem. Zeit. 1894, 18, 363.

HANAUER has recently resuscitated this question (Chem. Zeit. 1894, 18, 288), and Procter has replied (this Journal, 1894, 747). It appears that the dictum that tannin is incapable of tanning hides originated with Wagner, who classified tan-stuffs into physiological and pathological, denying the latter kind any function in the tanning process. Physiological tan-stuffs are, according to Wagner, such as are products of normal metabolism in the plant, and include the tanning-principles of oak-bark, pine-bark, willow-bark, valonia, myrabolans, divi-divi, algarobilla, canaigre, sumach, and of other tanning materials. Pathological tannins, on the other hand, are products of morbid metabolism in the plants, especially in those of the species *quercus*; they are generally formed as a result of the punctures of insects. Such tannins are contained in gall nuts, knopfern, and rove, and may be regarded as tannin proper, closely allied to one and the same chemical individual. Physiological tannins, on the other hand, are accompanied by other substances from which it is difficult to isolate the pure tannins.

The author tanned a sheep-skin with pure tannin and found that the product resembled leather in every respect, save that it lacked firmness and was not full. This failing has, however, nothing to do with the tannin, but is merely a result of the absence of acid in the liquor. In the ordinary tanning process the saccharine constituents of the bark or other tanstuff invariably undergo lactic and acetic fermentation, so that acids are never absent from the liquor even in "sweet-tanning." It is these acids, says the author, which impart the necessary fulness and firmness to the leather. A calf-skin which was tanned in pine extract under conditions which precluded the formation of acids, suffered from the same defects as the sheepskin tanned with pure tannin. When a pure tannin or a pathological tannin is used in conjunction with an ordinary tanstuff which contains acid-yielding constituents, a marketable leather is produced; indeed, pure tannin with an appropriate addition of lactic and acetic acids will be equally effective.

Pathological tannins are sometimes used in practice, as, for instance, that in knopfern galls which are formed

on the cups of the oak from the puncture of *cynips quercus calicis*. Rove, or Bassorah galls or apple of Sodom, are the galls produced by the puncture of a gall-wasp on the young shoots of a dwarf oak of Asia Minor. These galls are considerably larger than the usual oak-apples, and contain a high percentage of tannin; they come into the market in a crushed condition, and yield a liquor of excellent strength, the tannin being easily soluble in cold water. The common oak-apple and Chinese galls are forms of tannin too expensive for the tanner.—A. G. B.

## PATENTS.

*Improvements relating to the Manufacture of a Substitute for Leather.* H. H. Lake, London. From G. Sachsenröder, Barmen, Germany. Eng. Pat. 15,937 August 23, 1893.

ORDINARY vegetable parchment, or a combination of any suitable fabric with parchment paper manufactured according to known processes, is suitably dyed, imperfectly dried, and then conducted through a hot bath of fats, paraffin oil, wax, stearin, or the like. To promote the impregnation of the material by the fatty matter the fabric may be passed through rollers. After having been allowed to dry in the air and polished, the substitute is ready for use. Greater suppleness may be imparted to this artificial leather. It may be impregnated with some hygroscopic substance, such as glycerin or calcium chloride; in certain cases glue, casein, dextrin, &c. may be used as "covering substances" to diminish the unctuousness of the product.—A. G. B.

*An Improved Process for Colouring Tanned Hides by Means of Smoke.* A. Herrmann, Schweidnitz, Silesia. Eng. Pat. 13,414, July 11, 1894.

THE white tanned or bleached tanned hides are stretched over hurdles in a closed chamber, on the floor of which is a flat hearth designed to hold a smoking fire, the fuel being horse-dung, with or without straw. Only the grain of the leather becomes coloured by the smoke, the shade of colour depending on the duration of the process, and varying from dull light yellow to golden brown. The colour is durable and the hide remains soft.—A. G. B.

## XV.—MANURES, Etc.

*Examination of Artificial Manures.* Chem. Zeit. 1894, 18, 361.

See under XXXI., page 980.

*Detection of Adulterants in Basic Slag.* O. Böttcher. Chem. Zeit. 1894, 18, 565.

See under XXXI., page 978.

## PATENT.

*Improvements in Making Manure from Sewage and Sewage Sludge.* J. Carter, London. Eng. Pat. 22,559, November 24, 1893.

THE inventor describes in detail in this specification a process which chiefly consists in covering the drained sewage or sludge with dry ash dust, and when dry mixing by means of a steam harrow travelling on rails. Other materials besides dry ash dust may be used, such as powdered chalk, burnt clay; also soda, soot, resin, tar, and carbolic acid may be added. The whole process is carried on under a roof of corrugated iron or glass.—J. C. C.

## XVI.—SUGAR, STARCH, GUM, Etc.

*Calculation of the Rendement of Raw Sugars.* Seyffert. *Zeits. Zuckerind.* **44**, 399.

INSTEAD of the non-sugar rendement which was introduced about a year ago, and which is arrived at by deducting  $2\frac{1}{2}$  times the total non-sugar from the polarisation, the author proposes the following. He calculates, from the sugar analyses made during the past year, that the ratio of the percentage of organic matter  $O$  to the difference  $100 - P$  ( $P$  = polarisation) is almost constant, and is equal to 3 in those sugars polarising from 94 to 97. So that since  $\frac{100 - P}{O} = 3$ , it follows that  $O = \frac{100 - P}{3}$ , which latter represents therefore the normal percentage of organic matter for the particular raw sugars referred to. The author then proposes to multiply the difference between this calculated percentage of organic matter and that actually found by analysis by 2, and to deduct or add as the case may be this product from the old rendement ( $P - \text{Ash} \times 5$ ). The calculations made by the author show that the mean values are the same as those obtained from the ash rendement; they are also said to be surer and more concordant than the non-sugar rendement.—A. R. L.

*Influence of Calcium Salts on the Yield of Sugar from Raw Sugar Masseccites.* L. Szyfer. *Gaz. cukr.* **1**, 541.

ALTHOUGH the amount of lime in the masseccites examined in the experiments described in this paper, varied between 0.015 and 0.086 per cent., the yield of sugar was found to undergo no great alteration. This confirms Herzfeld's conclusion that the presence of small quantities of calcium salts does not hinder the crystallisation of the sugar.

—A. R. L.

*So-called Scum Fermentation.* *Zeits. Zuckerind.* **44**, 611.

HERZFELD states that he cannot confirm the observations of Prinsen Geerligs (this Journal, 1894, 823) as to the ready decomposability of free glucinic acid; he does not agree with the views of Prinsen Geerligs regarding the cause of scum fermentation in alkaline liquors.

Classen thinks that derivatives of invert sugar have but little to do with scum fermentation, and that the phenomenon is brought about principally by unknown organic compounds. He believes that defecation at a temperature not exceeding 69°–75° C. (Prinsen Geerligs, *loc. cit.*) is of no service, but recommends maintaining a sufficient decided alkalinity, and drawing off the liquors at not too high a temperature. The extensive laboratory experiments of Weiland show that cold defecation has in no respect advantages over hot.—A. R. L.

*Decomposition of Sugar during Evaporation.* Lexa. *Zeits. Zuckerind. in Böh.* **18**, 503.

WHEN sound, alkaline liquor is evaporated within a short time, the decomposition of the sugar is slight—perhaps not more than 0.1 per cent. The effect of high temperature is small, inasmuch as it shortens the time necessary to perform a given amount of work; the temperature in the last member of the multiple effect evaporator ought not, however, to exceed 64° C., and that in the first member should not be above 112° C. Such temperatures as 120°, 128°, and even 134°, which are ordinarily adopted in Germany, are too high and should not be used. Greater losses are occasioned by boiling than by evaporating, but exact data as to the magnitude of these losses are wanting; the quotients give no information whatever in these cases. Sugar is decomposed by heating the juices prior to evaporating them, and indeed such losses amount to 0.3–0.4 per cent.—A. R. L.

*Loss of Sugar in Manufacture.* Feldmann. *Zeits. Zuckerind. in Böh.* **18**, 468.

ACCORDING to the author the total loss of sugar during its manufacture from beetroots, up to the boiling of the masseccite, amounts to 0.7 to 1 per cent. on the roots. Of this, however, when the process is carefully controlled, only 0.3 to 0.5 per cent. can be accounted for. The unknown losses are principally due to the decomposition of sugar during the boiling and evaporating of the liquor, and are greatly influenced by the construction and management of the apparatus, as well as by the temperature, concentration, condition, and alkalinity of the liquor. Herzfeld's exact laboratory experiments are not of direct service to the industry, because in the latter the decomposition of sugar by boiling, must be greater than that observed in the laboratory.—A. R. L.

*Defecation and Filtration of Diffusion Liquor.* Mittelmann. *Bull. de l'Assoc. Chim.* **11**, 707.

THE author recommends defecation with caustic lime, and careful mechanical filtration of the crude juice, for which purpose Bouvier's apparatus, which renders it possible to filter the hot juice rapidly, is serviceable. He points out the great advantages to the industry accruing from such a mode of procedure.—A. R. L.

*Defecation and Saturation.* Beaudet. *Bull. de l'Assoc. Chim.* **11**, 658.

FROM the results of a detailed investigation carried out by the author, it would seem that defecation with caustic lime leads to the production of liquors containing less inorganic matter than those in which defecation with milk of lime or powdered slaked lime, has been adopted; the products are the better the lower the temperature of defecation and saturation. The practical application of these results is, however, beset with difficulties, and it is scarcely possible to introduce specific improvements which can be equally carried out everywhere. On this account it is necessary to prosecute exact investigations in every single factory; data of this kind are at present wanting even concerning the principal points.—A. R. L.

*Improvements in the Beetroot Sugar Industry.* Jarkovsky. *Zeits. Zuckerind. in Böh.* **18**, 436.

THE use of divided (short) diffusion batteries has not proved satisfactory in practice. The so-called Heckmann's diffusion (vacuum) process has been in use for many years in Austria, as has also the process of heating the beetroot slices previous to diffusion. Among new evaporation processes that of Classen gives the best results, and can be thoroughly recommended. The Karlik-Ehrmann rotation system has a promising future, but needs perfection at the hands of practical men.—A. R. L.

*The Drying of Potato Pulp with Molasses for Cattle-Food in North German Factories.* M. Dellbrück. *Zeit. f. Spiritusind.* **1894**, **17**, 141.

THE pulp is mixed with milk of lime and passed through filter-presses; the apparently dry mass is then carried along by a screw, which mixes it with a thin stream of molasses. On admixture it does not cake, but forms a crumbly mass, since molasses only contains about 20 per cent. of water. The mixture, after drying in the oven, is mechanically carried, along with a strong current of air, through a trough in which a reverse-acting screw arrests any undried lumps, the finer particles being carried forward ("Cyclone drying apparatus"). The air, which is then about 70° C., passes to the dust collector, leaving the dried stuff to be milled and compressed.

This method for utilising molasses is applicable:—1st. In sugar factories, where it can be mixed and dried with the root cuttings; 2, in places where the strontia recovery

process is worked: 3. in distilleries using molasses; and 4. in starch factories. The compressed material it is proposed to use as a nutritious cattle-food.—T. A. G.

*Quantitative Estimation of Carbohydrates.* E. Schulze. Chem. Zeit. 18, 527—528.

See under XXIII., page 985.

#### PATENT.

*Process for Purifying and Decolorising Saccharine Juices and Sugar Solutions generally.* C. Steffen, Vienna, Austria. Eng. Pat. 17,632, September 19, 1893.

THIS is a process for obtaining colourless sugar solution as pure as possible, and crystalline sugar therefrom, by treating the juices of beetroot and cane sugar manufacture, subsequently to defecating them, and in some cases after they have been saturated and freed from the defecation and saturation scum according to known methods, and cooled down to a temperature below that at which defecation was effected, i.e., below 60° C., and preferably between 30° C. and 40° C., with sulphurous acid in such quantities that the colouring and non-sugar substances are for the most part converted into sulphite compounds; these latter remain in solution in the acid juices, which are then subjected at the above-mentioned temperature to the action of proportionately small quantities of animal charcoal for the purpose of removing the sulphite compounds of the non-sugar substances. The free sulphurous acid is then got rid of by treating the filtered juices with the necessary quantity of lime, baryta, strontia, alumina, &c. The juices after being freed from the sulphites so precipitated are slightly alkaline or neutral, and free from colour and impurities. The application of this process to medium and thick juices of any degree of concentration, as also to all syrups of sugar manufacture, the treatment being repeated as often as necessary, and to the treatment of the clairee or fine liquors of beetroot and cane sugar refineries, and the syrups thereof, is also claimed.—A. R. L.

### XVII.—BREWING, WINES, SPIRITS, Etc.

*Estimation of Starch by Alcoholic Fermentation.* Albert Munsche. Zeits. für Spiritusind. 1894, 17, 202; 17, 209.

See under XXIII., page 985.

*Hop-Tannin.* M. Hayduck and F. Goldiner. Wochenschr. f. Brauerei, 11, 409—415.

ETTI showed (J. Chem. Soc. 1876, i, 927) that in the tannin from hops there is a tannin,  $C_{15}H_{25}O_{13}$ , and a phlobaphen of the probable formula  $C_{30}H_{46}O_{25}$ , and which he considered as probably formed by the coalescence of two molecules of the tannin with the separation of water. The authors have re-examined these substances, and studied their properties from a brewing point of view.

After extraction of the hops with ether and then with absolute alcohol, in both of which the tannin is insoluble, the tannin was extracted by repeated digestion with 70 per cent. alcohol. The alcoholic extract was then fractionally precipitated by means of a solution of lead acetate in alcohol of similar strength. The greater part of the phlobaphen was in the first brown precipitates, that of the tannin in the latter yellow precipitates. The precipitates suspended in water were treated with hydrogen sulphide, and the lead sulphide (which carried down with it most of the tannin, or phlobaphen) was extracted with 70 per cent. alcohol. The separation was completed by means of ethylic acetate, as the phlobaphen is insoluble, the tannic acid soluble, in that solvent.

The hop-tannin so obtained is a light brown amorphous powder, soluble in water, dilute alcohol, and ethyl acetate, very sparingly soluble in absolute alcohol, and insoluble in ether. A 0.2 per cent. solution in water was slightly yellow, and showed a green fluorescence. Ferric chloride produced an intense green coloration, but no precipitate: the reaction is very delicate. This tannin has the characteristics of an acid, slightly reddens blue litmus, precipitates dissolved albumin but incompletely, as the precipitate is slightly soluble in water, and (contrary to the statement of Etti) is precipitated by animal skin. It is very unstable, and, even on evaporation on the water-bath, a part is converted into an insoluble substance, mostly phlobaphen. When an alkaline carbonate is added to the solution, the latter takes a dark brown colour, and on evaporation on the water-bath the whole of the tannin is then converted into phlobaphen. The same conversion takes place rapidly if the dry tannin is heated at 140° C.

The phlobaphen forms a reddish-brown powder, partly soluble and partly insoluble in boiling water or dilute alcohol. The yellow solution gives, with ferric chloride, a dirty green precipitate: soluble albumin is precipitated by it in an insoluble form, and it is itself precipitated by animal skin. Heated at 130°, phlobaphen becomes insoluble, probably by condensation by loss of water, and this condensation takes place, to some extent, at lower temperatures, as shown by the presence of insoluble material in the phlobaphen prepared as described. It is soluble in alkaline carbonates to a brown liquid.

Both phlobaphen and tannin and their compounds with iron are slowly decomposed by continued boiling or heating.

*Estimation of Tannin in Hops.*—The author has found Schröder's modification of Löwenthal's method, in which the tannin extract is titrated with permanganate both before and after the precipitation of the tannin by skin, the best for estimating the tannin in hops. The air-dried hops are coarsely ground, then extracted six times by boiling each time with 100 cc. water in a Schröder's boiler. This latter consists of an exactly cylindrical tin vessel, into which is fitted, as a closely but evenly moving piston, a perforated plate, covered with fine wire gauze, and fitted with a handle. Ten grms. of the hops and 100 cc. water are introduced into the boiler, and the piston then inserted. The boiler is put into a water-bath at 100° for an hour, then removed, the piston pressed down slowly and firmly, and the solution, which is thus separated from the hops, poured off. A second 100 cc. of water is then added, and the heating repeated, but now for half an hour each time. The sixth extract, which only contains negligible quantities of tannin, is used to make up the bulk of the first five extractions to 500 cc. About 20 cc. of this extract is taken, 5 grms. of powdered and well-soaked skin (of which the percentage of moisture is known) added, and the whole well and often shaken up and allowed to remain for 24 hours. The skin is then filtered off, 10 cc. of a dilute indigo solution added, the whole diluted with water to about three-quarters of a litre, and titrated with permanganate. The colour, which is first blue, passes into green, and then suddenly, when the extracts and indigo are oxidised, to a bright golden yellow. The end point is very sharply indicated. Correction must be made for the moisture of the skin and the permanganate required by the indigo used as indicator. A similar titration of hop extract which has not been treated with skin is made, and the difference gives the quantity of tannin. The permanganate is standardised against a solution of pure tannin. Special trials proved that the resin present in hops does not affect this reaction, so that extraction of the hops with ether is unnecessary and best omitted, as the long digestion with ether probably decomposes some of the tannin. The same method may be used for estimating the tannin in beers, after boiling off the alcohol, but the quantity of tannin present is so small that the influence of experimental error becomes very large. The following numbers were obtained with some beers:—English ale, 0.024 per cent.; Pilsen beer, 0.018 per cent.; Munich beer, 0.012; Berlin beer, 0.012.

**Influence of Hop-Tannin on Beer.**—The phlobaphen, as already mentioned, precipitates albumin in an insoluble form. The hop-tannin, however, forms a compound soluble in boiling water, but almost insoluble in cold water. This is seen in the wort, after treatment with hops, becoming thick on cooling. The cool and cleared wort still contains some of the albumin-tannin compound, and, though more of this is precipitated during fermentation, a trace still remains in the finished beer. The influence of hop-tannin is thus to remove a part of the very unstable soluble albumin from the wort, and indirectly to act as a preservative; it has, however, no direct antiseptic properties. The bitter hop-resins, on the contrary, have a decided antiseptic power. The influence of the hop-tannin is shown in the much smaller quantity (mere traces) of soluble albumin present in strongly hopped English ale, than in the much less hopped German beers. Analyses of a number of hops for tannin also showed that the hops generally considered the best are richest in hop-tannin. The following numbers were obtained, calculated on the dry hops:—Saaz, 2.9 per cent.; Spalt, 2.25 per cent.; Neutomschel, 1.69 per cent.; Wolnzach, 1.66 per cent.; Mainburg, 1.44 per cent.—L. T. T.

**The Carbohydrates Pre-existing in Malt.** E. Jalowetz. Chem. Zeit. Rep. 18, 39.

THE author has previously stated that the carbohydrates present in malt are saccharose, maltose, dextrose, and dextrin. He now comes to the following conclusions:—(1.) Almost all the carbohydrates present can be extracted from 50 grms. of malt by treatment, six or seven times repeated, with 300 cc. of 90 per cent. alcohol, or still more completely by a two hours' hot extraction with 90 per cent. alcohol, followed by one hour's digestion with water of the malt freed from the alcohol and fat of the extraction-liquid and dried. The carbohydrates are saccharose, dextrose, levulose, and an unfermentable substance identical in rotatory and reducing properties, with maltose. (2.) By digestion of the alcohol-extracted malt with water at the ordinary temperature for one hour, followed by precipitation of the aqueous extract with alcohol, a body is obtained, levo-rotatory, not reducing Fehling's solution, and giving a violet coloration with iodine solution. This may contain the already known levo-rotatory gum of malt, with perhaps dextrin, either originally present or formed during the extraction with alcohol. (3.) By digestion of malt with water at 18°–20° C. for one hour a solution results containing the carbohydrates, together with certain transformation products of starch, of which maltose, dextrin, and dextrose can be recognised. (4.) Digestion for several hours with water at 18°–20° C. brings about inversion of the saccharose; after three hours about half of the saccharose is inverted. (5.) The amount of saccharose in (a) the alcoholic extract, (b) the aqueous extract after one hour at 20° C., and (c) the wort obtained in the usual manner in the laboratory, is almost constant, on the average 3.2 per cent. (malt containing 10 per cent. of water). (6.) The reducing carbohydrates present are dextrose (3.1 per cent.), levulose (1 per cent.), and maltose (0.7 per cent.). It is not established whether dextrin is originally present or formed during extraction. (7.) Iso-maltose is not present either in the alcoholic or the aqueous extract. (8.) The starch of the malt grain is so changed by the growth of the barley, that the breaking-down of the starch has already taken place. It is not possible to identify the results of the action of cold malt extracts or diastase solutions on starch, brought about in a mechanical way, with the results of the mashing process.

Two other ferments besides diastase are present in malt, an inverting and a dextrose-forming ferment (glycose).

—R. B. B.

**Note on the so-called "Gluten Particles" occurring in Wort, Beer, and Yeast.** H. Will. Wochenschr. f. Brauerei, 1894, 937–938.

IT is well known that bright mash-tun or copper wort becomes turbid on cooling owing to the separation of minute, highly refractive particles of nitrogenous matter.

Although a portion is deposited on the coolers, much of this gluten remains in suspension in the wort and passes partly into the yeast, partly into the new beer, from which it only separates during storage. Nevertheless, even finished beer frequently contains gluten particles; and the deposits formed in pasteurised beer, according to the author, often consist wholly of these particles in a more or less shrivelled or otherwise changed condition. Microscopically, the gluten particles separated from wort are perfectly homogeneous, and up to 2 $\mu$  in diameter. But in yeast and also stored beer they present a vacuolated appearance and resemble air-bubbles. In beer they also frequently occur in the form of minute granules. It is evident, therefore, that the gluten particles suffer some change during the process of brewing. The author has, therefore, investigated the behaviour of the gluten particles (obtained from frozen beer) towards various solvents, with the following results:—

In contact with water the contents of the particles become swollen, and dissolve slowly—more rapidly on warming—the outer membrane being left behind. Absolute alcohol exerts no solvent action, but alcohol of 65 per cent. rapidly dissolves the cell-contents. In concentrated hydrochloric acid the gluten dissolves almost completely to an intense cherry-red solution, from which, by the addition of water, a violet-red precipitate is separated. Dilute acids in general readily dissolve the contents of the particles, whilst stronger acids, and also alkaline solutions, dissolve the outer envelope as well. From the above and other considerations the author concludes that the bulk of the cell-contents of the gluten particles consists of mucidin.

Beers suffering from gluten turbidity either contain in suspension extremely minute flocculent particles, or, more frequently, possess an opalescent appearance. In the latter case, the turbidity almost entirely disappears on warming the beer to 30°–40° C., but reappears on cooling. The addition of alcohol has a similar brightening influence.

—H. T. P.

**The Influence of the Mashing Process on Attenuation.** Windisch. Wochenschr. f. Brauerei, 1894, 885.

IT is well known that the conditions of mashing largely influence the degree of attenuation of beer. In this connection the author relates an interesting practical experience. The worts in a certain brewery were found to attenuate insufficiently. In order to increase their fermentability, the mashing heats were lowered and the time of standing increased, the modified process being applied to two different malts, the one cured at 45° R., the other at 65° R. The result was that the degree of attenuation increased by 11 per cent. in the case of the low-cured malt, but remained absolutely stationary in the second instance. This peculiarity may possibly be explained on the assumption that the diastase of the second malt was so greatly restricted by the high curing heat, that the variation in the mashing process was insufficient to sensibly affect the type of extract produced.—H. T. P.

**The Treatment of Boiling (Foaming) Fermentations.**

A. Hesse. Zeits. für Spiritusind. 1894, 17, 153.

DURING 1885 the author made no less than 1,068 mashes, not one of which showed boiling fermentation. In the year following, the ordinary mash tun was replaced by an Eckert's centrifugal machine, and boiling fermentations began. These were at the time wrongly attributed to the new machine. On reverting again to the old process of mashing, the "boiling" ceased, but inferior fermentations resulted. Whilst in Hellefreund's old method the malt is all mixed at once with the whole of the potato, in the centrifugal machine the mixing is done in several portions, so that much more complete saccharification results, and to this cause the boiling fermentation is due.

The following method of procedure was adopted:—

One-third of the malt was added at the beginning of the mash, and the whole of the potatoes blown out of the vessel at a finishing temperature of 49° R. The rest of the malt was then added, and the mash cooled. A marked decrease of boiling fermentation resulted. Finding that the addition of malt to the cold mash caused no bacterial acidity

the plan was adopted of reserving part of the malt for addition at this stage. In extreme cases the malt should be added at a temperature as low as 14° R. At a temperature of 30° R. moderately vigorous boiling can be suppressed.

Boiling fermentation begins when the normal relation of maltose to dextrin exists in the mash: when this relation is upset frothing or foaming does not take place. Boiling fermentation is the normal form with good yeast and a good mash tun.—T. A. G.

*Boiling Fermentations: A Criticism of the Results obtained by A. Hesse (see preceding abstract).* G. Heinzelmann. Zeits. für Spiritusind. 1894, 17, 161.

THE author has tabulated a series of experiments conducted under different conditions, and gives the saccharometer readings at different stages of fermentation, the alcohol percentage, the petroleum required for sprinkling (to allay froth or boiling fermentation), the amount of malt used, and the result with respect to boiling fermentations. In cases where the whole of the malt was used at mashing he did not always obtain boiling fermentation, nor was it always prevented by reserving a portion for addition at a later stage. He supports the contention of Hesse that the addition of malt to the cold mash has no undesirable action on the fermentation, and does not favour acidity. The amount of malt to be used depends upon the kind of potato used, and must be determined for each kind. Thick mashes are recommended as a general means of avoiding "boiling," since diastatic action is not so intense as with thin mashes. When a small quantity of malt is used for the mash, a restricted saccharification results, and the maltose molecule is not so readily fermented, because surrounded by dextrin molecules. Consequently fermentation proceeds more regularly, and on adding malt to the cold mash, dextrin is gradually degraded to maltose and then fermented. Malt extract made by soaking malt for three hours in water, and filtering, does not give as good results as the dry malt itself.—T. A. G.

*Boiling Fermentations.* Zeits. für Spiritusind. 1894, 17, 225 (compare preceding abstracts).

A SERIES of experiments was conducted with different sorts of potatoes. The extent to which different acids influence "boiling" could not be established.

The author does not endorse Hesse's statement that "boiling" disappears when the saccharification in the first mash is unfavourably influenced, or when the malt is added in two portions, one at mashing and the other during cooling. When only one-third of the malt was used at mashing and the remainder on the cooler at 17–19° R., the primary fermentation was certainly quieter, but the effect on the after-fermentation was, on the other hand, to make it more vigorous than by the old method. Unlike Hesse, the author obtained boiling fermentations with Bellefreund's method, and claims that this system is just as bad in this respect as Eckert's. In one case boiling fermentations were got rid of by changing the yeast. Species II. had been used, and on changing it, although "boiling" (foaming) was decreased, such good fermentations were not obtained as before.

—T. A. G.

*The Influence of Fluorine Compounds on Beer Yeast.* Zeits. für Spiritusind. 1894, 17, 227.

ERRONT has shown that beer-yeast will accustom itself to gradually increasing quantities of fluorine salts until an amount can be added which would render the original yeast incapable of fermentation.

Experimenting further with different species of yeast, he finds that under the above conditions the physiological life of the yeast cells is quite changed—the power of multiplication being diminished whilst fermentative energy increases. At the same time an influence on the chemical

action is produced, which, although small, is constant under changing conditions of yeast, worts, and fermentation.

	Yeast.	
	Ordinary.	Fluorine-treated.
Alcohol per litre .....	115 cc.	111.5 cc.
Carbon dioxide .....	84.06 grms.	83.51 grms.
Ratio of alcohol to carbon dioxide.	1:0.731	1:0.749

In every case the fluorine-treated yeast gave less than the theoretical quantity of CO<sub>2</sub>.

On fermenting a glucose solution he obtained:—

	Yeast.	
	Ordinary.	Treated.
Unfermented glucose .....	0.55 per cent.	1.21 per cent.
Alcohol formed .....	7.29 "	6.67 "
Alcohol per 100 parts of fermented glucose.	50.49	48.37

The number 50.49 is almost the same as Pasteur's, whilst the second, 48.37, approaches closer to the calculated theoretical amount. The fluorine-treated yeast produces only  $\frac{1}{15}$  to  $\frac{1}{12}$  of the glycerol, and only  $\frac{1}{3}$  of the succinic acid produced by yeast under ordinary circumstances.

—T. A. G.

*The Employment of Sulphurous Acid in Malting.* Kukla. Wochenschr. f. Braueri, 1894, 885–887.

THE primary object of adding sulphurous acid to the steep liquor in malting, is the production of relatively pale malts. In addition to this, the author has made the following observations:—When using acidified water, the duration of steeping is reduced by as much as 20 hours, and subsequent growth on the floors is more rapid and regular, so that the operation at this stage may be shortened by 2–3 days. The resulting malts are stated to be more thoroughly modified, and to yield a better type of extract, although its amount is somewhat smaller. The development of mould-growth is entirely prevented. In practice, the author proceeds as follows:—The barley is at first steeped in the usual way in water alone, which is drawn off at the end of a few hours, and replaced by water, previously thoroughly mixed in a separate vessel with the required volume of sulphurous acid. After 12–14 hours the acid water is drawn off and the barley washed in running water; steeping (in water alone) may then be continued as usual. It must be remembered, however, that the operation will be finished more quickly than usual, and care be taken to avoid over-steeping.

As regards the amount of sulphurous acid to be used, this should be such that 1 cc. of the treated water requires 0.05 cc. of decinormal alkali for its neutralisation. Less may be employed, but on no account more. The precise strength of the acid used must therefore be determined by titration and the calculated amount added to the water, allowance being made for the quantity neutralised by the alkaline and earthy carbonates contained in the water (determined by direct titration, using litmus as indicator). Waters containing much calcium carbonate are unsuitable for the above process, owing to the deleterious influence on the germinating power of barley, of the calcium sulphite formed.—H. T. P.

*Alteration of the Sulphurous Acid in Wines.* E. Chuard and M. Jaccard. *Chem. Zeit.* **18**, 1894, 702.

THE sulphur treatment of wine is based upon the antiseptic properties of the sulphurous acid, a small quantity of which dissolved in the wine, prevents the development of obnoxious micro-organisms. The sulphurous acid as such, however, does not long remain permanent in a wine, part of it escaping into the atmosphere, part becoming oxidised into sulphuric acid. Recent investigations by Schmitt further showed that part of the sulphurous acid combines with the small quantities of aldehyde present in most wines. The compound thus formed received the name of aldehyde sulphurous acid, and it is characterised by a pleasant odour and indifference to the living organism. These various changes show that after a certain time, even strongly sulphured wines will only contain very small proportions of free sulphurous acid. A series of experiments showed that three to four months after sulphuring, most of the free sulphurous acid had disappeared from the wine.

—C. O. W.

*Butylic Alcohol Fermentation and the Butyl-Ferment.* Beijerinck. *Zeits. f. Spiritusind.* **17**, 233—234. From *Centralbl. f. Bakteriologie*. **15**, 171 et seq.

THE author has investigated this subject and finds that a considerable number of bacteria produce butylic alcohol more or less freely during fermentation. He proposes to give the name of *Granulobacter* to this group of organisms which he describes thus:—Wholly or temporarily anaerobic ferment-bacteria, which, when entirely anaerobic become filled with granules and then resemble the clostridium. Carbonic anhydride and hydrogen are always among their products of fermentation, but methane is always absent. The following members of this species (some of which are already known under other names) are described. *Granulobacter butylicum* (Gruber's *Bacillus amylobacter* L.) producing butylic alcohol as principal product. *G. saccharobutyricum* (*Bacillus butylicus*, Fitz.); *G. lactobutyricum*; *G. polymyxa* (Prazmowski 1890).

After discussing at length many subjects connected with fermentation, the author draws the following conclusions:—

a. There are three forms of anaerobiosis, viz., the *facultative*; the apparently *facultative* or *temporary*; and the *essential* (obligate). The facultative anaerobiosis (as for instance lactic fermentation) is independent of the presence or absence of air but requires the presence of reducible materials. The temporary anaerobiosis (yeast, &c.) depends on a reserve of combined oxygen in the cell capable of permitting considerable cell partition (20 to 30 times) before fresh free oxygen becomes necessary. The essential anaerobiosis requires total absence of free oxygen but presence of reducible materials.

b. The fermentative and reductive functions are independent of one another.

c. Alcoholic fermentation may take place in the combined presence of all three forms, and is only impossible in the presence of essential anaerobiosis alone.

d. Facultative and even essential anaerobes can live and grow apparently as aerobes in the absence of assimilable or reducible materials.

e. Fermentation does not occur without accompanying evolution of gas.—L. T. P.

*Note on the Alleged Disappearance from Beer of added Salicylic Acid and Saccharine during Protracted Storage.* J. Wauters. *Wochensch. f. Brauerei*, 1894, 910.

A NUMBER of beers, to some of which salicylic acid, to others, saccharine had been added, were kept for four years in a warm place. At the end of that period, the beers were all acid, but in no case was any difficulty experienced in detecting the added antiseptic.—H. T. P.

*Aluminium Foil as a Beer Clarifying Agent.* Windisch. *Wochensch. f. Brauerei*, 1894, 940.

A SUMMARY of various investigations concerning the practical utility of aluminium for clarifying purposes. Metallic aluminium is employed in the form of corrugated strips, 50 cm. long, and 4 cm. wide, weighing 15 grams. Apart from other considerations aluminium strips possess the advantage over wood shavings of being non-absorbent, and of being readily cleaned. The evidence as to the efficiency of these strips for clarifying purposes is somewhat conflicting, but it appears that they are, at the least, equal in this respect to wood-shavings. As regards the influence of aluminium on the properties of beer, general experience shows that the stability, flavour, condition, &c., are quite unaffected thereby. Hygienically, too, no difficulties present themselves. The amount of aluminium dissolved by beer, even after prolonged contact, is absolutely inappreciable.—H. T. P.

## XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY AND WATER PURIFICATION, DISINFECTANTS.

### (A.)—CHEMISTRY OF FOODS.

*Estimation of the Insoluble, Non-volatile Fatty Acids.* Meillère. *J. Pharm. Chim.* **29**, 60.

See under XXIII., page 983.

### PATENTS.

*Improvements in the Treatment and Preparation of Butter, Butter Substitutes, Margarine, and Alimentary Fats or Compounds.* W. P. Thompson, Liverpool. From C. Artus, Paris, France. Eng. Pat. 20,027, October 24, 1893.

THIS invention relates to a process for the treatment and preparation of butter, butter substitutes, margarine, and alimentary fats, salted or otherwise, without the use of chemicals, with the object of preserving them from putrefaction. The butter or other like product is introduced into suitable vessels perfectly opaque and hermetically sealed and heated therein to a temperature of 60—120° C. It is thus Pastenised (sterilised). The patentee also claims a process for "reconstituting" sterilised butter or like product. It consists in vigorously agitating the butter or the like at a suitable temperature approaching that of solidification, whereby, it is said, the "liquid fatty volatile and aromatic principles dissociated during the sterilisation are emulsified or reconstituted," the solidification is then effected by rapid cooling.—A. R. L.

*Improvements in and relating to the Preservation of Food.*  
H. L. C. Paulsen, Hamburg, Germany. Eng. Pat. 13,031.  
July 5, 1894.

This invention relates to the preservation of articles of food, such as meat, fish, fowl, game, caviare, &c. The process consists in surrounding the articles of food to be preserved with a mixture of an aqueous extract prepared preferably from the following plants:—*Gelidium amansii*, *Gelidium cornutum*, *Gelidium cartilagineum*, *Gelocopeitis filicina*, and *Chondrus crispus*, glycerol and an antiseptic. The plants are steeped in water for 24 hours, and heated to 200° C. for 5–6 hours. After this the juice is strained, and when cold assumes the appearance and consistency of a jelly; it is transparent. This jelly is heated in a paraffin bath to 200° C., and to every 1,000 parts by weight there are added water (2,000 parts), glycerin (250 parts), and alum (50 parts), or boric acid (30 parts); the boiling is continued until the liquid weighs 1,800 parts, when it is cooled down to 8° C.—A. R. L.

#### (B.)—SANITARY CHEMISTRY AND WATER PURIFICATION.

*Dyeing with Lead Chromate from the Hygienic Standpoint.*  
Cazeneuve Rev. d'Hygiène, 1894, 16, 382.

THE Board of Health for the Department of the Rhone has prohibited the use of lead chromate in dyeing cotton hanks intended for reeling. This order is due to the occurrence of several cases of lead-poisoning among the women employed in this industry. The hanks are not thoroughly washed to remove excess of chromate, as is usually the case with fabrics dyed in this manner. In a room in which reeling of the yarn, and spinning of it together with metal threads were carried on, was found:—

	Per Cent. PbCrO <sub>4</sub>
In the thread.....	10.1
In the waste.....	17.9
In the dust on the floor.....	44.2

It is thus easy to understand the occurrence of lead-poisoning, and the necessity for the above prohibition.

—R. B. B.

#### PATENTS.

*Improvements in the Construction of Tanks for the Subsidence of the Precipitate or Sludge resulting from the Chemical Treatment of Sewage or other Foul Waters.*  
H. Lockwood, Manchester. Eng. Pat. 19,069, October 11, 1893.

IMPROVEMENTS are described for the construction of a tank figured in Eng. Pat. 19,308, 1892 (this Journal, 1893, 540). The claim is for a cylindrical settling tank with a conical bottom, and having an inlet opening admitting the sewage at a point considerably below the surface so as not to disturb the subsidence of the sludge. A sudge pipe is also provided, opening at or near the bottom of the conical part of the tank in such a way that the downward pressure of the supernatant liquor will force the sludge through the outlet, so as to dispense with the necessity of pumping.—J. C. C.

*Improvements in Making Manure from Sewage and Sewage Sludge.* J. Carter, London. Eng. Pat. 22,559, November 24, 1893.

See under XV., page 964.

*Improvements in Channels or Receptacles for Sewage and the like Materials and in the Method of Deodorizing or Disinfecting the same.* H. Stoffert, Hamburg, Germany. Eng. Pat. 14,733, August 1, 1894.

ALL parts of the receptacles or channels with which the sewage comes into contact have double or hollow walls forming a space in which the deodorising or disinfecting material is contained; the outer walls are made impervious to liquids and the inner walls are porous, thus allowing the disinfectant to permeate through, and come into contact with the sewage.

—J. C. C.

#### XIX.—PAPER, PASTEBOARD, Etc.

*Improved Apparatus for Raising, Forcing, and Circulating Semi-fluid and Liquid Substances.* J. Taylor, Wandsworth Common, Surrey. Eng. Pat. 13,709, July 16, 1894.

See under I., page 931.

#### XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

*Manufacture and Compression of Nitrous Oxide.* J. Thilo. Chem. Zeit. 18, 532.

AMMONIUM nitrate (16–18 kilos.) is heated in cast-iron retorts of 30 litres capacity furnished with long narrow necks. This is at least the plan adopted in certain German works. The use of larger quantities of material is attended with danger, inasmuch as a sudden evolution of nitrous oxide may cause explosion. The connections with the washing-flasks are best made by means of caoutchouc stoppers and glass tubing. The principle impurities of the gas as thus prepared are chlorine, hydrogen chloride, and higher oxides of nitrogen. Three washing-flasks are employed for every retort; the first contains water, the second ferrous sulphate solution, and the third caustic soda solution. Whereas the object of the second flask is to render the gas innocuous by freeing it from other oxides of nitrogen, that of the third is to free it from chlorine and chlorine compounds. For the manufacture of nitrous oxide an almost absolutely pure ammonium nitrate only is admissible.

After the gas has passed through the washing-flasks, it is led into a large empty flask which is kept cool by ice, in which the greater part of the moisture of the gas is condensed, and from whence it finally reaches the condenser. It has now to pass through the second phase of the process, viz., compression and liquefaction. Two compressors, giving at most 16 atmospheres pressure, are employed, the remainder of the compression work is accomplished by cold. When the gasometer is completely filled with gas the two double-action pumps are set in motion; the gas is thus sucked out of the gasometer into a tube of 6 litres capacity, tested up to 250 atmospheres, which is surrounded with a copper jacket having inlet and outlet tubes. In this copper jacket enters a cooling fluid consisting of a mixture of carbonic and sulphurous anhydrides (Pictet's fluid) which is drawn out of the same by three other steam pumps and liquefied in a worm condenser, cooled by water at 2–3 atmospheres pressure. It has yet to be mentioned that also between the gasometer and the suction cylinders of the first machine the gas has to pass a similar refrigerator where it is cooled to –20° C. in order to free it from the last traces of water.

By means of the cooling fluid, the temperature of the tube containing the nitrous oxide remains constant at about  $-60^{\circ}$  to  $-70^{\circ}$  C., at which temperature a pressure of 12–14 atmospheres is sufficient to cause liquefaction of the gas. When the latter is accomplished, the tap of the tube is shut off from the compressor and the surplus pressure between this tap and the second compressor allowed to go back into the gasometer through a tube leading to the latter.

As the tube in which the liquefaction is accomplished contains only a little more liquid nitrous oxide than corresponds with that present in the gaseous state in the gasometer the complete evacuation of the gasometer is the signal for the end of the liquefaction. If the pressure rises above 14 atmospheres without the gasometer being empty, this indicates that the gas contains air or other gases compressible with difficulty, which can be let off by a valve placed between the high pressure compressor and the compression tube. The yield amounts generally to 85–95 per cent. of the theoretical.

The liquid nitrous oxide can now be introduced into steel flasks, which resemble those used for carbonic anhydride. These flasks are likewise surrounded with the Pictet refrigerating liquid,  $\text{SO}_2$ ,  $\text{CO}_2$ , contained in a jacket which is in connection with the cooling jacket of the compression tube for the gas, the steel flasks being connected with the compression tube itself; on the connecting tube is placed a valve with a copper tube leading back to the gasometer. In order, therefore, to fill the flasks, which must be previously rendered vacuum, these are placed in the refrigerator and hung on a balance devised for the purpose, and when sufficiently cool, a little nitrous oxide is run in and this is led back into the gasometer through the tube already mentioned. The flask is now sufficiently cool to be charged with the liquefied gas in the compression tube. The increase in weight of the flask due to the liquefied gas is indicated by the balance. The following sketch shows the complete arrangement:—

The nitrous oxide enters at *a* under a pressure of 12–14 mm. which is denoted by a manometer *b*; at *c* the gas passes into the compression tube through the cock. It is here cooled by the  $\text{SO}_2$ ,  $\text{CO}_2$  contained in the jacket. The  $\text{SO}_2$ ,  $\text{CO}_2$  enters the jacket at *g* and can also be led into the second cooling jacket surrounding the flask *i*. The entrance of the cooling liquid in the last-mentioned refrigerator is at *k*, the exit of the gas, which is aspirated by pumps and again condensed, is at *l*, and from the horizontal refrigerator at *m* the gas must yet pass the widened portions *n* and *o* of the tubes. In the tube *cd* the nitrous oxide is liquefied and led into the flask *i* through the tube *df*. At *f* the non-liquefied or re-gasified nitrous oxide is driven back into the gasometer. The cross-piece *p, q, r, s* has the following object:—When the tube *cd* is full of liquefied nitrous oxide and the gasometer is empty, the pressure which still exists between *c* and the compressor is let off into the gasometer through *p, r*. If non-compressible gases have collected, due to impurities, their presence may be recognised by opening the valve *s*,

which is in connection with the manometer *h*, they are eliminated through the valve *q*. The flask *i* hangs on a balance at *t*—A. R. L.

*The Recovery of Residual Tinctures from Mares.* R. H. Parker. Proc. of the Pharm. Conference, 1894 (Oxford). Chem. and Druggist, 45, 1894, 189–191.

*Displacement by Water.*—“Downward” v. “Upward.”—Two parallel experiments were conducted. In each case 2 oz. cort. cinchona flav. (in No. 10 powder) and 10 oz. proof spirit were mixed in a 12-oz. bottle, and occasionally agitated during three or four days, and poured into a glass tube percolator (2 ft. long, 1 in. wide) having muslin tied over the lower end and resting in a funnel and bottle-receiver. As soon as the mare filled the tube, and without allowing the liquid to drain away, the upper end was closed with a perforated cork carrying a tube connected with a water supply.

In one experiment the water was forced in at the top, and the displaced tincture collected in fractions at the bottom.

In the other case the water was forced in at the bottom, and the displaced tincture collected in fractions at the top.

The sketch illustrates the process:—

“DOWNWARD” v. “UPWARD” DISPLACEMENT.

- a.* Glass tube filled with mare.
- b.* Pressure water-supply.
- c.* Bottle to collect displaced tincture.

The following deductions may be made from an examination of the tables given:—

(1.) That the precision of displacement depends upon the relative affinities and miscibility of the superposed fluids at the contact surface; an alcoholic solution being more perfectly displaced by water than by alcohol, especially if each fluid holds in solution a substance insoluble in the other, as in alcoholic percolates of ginger, belladonna, aconite, &c.

(2.) In the downward displacement of alcoholic tinctures by water, diffusion of the latter into the tincture in advance of the rate of percolation takes place to an inconsiderable extent only.

*Conclusion.*—The preparation of tinctures, liniments, &c. by percolation and displacement by water, is much more economical than by screw-pressure of the mare; the process is quite reliable if carefully conducted, but is better adapted to stronger spirituous preparations than to proof spirit compounds. However, the method is unsuitable for operations on a large scale.

The chief points to be observed in order to secure good results are:—

(1.) The materials should be in fairly uniform powder: No. 20 for porous, readily permeable substances; No. 40, or finer, for drugs of denser structure.

(2.) The ingredients should be fairly macerated in the whole of the menstruum (either stirred in the percolator or agitated in a bottle) until extraction is complete.

(3.) The most important point of all is that the marc shall be entirely free from air-spaces and air-channels. To ensure this, particular attention must be paid to the method of packing the marc, and the precise moment when water should be superposed. The marc should be stirred in the percolator with sufficient menstruum to form a semi-fluid mixture; when quite uniform and free from air-bubbles it should be allowed to drain, occasionally jarring the side of the percolator against the hand until it acquires solidity; water should be immediately floated on so as not to disturb the marc. A convenient method is to pour the water through a funnel into the inverted lid of an ointment-pot, previously laid on the surface of the marc.

(4.) The displacement should not be rapid, and the percolate should be collected in relatively small fractions when the total quantity approaches completion—cloudiness, altered gravity, and colour indicating the termination of the process.

*Crystallised Guaiacol.* G. Freyss. Chem. Zeit. 1894, 18, 565—566.

LIKE other phenols of low melting-point, guaiacol gives a different value for this constant, according to whether the determination is made in a test tube or in a capillary tube. The purity should therefore be ascertained through the crystallising or solidifying point, which is always constant, even if the specimen be superfused. Pure guaiacol solidifies at 28.5, not 27 (Seifert, Chem. Zeit. Rep. 1894, 18, 19), and distils at 202.4 at 738 mm. (thermometer in vapour); a very little impurity lowers the solidifying point. Pure guaiacol has a characteristic odour; it crystallises in long, vitreous, transparent prisms, which become rose-red in sunlight. The crystals belong to the hexagonal system;  $a:c = 1:0.9933$ ; other measurements are described in the paper. For therapeutical use only very pure guaiacol should be employed. Gilbert and Maurat (Münchener med. Wochenschr., 1893, 979) found that the toxic dose of crystallised guaiacol for guinea-pigs is 0.8—0.9 gm. per kilo. of body-weight when subcutaneously injected, and 1.5 grms. when internally exhibited; experiments made with the author's pure guaiacol on a dog of 9—10 kilos. body-weight showed that 10 grms., internally exhibited, produced no ill-effect. Gilbert and Maurat have experimented with phthisical patients and have found that crystallised guaiacol, administered in capsules before meals, have had good effect. Wyss (D. med. Wochenschrift, 1894, No. 13) found that 5 cc. of commercial liquid guaiacol (which could not have been pure) was fatal to a girl of nine years and 21.7 kilos. body-weight, when internally exhibited.—A. G. B.

*Technical Analysis of Ethereal Oils.* J. Klimont. Chem. Zeit. 19, 641—642 and 672—673.

See under XXIII., page 985.

#### PATENTS.

*An Improved Method of Producing Carbon Tetrachloride.* A. Muller and H. Dubois, Rheinau, Germany. Eng. Pat. 19,628, October 18, 1893.

THE method consists in heating a mixture of sulphur chloride and carbon bisulphide with addition of metals or metallic haloids, especially iron or ferric chloride, when carbon tetrachloride is produced in accordance with the equation— $\text{CS}_2 + 2\text{SCl}_2 = \text{CCl}_4 + 6\text{S}$ . An excess of sulphur chloride renders the reaction less violent, and increases the yield.

The following example is given to illustrate the manner in which the process may be carried out:—A mixture of carbon bisulphide (76 kilos.), sulphur chloride (405 kilos.), and pulverised iron (500 grms.), is heated to about 60° C. in an iron vessel coated with lead, and provided with a lateral man-hole, a reflux condenser, and a steam coil. The reaction commences spontaneously, and at the end the mixture is heated to boiling for a short time. On cooling, the sulphur separates in large crystals, and may be reconverted into sulphur chloride or carbon bisulphide so as to be again included in the cycle of the reaction.

The liquid run off from the sulphur is subjected to fractional distillation in order to separate the carbon tetrachloride from the excess of sulphur chloride. The crude carbon tetrachloride thus obtained is further purified by the known methods.—A. R. L.

*Improvements in the Manufacture of Antiseptics.* H. E. Newton, London. From The Farbenfabriken vormals F. Bayer and Co., Elberfeld, Germany. Eng. Pat. 19,622, October 18, 1893.

IN Eng. Pat. 3301, 1892 (this Journal, 1893, 172) the inventors claim for antiseptic, deodorising, and disinfecting purposes the use of salts of dinitro-ortho-cresol. They now find that free dinitro-ortho-cresol possesses a high degree of antibacterial power, although the metallic salts exhibit this property in only a slight degree. The solubility is about one part of dinitro-ortho-cresol in 4,000 to 5,000 parts of water, but even this strength of solution is more powerful than a 0.5 per cent. solution of the potassium salt. Stronger solutions of the body may be obtained in the solution of its potassium salt, but a 10 per cent. solution of borax will dissolve 10 per cent. of free dinitro-ortho-cresol, or dry mixtures of one part of the free body, and two parts of borax may be prepared.—J. C. C.

*A Process for Converting Compounds of the Citral Series (Geranium Series) into Isomers having a Higher Specific Weight and a lower Boiling Point than the Original Bodies.* J. C. W. F. Tiemann, Berlin, Germany. Eng. Pat. 22,114, November 18, 1893.

WHEN geranic acid,  $\text{C}_{10}\text{H}_{16}\text{O}_2$ , which is an oil boiling at 153° C., under a pressure of 13 mm., is added with agitation to 70 per cent. sulphuric acid cooled below 0° C., it is transformed into a solid isomeric acid which crystallises from ligroin. The isogeranic acid melts at 103.5° C., and boils at 138° C. under a pressure of 11 mm.

In the same manner geraniumitrile,  $\text{C}_{10}\text{H}_{15}\text{N}$ , which boils under a pressure of 10 mm. at 116° C., and has a specific gravity of 0.8709, may be transformed into the nitrile of isogeranic acid which boils at 87°—88° C. under a pressure of 11 mm., and has a specific gravity of 0.9208.

Geraniolene,  $\text{C}_{10}\text{H}_{16}$ , the hydrocarbon obtained by removing the elements of carbonic anhydride from geranic acid boils at 142°—143° C., and has a specific gravity of 1.4368. When heated with 60 per cent. sulphuric acid for 3—4 hours it is converted into isogeraniolene, which boils at 138°—140° C., and has a specific gravity of 1.4434.

Phosphoric acid or metaphosphoric acid may be substituted for sulphuric acid, but the latter gives the best results. The iso-compounds of the citral series are intended to be used for perfumery purposes.—A. R. L.

## XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

## PATENT.

*Improvements in the Process of Making Photographic Films.* E. Edwards, London. From R. Reissner and G. C. F. Hauser, Erlangen, Germany. Eng. Pat. 18,237, September 28, 1893.

This is a process for rendering gelatin films insoluble in hot water, and consists in dissolving the gelatin in a weak solution of formaldehyde, forming films from this, and drying, the rendering insoluble of the films being effected during the drying; 0.2 part of formaldehyde being sufficient to render insoluble 1 part of gelatin.

In place of formaldehyde, a solution is claimed, the component parts of which, by their mutual influence, yield formaldehyde.—J. C. C.

## XXII.—EXPLOSIVES, MATCHES, Etc.

*Researches on Modern Explosives.* W. Macnab and E. Ristori. Proc. Royal Society, 56, 8—19.

This paper chiefly records the results of experiments made to determine the amount of heat evolved, and the quantity and composition of the gases produced, when certain explosives and various smokeless powders now in use were fired in a closed vessel from which the air had been previously exhausted.

The explosions were carried out in a "calorimetric bomb" of Berthelot's pattern, details of the procedure are given in the paper and special care was taken to accurately determine the amount of water produced.

The principal results are given in the following tables:—

The figures in columns headed "Coefficient of potential energy" serve as a measure of comparison of the power

of the explosives, and are the products of the number of calories by the volume of gas, the last three figures being suppressed in order to simplify the results.

The amounts of water found were calculated for comparison as volumes of H<sub>2</sub>O gas at 0° and 760 mm.

EC powder consists principally of nitrocellulose mixed with barium nitrate and a small proportion of camphor; SS, of nitroguin mixed with barium nitrate and nitrobenzene.

Troisdorf powder is gelatinised nitrocellulose; rifleite is made of gelatinised nitrocellulose, to which is added a certain proportion of nitrobenzene; BN consists mainly of gelatinised nitrocellulose.

Cordite contains 58 per cent. of nitroglycerin, 37 per cent. of gun-cotton, and 5 per cent. of vaseline.

Ballistite of Italian manufacture contains equal parts of nitrocellulose and nitroglycerin, with the addition of  $\frac{1}{2}$  per cent. of aniline.

The German ballistite contains a slightly higher percentage of nitrocellulose.

TABLE IV.—SHOWING the HEAT developed and the ANALYSIS of the PERMANENT GAS produced in a closed VESSEL from which the AIR has not been exhausted, the EXPLOSIVE being in every case BALLISTITE of ITALIAN MANUFACTURE.

Charge.	Calories per Grm.	Analysis of the Permanent Gas.

—W. M.

PATENTS.

*An Improved Apparatus for Use in Measuring the Pressure of Gas in Guns.* A. Castenholz, Karlsruhe, Germany. Eng. Pat. 11,991, August 4, 1893.

See under L, page 929.

*Improvements in the Manufacture of Gunpowder.* A. Schindler, Breslau, Germany. Eng. Pat. 20,327, October 27, 1893.

THE proposed powder consists of 12 parts by weight of potassium chlorate, 3 parts of sugar, and 5 parts of anthracite, all finely ground and mixed. It is stated that anthracite, being denser and less easily combustible than ordinary charcoal, prevents the chlorate powder made in the way described from being too rapid in its action.

—W. M.

*Improvements in the Manufacture of Explosives.* H. H. Lake, London. From C. Pieper, Berlin, Germany. Eng. Pat. 23,773, December 2, 1893.

THIS invention relates to explosives composed of ammonium nitrate and dinitrobenzene or nitronaphthalene, &c., and consists in using a solvent for one or other or both of the ingredients, effecting the mixing in the wet state, and then evaporating off the solvent, care being taken that the temperature used for this purpose is not sufficiently high to melt the nitrohydrocarbon. In this way more intimate contact is ensured between the particles of the components, and the explosives thus prepared can be fired by a much smaller detonator, viz., an ordinary dynamite detonator containing 0.54 grm. of fulminate.—W. M.

*Improvements in and relating to the Method and Apparatus for Blasting.* A. W. Schwarz, Leipzig, Germany. Eng. Pat. 7098, April 10, 1894.

THIS improvement consists in making chloride, bromide, or iodide of nitrogen as required in the blasting cartridge itself, and exploding the same in a manner described in the specification.—J. C. C.

*Employment of Trinitroresorcine as Smokeless Driving Powder.* J. Hauff, Stuttgart, Germany. Eng. Pat. 9798, May 19, 1894.

THE claim of this patent is: "The employment of trinitroresorcine as smokeless driving powder, either in granular form, which is obtained from crystallisation by alcohol, pulverisation and sifting, or in grains pressed in the manner of black powder, or by appropriate gelatinising mediums brought to a colloidal form, grain or lamina, and covering single grains with a thin coating of indifferent bodies—for example, paraffin—whereby the burning goes on slowly, and therefore the explosive force is diminished."—W. M.

*Improvements in or relating to the Exploding of Blasting Charges in Mines.* L. Jaroljmeck, Prague, Bohemia. Eng. Pat. 13,714, July 16, 1894.

IN this invention the heat necessary for firing a charge in a borehole is generated in the first instance by allowing the water used as tamping to act on quicklime or a similar substance. By arrangements which are described and illustrated in the specification, the heat resulting from the hydration of the lime is caused to ignite a sensitive detonator which fires the explosive, or it melts a plug of fusible metal and allows sulphuric acid to flow from another compartment of the cartridge into the explosive, or the swelling of the lime is caused to exert pressure and rend asunder an ignition capsule which detonates the explosive.—W. M.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS, ETC.

*Some Notes on Sampling.* David Surley. A paper read before the Glasgow City Analysts' Society, 1893-94. No. 1.

Iron Ore should always be sampled at the ship's side from waggons, as the ore is there weighed for invoice purposes, and subsequent fluctuations in the proportion of water will not then affect buyer or seller. Sampling from the "bing" at the ironworks should not be attempted, except as a last resource, as the lumps are used for making the face of the bing, the smaller ore, which is different in composition, forming the centre; as the sample at best can only be taken from the surface, a fair average cannot be obtained. In sampling iron ore the instruments required are a geological hammer, a small hand shovel, and a canvas bag to hold the sample. To draw a sample from trucks proceed thus:—Note carefully the proportions of "lumps," "rubble," and "smalls" in the waggon in which you are standing. Take your proportion of smalls from different parts of the waggon in quantities of about a teaspoonful at a time, and place these on the shovel. Take samples of the rubble and lumps in the same way. In sampling the lumps, the whole piece must be broken and chips taken from both the outside and the inside; no piece should be larger than a cherry. The quantity taken from one waggon will thus weigh about 10 oz., and is at once placed in the bag. Now go into the other waggons and proceed in precisely the same way, judging the proportions as it each waggon contained a separate cargo. The sample is next ground in small portions at a time on a planed steel plate by means of hammers, till the ore is fine enough to pass through a sieve having five meshes to the linear inch. The whole is thoroughly mixed, spread out, quartered, and two opposite quarters further ground finely enough to pass through a 10-mesh sieve. From this a fair average sample is taken to the laboratory. Sampling on a larger scale, as sometimes carried out, the sample taken even weighing as much as 2½ tons, involves more labour, and, though giving equally good, yields no better results. In a recent case the same cargo was sampled in both ways, and the two samples showed a difference of only 0.09 per cent. of iron. The author objects to "tub" sampling and to a common English practice in which the sampler estimates the proportion of lumps, rubble, and smalls by the appearance of the cargo in the ship's hold, afterwards drawing intermittent samples from, say, eight waggons in the course of the day. Joint sampling, in which representatives of the buyer and seller draw the sample jointly, is highly undesirable. It is noteworthy that the smalls of Campanil and Vena iron ores contain about 2 per cent. more iron than the lumps, whereas the lumps of Rubis ore are richer than the smalls in the same proportion.

*Pyrites Residues* from the roasting of pyrites should be sampled from waggons, as in the case of iron ore, if at all possible, as it is very irregular. Care must be taken to break the lumps, and to take portions from the centre as well as from the outside, as if there be any unburnt sulphur it will be there.

*Basic Slag* in the form of meal is simply sampled from the bags with a sampling needle in the usual way. When unground, it is sampled very carefully from each hutch as it is being conveyed to the grinding machinery. Two samples are taken: moisture is estimated in one without grinding, while the other is finely powdered for analysis.

*Pig Iron* is sampled by breaking the pig and taking borings to the depth of 1 in. from the clean fractured surface.

*Wood Pulp* is imported in bales or bundles weighing from 20 lb. to 1 cwt. In sampling, the bale is opened out and a diagonal strip is cut from one of the sheets. The portion taken out is cut into small pieces and bottled quickly to prevent loss of water from the wet pulp.

In sampling *Sulphate of Ammonia*, *Sulphate of Potash*, and salts in general, care should be taken to get an average

sample from the whole depth of the bags, as such salts drain rapidly, the bottom layer becoming wetter and the top layer drier.—L. A.

*Table for the Comparison of Hydrometers.* Reprinted from "The Chemical Trade Journal" of October 13, 1894.

*Vacuum Evaporating Apparatus for Laboratory Purposes.*  
Soxhlet. Chem. Zeit. 18, 721—722.

THE evaporation of large volumes of liquids in the chemical laboratory is a tedious and lengthy operation; if a free flame is employed there is a danger of loss of material, and there is no alternative but to use the water-bath. But many solutions—for example, sugar solutions—cannot be heated at the temperature of the water-bath without decomposition, besides which they cannot be concentrated to a syrupy condition as quickly as is desirable. The most rapid mode of procedure, in which decomposition is prevented, is evaporation under diminished pressure. By the aid of the apparatus figured below, 4 litres of water per hour may be evaporated at a temperature of 32—35 C.; or, if the condenser be surrounded by a freezing mixture, the same quantity of water per hour may be evaporated at 24—26 C.

LABORATORY VACUUM EVAPORATING APPARATUS.

The glass flask A, which serves as a vacuum pan, rests on a copper water-bath B, having a rim adapted to it. The pear-shaped piece C is in connection with an arrangement for charging the flask. The caoutchouc tube E surrounded by wire spiral, serves to connect the flask with two large globular condensers of the author's well known construction. The tube G, furnished with a tap, leads to a graduated Wulff's bottle, which receives the distillate. To the second tubulus of the Wulff's bottle is attached a T-piece, one limb of which is in connection with a Korting's water-pump and the other with a mercury manometer.—A. R. L.

*Extraction Apparatus for Liquids.* A. Kurbatow. Russ. phys.-chem. Gesellsch. 1894, 10. Chem. Zeit. Rep. 1894, 18, 101.

The apparatus shown in the figure resembles an ordinary Soxhlet's extractor for solids, save that the tube C is connected with the upper instead of the lower end of the extraction chamber A, and thus no longer functions as a siphon, but as a simple delivery tube back into the flask containing the solvent. The vapour of the solvent ascending

through the tube E, passes through slots in the sides of the funnel B to the condenser, and the resulting liquid flows down the stem of the funnel to the bottom of the liquid to be extracted, through which it rises and trickles over through C to the flask below. D is a glass rod that can be used as a stirrer without opening the apparatus.—B. B.

*An Improved Form of Hard Glass Beakers for Dyeing Tests.* R. Lepetit. Färber Zeit. 5, 1894, 183.

THE china beakers with a ring round their middle are well known, but their expense militates much against their general use. In France conical china beakers, without the ring, are much in vogue. They are considerably cheaper, and the depth to which they may be immersed in the bath is determined by their increasing circumference. These conical china beakers have several advantages over the frequently used cylindrical hard glass beakers, the most important of which is that more concentrated baths with small volumes of water can be used in them. This allows of an approach to the conditions under which the dyeing on a large scale is performed, the volume of the dye-bath used in proportion to the weight of fibre dyed in it, being relatively far greater in the experiment than in practice. This is particularly important when experimenting with slow-dyeing colours, which with the same depth of dye-bath produce from 10 to 20 per cent. stronger shades in conical than in cylindrical beakers. On the other hand, the opacity of the china beaker is certainly a drawback, as it does not admit of the ready observation of the degree of exhaustion or formation of sediments in the bath. This drawback is avoided, without losing the advantage of the conical beaker, by making these conical beakers of hard glass. The capacity of these beakers is about 400 cc., but it is important to see that the dimensions of all the beakers used for comparative tests are exactly identical.—C. O. W.

## INORGANIC CHEMISTRY.—QUALITATIVE.

*Detection of Adulterants in Basic Slag.* O. Böttcher. Chem. Zeit. 1894, 18, 565.

A NUMBER of "Thomas phosphate meals," "Thomas slags," and the like are now on the market. They are merely ground mineral phosphate coloured with powdered charcoal, &c.

Wrampelmeyer has pointed out that a microscopical examination should form the preliminary operation in detecting mineral phosphate adulteration of basic slag; natural phosphates are lighter in colour, and when considerably magnified, more rounded in structure than is basic slag, which consists of sharp-angled splinters which scatter the light. Loss on ignition, specific gravity and solubility in water should also be determined; if the first of these be low and the two last high, the slag is genuine. As a last resort the citrate solubility may be determined.

The author advocates a test for fluoride in the suspected slag, as suitable for the use of the layman. It is of importance on account of the constancy with which fluorides are present in mineral phosphates. 10—15 grms. of the slag in a beaker are covered with 15 cc. of concentrated sulphuric acid, and stirred with a glass rod; the beaker is covered with a clock glass to which a drop of water is suspended, the usual deposit of silica being detected if fluorides be present. After 5—10 minutes the clock glass is cleaned and inspected to see if etched. In this way the author has detected Florida phosphate, sand phosphate, river phosphate, Carolina phosphate, Hungarian phosphate, and a prepared phosphate, respectively, when mixed to the extent of 10 per cent. with basic slag.—A. G. B.

## INORGANIC CHEMISTRY.—QUANTITATIVE.

*Colour-Gauges for Carbon Testing.* W. G. McMillan. Iron and Steel Institute, Autumn Meeting, 1894.

IN respect of accuracy, rapidity, and general convenience the author considers the colorimeter, even in its existing form, to be greatly superior to the old colour tubes used in the Eggertz process for carbon determination. He, however, points out certain possibilities of error in the use of the internally illuminated (disc) chromometers, owing *inter alia* to the necessarily unequal illumination of the tubes, and lays down the following, amongst others, as the essentials of a good colour gauge:—All portions of the apparatus with which the coloured liquid shall come in contact should be of glass or glazed porcelain and free from cement. Every such part must be accessible and capable of being readily cleaned. The illumination of the two tubes must be equal and uniform. Following out these rules the author has devised two colour gauges, one internally illuminated, the other externally; both are fully described and illustrated by drawings. The former, or disc-colour gauge, has necessarily such errors as are inseparable from this form of instrument, but the author has endeavoured to simplify the mechanism. Two graduated tubes stand side by side, each with a porcelain disc near the bottom at the zero of the graduations. One of them is connected by a narrow glass tube sealed on to the bottom with a third vertical tube (wider than the others) in which a glass plunger works up and down, displacing the liquid and altering the level in the graduated tube connected with it; the plunger may be fixed at any point by means of a set screw. In the externally illuminated or transmittent colour-gauge, which the author prefers as being more scientific, and free from the errors of the disc instrument, the comparison tubes stand in a wooden box having a longitudinal slot in the bottom with a white opaque reflector beneath, so that the colour tubes are equally illuminated by direct rays, and only from beneath. The alteration in the level of the liquid is made by sliding into the comparison tubes inner glass tubes, the bottoms of which are rounded like those of the outer tubes, so that when they are in the lowest position all the liquid in the

outer tubes is displaced into reservoirs formed by enlargements in the latter, and on looking through the inner sliding tubes from above only colourless discs are seen. On raising the displacement tubes any required density of colour may be obtained, according to the position in which they are fixed; and as the two displacement tubes work independently a comparison of colour is readily made. The heights of the columns of liquid are given by indicators attached to the displacement tube and travelling over a fixed scale. To obviate the irregularities of the illuminated field introduced by round ended glass tubes, the bottoms of the outside tubes are dipped into a trough of water, and the interiors of the displacement tubes are also filled with water, the meniscus of which is flattened by a glass disc. Separate eye-piece tubes are provided. The author prefers the word *Colour-gauge* to other current terms.—W. G. M.

*The Determination of Carbon in Steel.* H. Koch. Chem. Zeit. 1894, 18, 485.

THE flask shown in the accompanying figure is used for the determination of carbon in steel by direct oxidation with chromic acid in sulphuric acid solution. Its dimensions are given in the figure. It will be seen that it consists of two principal parts, the flask proper with a side tube at its lower part for leading in air free from  $\text{CO}_2$  to sweep out the gases evolved by the oxidation of the steel, and a second side tube

at the upper part of the neck to deliver the evolved gases into the combustion tube containing heated cupric oxide in which the oxidation of any hydrocarbons is completed. The quantities of reagents used are 8 grms. of  $\text{CrO}_3$  and 120 cc. of sulphuric acid of sp. gr. 1.62, the amount of steel (in fine borings) taken, being 2 grms.

The second main part of the apparatus is the condenser with appropriate tubes for leading the cooling water in and out, projecting down the neck of the flask and ground in at the upper end which is constricted for that purpose. By the use of a condenser thus placed, the contents of the flask may be freely boiled to effect the oxidation of the steel and the contained carbon which is to be determined. The apparatus has also been used by the author for the determination of carbon in coal.—B. B.

*Apparatus for the Valuation of Manganese Dioxide by Bunsen's Method.* C. Ullmann. Chem. Zeit. 1894, 18, 487.

THE Bunsen method for the valuation of manganese dioxide is less used than is warranted by its intrinsic merits, chiefly on account of the defects of the apparatus commonly employed. The author claims that the device shown in the figure is free from such shortcomings. The method to be employed

is obvious from the illustration. It suffices to remark that the beaker can be supported on a wooden block, and that when the whole of the chlorine has been evolved the block

can be removed and the beaker lowered before taking the burner from under the flask, thus avoiding the possibility of regurgitation. The bulb on the delivery tube of the flask serves to prevent the return to the flask of any liquid remaining in the rectangular bend. During the absorption of chlorine by the potassium iodide solution contained in *a*, the upper layer of the liquid in the beaker remains colourless. After the distillation the liberated iodine is titrated in the usual manner.—B. B.

*Detection and Separation of Arsenic in the Presence of Antimony and Tin.* F. A. Gooch and B. Hodge. Chem. Zeit. 1894, 18, 156 (Rep.).

THE sample is dissolved in hydrochloric acid and potassium iodide, and the solution distilled nearly to dryness. The distillate is condensed in hydrochloric acid, and the colour due to the iodine discharged by adding a solution of chloride of tin in hydrochloric acid. The arsenic is then precipitated by passing sulphuretted hydrogen through the solution. By this method 0.0001 grm. of arsenic can be detected in the presence of 0.4 to 0.5 grm. of antimony or tin, and 0.003 grm. of arsenic separated by it.—B. B. P.

*The Analysis of Potassium Nitrate.* A. Hellich. Chem. Zeit. 1894, 18, 485—486. (See p. 947.)

THE author, in examining a sample of potassium nitrate which contained only a trace of chlorine as chloride, tested it for the possible presence of bromate by deluging it with sugar, dissolving the residue in water, acidifying with nitric acid and adding silver nitrate solution. A precipitate was obtained which proved to be silver chloride instead of bromide. Further trials with starch, cotton, and sulphur as reducing agents in place of sugar gave similar results. On fusing the nitre *per se* in a platinum dish for some minutes, no reaction with silver nitrate in the subsequent aqueous extract was observed, but on continuing the heating and raising the temperature of the fused salt a definite reaction for a chloride was obtained; this became more marked on adding manganese dioxide to the fused salt and

heating strongly. In the remainder of the investigation the only reagents used were manganese dioxide and sulphuric acid, the freedom from chlorine of which had been previously ascertained. The plan thus modified was carried out as follows:—10 grms. of the sample of nitre were mixed with 0.5 gm. of powdered manganese dioxide and the mixture was strongly heated until the melt had become green. It was then extracted with water (50 cc.), and to it 20 cc. of dilute sulphuric acid were added. The solution was allowed to stand and was then filtered through a filter previously extracted with dilute sulphuric acid. The filtrate when tested with silver nitrate gave a white turbidity. Twenty samples of nitre were examined by this method and chlorine recognised in all, the quantity varying from that corresponding with a slight turbidity to that represented by a curdy precipitate. Examination of the precipitate obtained from a number of samples showed it to be actually silver chloride. The deduction drawn by the author is that these samples of nitre contained some chlorine compound incapable of giving a reaction with silver nitrate. Organic substances containing chlorine are excluded, as such bodies would be broken up on fusing the nitre containing them, whereas the addition of manganese dioxide and strong heating are necessary to develop the full reaction. The absence of chlorates appeared assured from the fact that a portion of the nitre treated with strong sulphuric acid developed no coloration; direct experiment showed that this test suffices for the detection of 0.1 mgrm. of potassium chlorate in 1 gm. of nitre. Another proof of the absence of chlorate was afforded by slightly colouring the nitre solution with a solution of indigo and adding sulphurous acid, when the colour of the indigo was not discharged. The author concludes that the impurity in nitre which contains chlorine is a perchlorate, the quantity amounting to about 0.25 per cent. in a sample giving evidence of considerable contamination. Definite proof of the correctness of this view can best be obtained in a nitre refinery in which fractional separation by crystallisation of large quantities of nitre is feasible. Every sample of the salt hitherto examined has shown the presence of perchlorate, which exists even in those labelled "chemically pure." The reaction was also given by a sample of nitre some 20 years old made by an obsolete method of manufacture.—B. B.

*Examination of Artificial Manures.* Chem. Zeit. 1894, 18, 361—363.

This paper is a summary of the methods now in use in the German Experiment Stations.

*Preparation of Samples.*—One-half of the sample is prepared for analysis immediately after its arrival, whilst the remainder (up to 1 kilo.) is bottled and stored in a cool room for three months, in case it be required for reference. Dry samples are sifted and mixed; moist samples, can, of course, only be mixed. Raw phosphates and bone charcoal are dried at 105°–110° C. for the estimation of moisture; if ammonia be present the proportion of this lost at the temperature of drying is determined. In the case of substances which suffer a variation of their water-content during pulverisation, a determination of moisture must be made both in the original substance and in the powdered sample, and the results of the analysis must be appropriately connected.

*Estimation of Moisture in Superphosphates.*—Ten grms. are dried for three hours at 100° C.; the loss of weight is determined as moisture.

*Estimation of Soluble Phosphoric Acid in Superphosphates.*—Twenty grms. of the sample are shaken with 800 cc. of water in a litre flask for 30 minutes; water is added until the flask is filled to the mark and the liquid is again shaken, and filtered. The phosphoric acid is estimated in the filtrate either by the citrate method or by the molybdate method, the latter being alone admissible in arbitration cases. In the citrate method 50 cc. of the solution, thus prepared, are mixed with 50 cc. of citrate solution (see below) and 25 cc. of magnesia mixture are added; the liquid is shaken for half-an-hour and filtered through a Gooch crucible. The dried precipitate is heated for 3–5 minutes in a Rössler's furnace.

When a double superphosphate is under examination, the solution must be heated with nitric acid before the phosphate is precipitated, in order that any pyrophosphate which may be present shall be converted into orthophosphate. Twenty-five cc. of the solution, prepared as described above, are diluted with 50–75 cc. of water, 10 cc. of nitric acid (sp. gr. 1.4) are added and the solution is heated for one hour on the sand-bath, an excess of ammonia is then added and sufficient nitric acid to acidify the liquid. After cooling, the citrate and magnesia mixture are added in the manner already prescribed and the precipitate is heated for 10 minutes in the Rössler's furnace.

The citrate solution is prepared by dissolving 1,100 grms. of citric acid in water, adding 4,000 cc. of 24 per cent. ammonia and diluting to 10,000 cc.

In the molybdate method, 200 cc. of the molybdate solution (see following) are added to 5 cc. of the solution containing the phosphate, the mixture is digested for three hours at 50° C. on the water-bath, cooled, and the liquid poured through a filter. The precipitate is washed by decantation with diluted molybdate solution (1:1) until the washings no longer contain lime, and ammonia is poured through the filter paper into the beaker until the portion of the precipitate on the filter and that in the beaker are dissolved. The ammoniacal solution is nearly neutralised with hydrochloric acid and 20 cc. of magnesia mixture (550 grms. of crystallised magnesium chloride and 1,050 grms. of ammonium chloride dissolved in 3,500 cc. of 24 per cent. ammonia and 6,500 cc. of water) are added drop by drop, with continued shaking, followed by 25 cc. of 25 per cent. ammonia. After two hours the precipitate is filtered, washed with 5 per cent. ammonia until the washings are free from chlorides, and burnt as usual.

The molybdate solution is prepared by dissolving 1,500 grms. of ammonium molybdate in 10 litres of water, and pouring the solution into 10 litres of nitric acid (sp. gr. 1.2).

*Estimation of Insoluble and total Phosphoric Acid.*—Five grms. of the substance in a 500 cc. flask are dissolved in 50 cc. of *aqua regia* (three parts of hydrochloric acid of sp. gr. 1.12 with one part of nitric acid of sp. gr. 1.25), or are heated with 20 cc. of nitric acid (sp. gr. 1.42) and 50 cc. of sulphuric acid (sp. gr. 1.8) for half an hour. The solution is made up to 500 cc. with water and the phosphoric acid is estimated in 50 cc. by either the citrate method, or the molybdate method.

In the case of basic slag, 10 grms. are moistened with water and treated with 5 cc. of sulphuric acid (1:1) whereby the mass becomes hard. To this 50 cc. of concentrated sulphuric acid are gradually added, and the flask is heated on the sand-bath until thick fumes are evolved. Water is added before the flask has perfectly cooled, the cold liquid is made up to 500 cc. and filtered. The phosphoric acid is determined in 50 cc. by either the citrate method or the molybdate method.

*Estimation of the fineness of Basic Slag.*—This is carried out as usual.

*Estimation of Ferric Oxide and Alumina in Raw Phosphates.*—Five grms. are dissolved in 25 cc. of nitric acid (sp. gr. 1.2) and 12.5 cc. of hydrochloric acid (1.12), and the solution is diluted to 500 cc.; 100 cc. of the filtrate are brought into a litre flask, and 25 cc. of sulphuric acid (sp. gr. 1.84) and, after five minutes shaking, 100 cc. of alcohol (95 per cent.) are added. When this liquid has cooled alcohol is added to the mark, the flask is shaken and more alcohol is added to compensate for the contraction; after half-an-hour the solution is filtered, 100 cc. of the filtrate are evaporated in a platinum dish until the alcohol has been expelled, 50 cc. of water are added, the temperature is raised to the boiling point, and ammonia is added in excess, the excess being expelled by heat. The cooled liquid is filtered and the ferric oxide and alumina are washed with hot water, ignited and weighed.

*Estimation of Nitrogen.*—The nitrogen in blood-meal, Lone-meal, flesh-meal, and the like, is determined either by the Kjeldahl method or the soda-lime method. By the former, 0.8–1.5 gm. of the finely ground substance is heated in a flask with about 1 gm. of mercury and 20 cc.

of sulphuric acid (3 vols. concentrated sulphuric acid with 2 vols. fuming sulphuric acid) until the solution is clear. The liquid is transferred to a 400 cc. flask, 100 cc. of soda solution (32° B.) and 1-1.5 gm. of zinc dust are added, and the ammonia is distilled over as usual. The addition of potassium sulphide is unnecessary.

Nitric nitrogen in mixtures is determined according to the method of Schlosing-Grandeaun or that of Lunge. The total nitrogen is determined as follows:—1 gm. of the finely ground sample is mixed with 2-3 grms. of gypsum and introduced into the reaction flask; 25 cc. of phenol sulphonic acid are cautiously added and mixed by careful shaking with the substance, the flask being kept cool. After some time 1 gm. of mercury, and 3 grms. of zinc-dust are added; the flask is allowed to stand for half an hour and then heated until its contents are no longer coloured. The ammonia is then distilled over as usual.

Nitrogen in nitrates may be determined by the Böttcher method:—10 grms. are dissolved in 500 cc. of water; 25 cc. of the solution are mixed in a 400 cc. distillation flask with 120 cc. of water, 5 grms. of zinc-dust, 5 grms. of iron powder and 80 cc. of soda solution (32° B.). After the mixture has remained (connected with the condenser) at the ordinary temperature for 1-2 hours, during which time it has been frequently shaken, the ammonia is distilled over in the usual manner.—A. G. B.

## ORGANIC CHEMISTRY.—QUALITATIVE.

*Comparison of the Analytical Methods for the Detection of Margarine in Butter.* Seyda and Woy. Chem. Zeit. 18, 1894, 906.

**I. Koettstorfer's Method.**—By this method the saponification equivalent of the fatty acids in the butter is estimated. Using 2 grms. of butter and  $\frac{1}{2}$ -normal hydrochloric acid the maximum error of the titration is 0.05 cc. The analysis of 185 samples of butter gave the following results:—

From 221.5 to 223.....	4 per cent.	} 11 per cent.
" 223 " 225.....	7 " "	
" 225 " 226.....	7 " "	} 64 per cent.
" 226 " 228.....	15 " "	
" 228 " 230.....	21 " "	
" 230 " 233.....	28 " "	
Above 233.....	18 " "	

A very small proportion of these results falls below 225°, and a lower result than 221.5 has never been obtained from any pure butter. The saponification number of margarine is about 195.5; generally rather lower. Therefore a Koettstorfer number below 221 is sufficient proof of adulteration. Samples showing numbers from 221 to 225 may be considered doubtful, and 225 is the lowest number which should be accepted for pure butter.

**II. Reichert-Meißl's Method** is one by which the volatile acids contained in butter fat may be estimated. No other method has undergone so many alterations and additions, owing to the numerous sources of error inherent in it. There is a great uncertainty as to the minimum value, which by his method may be held to represent unadulterated butter, indeed the question as to whether a given sample is adulterated is always doubtful, unless the so-called Reichert-Meißl number be below 18. But in this case the Koettstorfer number will have been found so low as of itself to indicate the adulteration of the sample with margarine.

**III. Hehner's Method**, by which the percentage of fatty acids insoluble in water is estimated, is, in the opinion of the author, the most tedious of all and contains, the author considers, some considerable sources of error. The method, it is stated, will be most useful as confirmatory of the results of the two before-named tests; it should not be employed alone as a final and decisive test.—C. O. W.

## Detection of Castor-Oil in Olive-Oil. V. di Vetere.

Selmi, 1894, 4, 48.

OLIVE-OIL is sometimes adulterated with castor oil in spite of the apparent improbability of such a sophistication. 15-20 per cent. of castor oil is not recognisable by taste, and strong-smelling rancid olive oils appear to be sensibly improved by the addition. The methods for detection of the adulteration which are used by the author, are as follows:—10 cc. of the oil to be tested and 5 cc. of hydrochloric acid (sp. gr. 1.186) are shaken together in a test glass graduated to 0.1 cc. When castor-oil is present the liquid separates into three layers. The lowest is hydrochloric acid, the top layer consists of olive oil, and the middle stratum contains the castor oil. The colour of this middle layer varies according to the character of the oil with which it is mixed. The separation is not complete, but the size of the middle layer is nevertheless a fair index of the quantity of castor-oil present. The author has proved the utility of the method for sesame, cotton-seed, colza, earthenut, and linseed-oil as well as for olive-oil. Other methods applicable for confirming the results thus obtained, are the use of the oleo-refractometer of Amagat and Jean, and the determination of the turbidity temperature with acetic acid (Valenta's test). The results obtained with known mixtures of olive and castor oil are given in the following table:—

Olive-oil.	Castor-oil.	Per Cent.		Volume of the Middle Layer.	Degree of Oleo-refractometer.	Turbidity Temperature.
		Found.	Calculated.			
100	..	..	..	1		95° C.
..	100	..	..	44		{ Sol. at ordinary temp.
90	10	0.5	1.0	5		
85	15	1.2	1.5	7		85° C.
80	20	1.8	2.0	8.5		35° C.
70	30	2.9	3.0	12.5		25° C.
60	40	3.9	4.0	16		{ Sol. at ordinary temp.

—B. B.

## Detection of Castor-Oil in Balsam of Copaiba. L. Maupy. J. Pharm. Chim. 1894, 29, 362.

ADVANTAGE is taken of the fact that castor-oil yields sebacic acid and caprylic alcohol on dry distillation with excess of alkali. Sebacic acid is insoluble in cold, but soluble in hot water. The test is made by heating 10 grms. of the sample in a silver dish with dry caustic potash. The mass is stirred until volatile oily matters have been driven off, during which process the presence of castor-oil can be detected by the smell of caprylic alcohol. The mass separates into an upper resinous layer and a lower white liquid portion. After thorough separation the resin is removed and the lower layer treated with 50 cc. of water, boiled and filtered. On cooling this solution, sebacic acid separates, if the original sample contained castor oil. Further identification of the acid can be effected by converting it into its lead salt.—B. B.

## Behaviour of Strychnine towards Vitali's Atropine Reaction. G. P. Menyazzi. Boll. Chim. farm. 1894, 33, 103.

THE colour reaction discovered by Vitali, according to which the alkaloid (atropine) is oxidised by gently warming it with nitric acid, the yellow residue being moistened with alcoholic potash, a violet coloration being produced,—is also exhibited by strychnine and its salts.

The colorations produced by the two alkaloids can scarcely be distinguished. The alcoholic potash employed must be freshly prepared, colourless, and not too concentrated.

—A. R. L.

*Logwood Extract.* E. Donath. Chem. Zeit. 18, 277—278.

THE waste liquors from dyeing with logwood extract contain a certain proportion of nitrogen. As logwood extract is entirely soluble in water, the nitrogen compounds contained in it must be so also; hence these compounds are not fixed on the fibre and appear in the waste liquors. The analysis of two samples of the unadulterated commercial extract and of an extract prepared by the author, from rasped logwood which had been exposed to air for some time, gave the following results:—

	I. Extract of German Make.	II. Belgian Extract, Superior Quality.	III. Author's Extract, Dry.
	Per Cent.	Per Cent.	Per Cent.
Water.....	8.26	11.34	..
Nitrogen (calculated on ash.....) dry substance.	0.78	0.58	0.81
	6.39	4.99	1.33

If the nitrogen be expressed as protein substances, by multiplication by the protein factor 6.25, we have 4.87 and 3.62 per cent. respectively in the commercial extracts.

The large quantity of ash in the commercial samples consists chiefly of alkaline chlorides and phosphates; the extracts being made from "aged" wood, these salts result from the use of stale urine for sprinkling the wood during the "ageing" process.

The chief adulterants added to commercial logwood extracts are chestnut extract, sugar by-products (molasses), and gum. They may be detected as follows:—

*Chestnut Extract.*—An analysis of a sample of chestnut extract gave—

	Per Cent.
Water.....	14.48
Nitrogen (on the dry substance).....	1.28
Ash (on the dry substance).....	1.00
Reducing substances (calculated as glucose).....	31.40

Chestnut extract is much less readily decolorised by animal charcoal than logwood extract, the former also contains tannin, and gives a precipitate with gum solutions, which logwood does not. In testing the logwood extract its aqueous solution is decolorised, the presence of chestnut extract being indicated by a difficulty in decolorising, compared with a solution of an unadulterated extract under similar conditions. If the colourless solution gives a considerable precipitate with Fehling's solution the adulteration is almost certain. A further test, with gum solution, is only decisive when at least 7 per cent. of chestnut extract is present.

*Molasses.*—If the decolorised extract solution gives no precipitate, or a very slight one, with Fehling's solution, but after inversion with hydrochloric acid a copious precipitate of  $\text{Cu}_2\text{O}$  is thrown down, the presence of sugar by-products is evident.

*Glue.*—If the nitrogen present be over 1 per cent. adulteration with glue is probable. If glue be present to the amount of 8 per cent. or more, it is detected by extracting the dried and pulverised extract with strong alcohol, dissolving the residue in water, and precipitating with excess of lead acetate solution. The precipitate is filtered off and excess of lead removed by sodium carbonate. Filter, to remove lead carbonate, and to the filtrate add a tannin solution. The presence of glue is indicated by a precipitate or by considerable cloudiness.—R. B. B.

## ORGANIC CHEMISTRY.—QUANTITATIVE.

*Sources of Error in Roesse's Method of Estimating Fusel Oil in Spirit.* M. Glasenapp. Zeits. für Spiritusind. 1894, 17, 169.

THIS method consists in shaking spirit, brandy, &c. of 30 per cent. volume strength with a measured volume of chloroform, which takes up the fusel oil, and the increased volume of the chloroform is then observed. With careful attention to details, very exact results can be obtained.

To clean the burette used for the shaking, it should be treated with concentrated sulphuric acid, and allowed to stand at least one hour. If this precaution be neglected, drops of the alcoholic liquid stick to the tube, and get into the chloroform layer, thus increasing its volume.

Many spirits, especially raw spirits, contain  $\text{CO}_2$ , since, in the distillation of a mash, this gas passes off with the volatile portion, and is absorbed by the alcohol.

Now, when the fatty acids are to be estimated by titration with  $\frac{1}{100}$  normal alkali, the amount indicated is too great because of the alkali used in titrating  $\text{CO}_2$ .

The most important influence of the  $\text{CO}_2$  however is to increase the apparent volume of fusel oil present in the spirit by increasing the specific gravity of the alcohol and by decreasing that of the chloroform.

A sample of "automatically-refined" spirit, of sp. gr. 0.81263, contained 0.844 gm. of  $\text{CO}_2$ , estimated with lime water, followed by back titration with oxalic acid. On diluting to 30 per cent. with water, it apparently contained 0.0696 per cent. by volume of fusel oil, equivalent to 0.228 per cent. by volume in the original spirit. A second portion was boiled for one hour with inverted condenser in order to drive off the  $\text{CO}_2$ , after which the specific gravity had decreased to 0.81232, and the fusel oil, estimated in a 30 per cent. solution, was equivalent to 0.049 per cent. in the original spirit. This is, then, only  $\frac{1}{3}$  to  $\frac{1}{4}$  of that found before removing the  $\text{CO}_2$ ; since, however, during distillation any acetaldehyde contained in the fusel oil is lost, the  $\text{CO}_2$  was removed from a third portion of spirit by exact precipitation with lime-water and the fusel oil then estimated. It was found to represent 0.079 per cent. or only about  $\frac{1}{3}$  of that in the spirit containing  $\text{CO}_2$ .

Sell states that an increase of 1 per cent. by vol. of alcohol causes an increased volume of 0.03 cc. in the chloroform. To investigate this point further, dry  $\text{CO}_2$  was passed through alcohol of 30 per cent. vol. until the gravity was increased from 0.96564 to 0.96588 equal to 0.950 gm. of gas or 478 cc. at N.T.P. In order to reduce the gravity again to 0.96564 the author calculates that 0.14 cc. of absolute alcohol per 100 cc. is requisite, and the solution then contains 30.14 per cent. by vol., which according to Sell indicates an increase in the chloroform of 0.042 cc., equivalent to 0.028 per cent. by vol. of fusel oil in the 30 per cent. solution.

The influence of  $\text{CO}_2$  on chloroform is, on the other hand, to increase its volume and decrease its specific gravity. Dry  $\text{CO}_2$  was passed into chloroform for  $\frac{1}{4}$  hour, when the specific gravity became reduced from 1.48207 to 1.48055. The above alcohol, specific gravity 0.96588, containing  $\text{CO}_2$ , when shaken up with chloroform, increased 0.04 cc., and if the alcohol is first reduced to its original gravity of 0.96564 before shaking with chloroform an increase of 0.082 cc. results. Of this, 0.042 cc. is due to the action of  $\text{CO}_2$  on the mixture of alcohol and water, and the remaining 0.04 cc. is due to the increased vol. of the chloroform. The increase 0.082 cc. is equivalent to 0.54 per cent. of 40 per cent. spirit.

It is necessary, then, to remove  $\text{CO}_2$  before estimating fusel-oil by this method, and this can be done by exactly precipitating with lime-water and estimating fusel-oil in a 30 per cent. solution, or by gently boiling for at least  $\frac{1}{2}$  hour in a flask provided with a condenser 1 metre long, with or without the addition of caustic alkali. The latter method is quicker, but gives rather too low results, due to loss of aldehydes through volatilisation or neutralisation with alkali.

The author invariably finds fusel-oil, even in the purest spirit. The shaking burette of Dr. Karl Windisch is recom-

mended in preference to all others, since readings can be made to 0.005 cc. representing 0.0033 per cent. fusel-oil in 30 per cent. or 0.011 per cent. in 35 per cent. alcohol. For specific gravity estimation a pycnometer is used.—T. A. G.

*Gravimetric and Volumetric Methods for the Determination of the Alkaloids in Alkaloidal Tinctures.* E. H. Farr and R. Wright. *Proc. of the Pharm. Conference, 1894* (Oxford). *Chem. and Druggist*, **45**, 1894, 184—185.

THE authors in this note referred to the work done by Lyons, Lloyd, Allen, and Cripps in the direction of volumetric estimations of the alkaloids in tinctures, &c., and then proceeded to the work of Caspari, who, in a note published in the *American Pharmaceutical Review*, November 1892, maintained that volumetric methods of estimation were superior to gravimetric ones, and that the alkaloids obtained by the latter invariably contained from 10 to 20 per cent. of impurity. A final reference was made to a paper read before the American Pharmaceutical Association last year by Messrs. Caspari and Dohme, entitled "The Value of Titration with Volumetric acid Solution as a Means of Assaying Drugs and Galenical Preparations," in which those gentlemen claim to show that the determination of alkaloids in galenical preparations may be effected more accurately by titration than by the usual plan of weighing.

As Messrs. Farr and Wright in their researches on tinctures had employed gravimetric processes of assay almost exclusively, they considered it necessary to test the conclusions of Messrs. Caspari and Dohme. With that object in view each of the alkaloidal tinctures previously submitted to examination was prepared in sufficient quantity and estimated as follows:—

1. Two gravimetric estimations by the methods published in their notes on tincture menstrua.

2. The crude alkaloid was extracted from the evaporated tincture by shaking with chloroform after addition of alkali; it was then purified by extraction from the chloroform with several portions of acidulated water, and finally recovered by addition of alkali and shaking with chloroform. The chloroformic solution thus obtained was washed with distilled water to remove any traces of adhering alkali, and then used for the direct titration of the alkaloids with  $\frac{N}{20}$  HCl, methyl-orange, iodosin, and phloxin being used as indicators in the separate experiments. In using methyl-orange a little distilled water is added along with two drops of the indicator, but with iodosin and phloxin a single drop of a  $\frac{1}{1000}$  solution is shaken up with the chloroformic solution until the latter has become distinctly coloured. The indication of the end-reaction is in the case of methyl-orange the appearance of a pink colour in the upper layer, whilst in the case where iodosin and phloxin are used the reaction is complete when the colour disappears from the chloroform.

3. The alkaloid obtained by the usual gravimetric method was dissolved in a known excess of standard acid and titrated back with standard alkali in a white porcelain dish, using methyl-orange and Brazil wood as indicators, supplemented by iodosin and phloxin where the volume of tincture permitted. In this case the indication of the end of the reaction when methyl-orange is used is the disappearance of the pink tint; and with Brazil wood the production of a purple colour. In the employment of iodosin and phloxin as indicators, except in direct titration, we have followed the plan recommended by Cripps of adding to the acid alkaloidal solution sufficient neutral ether to form a distinct supernatant layer after being shaken with the solution. At the end of the reaction the aqueous layer becomes pink.

The following were the test-solutions used in the work:—Standard  $\frac{N}{20}$  hydrochloric acid and standard  $\frac{N}{100}$  barium hydrate, which is recommended as giving a quicker end-reaction than potassium or sodium hydrate. The strength of the latter must be taken at the commencement of each experiment. The indicators used were as follows:—

*Methyl-orange.*—A solution of the strength of 1 gr. per fl. oz. in equal parts of S.V.R. and water.

*Brazil Wood.*—The U.S.P. test solution, made by boiling 50 grms. of finely-cut Brazil wood with 100 cc. of water for half an hour, replacing the water evaporated from time to time; the liquor is then cooled, strained, and made up to 100 cc., and 25 cc. alcohol added, then the whole filtered.

*Iodosin and Phloxin.*—An aqueous solution containing 1 part in 1,000 fluid parts.

The equivalents used were those of the principal alkaloid in each case, except cinchona, nux vomica, and veratrum, where the equivalents are calculated by taking the mean weights of the chief alkaloid.

The results obtained are embodied in the table given on next page.

*Notes on the Results.*—The authors conclude from their work that volumetric methods are useless in the case of the alkaloids of acenite, the large proportion of acenine (equivalent 0.02715) making the readings much too high, also in the case of preparations of colchicum, on account of the absence of basic properties in the alkaloids colchicine and colchicine.

For gelsemium they have used the formula  $C_{21}H_{27}N_3O_6$ , proposed by L. Spiegel, instead of  $C_{21}H_{27}N_3O_8$ , as proposed by Gerrard, their results being more in accord with the former.

In the titration of the cinchona alkaloids the results obtained were not satisfactory, the end-reactions being extremely difficult to observe, and the authors condemn the use of volumetric estimations in the case of these alkaloids.

On the other hand, they consider that in the case of the alkaloids of belladonna, henbane, stramonium, conium, jaborandi, nux vomica, lobelia, and opium, the application of the volumetric methods may be made without disadvantage, the results obtained being almost equally reliable, and somewhat more expeditious than by gravimetric processes.

The authors give a general process for estimating the alkaloids in tinctures by titration with standard acid. From 25 to 50 cc. of the tincture (or in the case of hyoscyamine 100 cc.) to be estimated, is evaporated over the water-bath to expel spirit, a little water being added if necessary. The residual extract is filtered into a separator, and the dish and filter washed. The acid liquid is next shaken with two successive small quantities of chloroform, and the latter drawn off. The separated chloroform is washed with a little acidulated water, and the latter, after separation, added to the contents of the separator, which are then made alkaline, and the alkaloids taken out by shaking with three successive small quantities of chloroform. The chloroformic solutions are drawn off into a cylinder provided with a good cork and washed with distilled water until free from adhering alkali. A drop of  $\frac{1}{1000}$  iodosin or phloxin is then added, and the whole shaken until the chloroform is distinctly tinted; after this  $\frac{HCl}{20}$  is gradually run in from a burette graduated into tenths of a cc., the mixture being shaken after each addition of acid, until the colour is discharged from the chloroform. The reading is then taken, and the proportion of alkaloid calculated from the proper equivalent.

The authors, in conclusion, whilst admitting that the application of volumetric methods of estimation to the alkaloids obtained from tinctures is useful as affording a check on the results obtained by gravimetric methods, maintain that the results yielded by the latter are, on the whole, the more reliable of the two, and that gravimetric processes are more suitable for use by the average practical pharmacist.

*Estimation of the Insoluble, Non-Volatile Fatty Acids.* Meillère. *J. Pharm. Chim.* **29**, 60.

FOR the preparation and storing of the fatty bodies preparatory to analysis, they are melted and poured into test tubes, and after cooling are each protected by a layer of mercury from the action of the air, and kept in the dark. Oils are poured into test tubes drawn out at one end, the narrowed portion being closed with gypsum and a layer of mercury. Butter is melted on the water-bath, mixed with burnt gypsum, and extracted with ether;

TABLE showing COMPARATIVE RESULTS obtained in ESTIMATING TINCTURES (a) GRAVIMETRICALLY, (b) VOLUMETRICALLY.

\* For the opium estimations, a solution of anhydrous morphia, obtained in estimating the tincture by the B.P. process, was employed. This was dissolved in excess of  $\frac{N}{20}$  HCl.

the ether is then partially driven off by evaporation. Milk is similarly extracted, or treated with Adams' solution. For saponification the fat is brought into a beaker, heated to 70° C. for one hour, and weighed. Five cc. of alcoholic potash (0.5 gram. in 5 cc.) are added, and the mixture again heated for an hour at 70° C. The saponification product is rinsed with hot water into a 2-litre flask, filled to the mark with cold water, and treated with 5 cc. of syrupy phosphoric acid. On vigorous agitation the fatty acids adhere together: they are then brought on to a weighed filter and dried at 70° C. until a constant weight is obtained. To estimate the volatile acids, the filtered acid liquid, after neutralisation, is concentrated to 110 cc., acidified with a non-volatile acid, 100 cc. distilled, and the acid titrated in the distillate. Butter gives on the average 87.7 per cent. of solid acids at 70° C., and butters from various sources show very slight variation in constitution.—R. B. B.

*Process for the Estimation of Small Quantities of Chlorine in Fats.* R. Benedikt and H. Zikes. Chem. Zeit. 18, 640—641.

THE authors were led to devise the method to be described, in view of the recent controversy as to the occurrence of chlorine in one kind of wool fat.

A hard glass tube, open at both ends, 100—110 cm. in length and 11—12 mm. internal diameter, is widened out at one end in the form of a funnel, and thereupon bent upwards at an angle of 45° at a distance of about 15 cm. from this end. An asbestos wad *b* is then inserted, and lime introduced in a layer of about 25 cm. in length, after which another asbestos wad *c* is inserted. A second layer of lime, 15—20 cm. long, is held in position by the wads *d* and *e*. The tube is now shaken in a horizontal position so as to form a canal, the spaces *v* and *v'* filled with pieces of porcelain, and the tube placed in a combustion furnace reaching from *v* to *v'*. The end *a* of the tube is fitted with a doubly-bored caoutchouc stopper. Through these borings pass the tube of a tap funnel bent at an angle of 45°, and a glass tube. A slow current of air is passed through the

latter, or, in order to avoid the formation of a trace of cyanogen, carbonic anhydride may be passed through it. At the end *f* of the tube, a test-tube is placed, in which

tar collects; the gas issuing at *g* is burned. The materials used for charging the tube must, of course, be free from chlorine. The asbestos employed is moistened with concentrated nitric acid, and, after volatilising the latter on the water-bath, it is washed with water by decantation and ignited. When lime free from chlorine is not obtainable, the amount of chlorine in that which is obtainable (not less than 100 grms.) is determined. The weight of the lime used, is then ascertained, and the results corrected accordingly.

The dropping funnel may conveniently be calibrated so that the quantity of fat introduced into the tube can be approximately determined. The tap funnel is charged with about 100 grms. of the fat, and its weight ascertained. After inserting the funnel, the tube is heated at a red heat from *b* to *c'*, but not between *c* and *b*: a gentle current of carbonic anhydride is passed through the tube, and the fat allowed to drop from the funnel at a rate of 8–10 drops per minute, or 7–10 grms. per hour. In the case of wool-fat, it is necessary to keep a small flame near the dropping funnel in order to maintain the fat liquid. The fat in the space between *v* and *b* is gradually warmed; the height of the flame at *g* is the indication of the speed of the distillation.

After the introduction of 25–50 grms. during 3–5 hours, the supply of fat is cut off until the flame *g* is extinguished. The gas flames of the furnace are now turned out, the lime transferred to a beaker, moistened with alcohol and water, and dissolved in dilute nitric acid. In the filtrate, the chlorine is estimated gravimetrically as silver chloride. When the operation has been properly conducted, the layer of lime between *d* and *e* should contain no chlorine.

Crude oleic chloride containing 21.39 per cent. of chlorine was mixed with technical oleic acid, and in this way mixtures containing known amounts of chlorine were prepared. The following values were obtained:—

	Chlorine found.		Chlorine calculated.
	I.	II.	
Mixture I. ....	0.0220	0.0235	0.0225
Mixture II. ....	0.0877	0.0869	0.0894
Mixture III. ...	0.235	..	0.232

—A. R. L.

*Technical Analysis of Ethereal Oils.* J. Klimont. Chem. Zeit. **18**, 641–642; 672–673.

THE author makes use of the property of ethereal oils of absorbing bromine as the basis of a method for their technical examination. The ethereal oil is diluted with chloroform and a solution of bromine in chloroform run in until the bromine is no longer absorbed, a point which is ascertained by the persistence of the brown colour. Misleading results are obtained by calculating the quantity of bromine absorbed by the amount of solution added or by titrating the excess, since on the one hand the solution of bromine in chloroform soon alters in titre, and on the other hand an excess of bromine is slowly absorbed by oil of turpen-

tine. As, however, in technical analyses theoretically accurate results are not required, the author makes a second test with pure terebenthene, prepared according to Ribau's directions (Bull. Soc. Chim. **5**, 6, 12) from oil of turpentine. By comparing the amounts of bromine absorbed in the two cases the terebenthene number of the ethereal oil is arrived at.—A. R. L.

*Colorimetric Methods of Estimating Carbohydrates.* Erich Reitzel. Zeits. für Spiritusind. 1894, **17**, 163.

THE known colour reactions obtained when sugar or other carbohydrate is mixed with sulphuric acid and an aromatic amine, alcohol, or phenol, are taken advantage of. A definite mixture is made, and the time which elapses until a given source of light can no longer be observed through the solution, is compared with the time required for a solution of known composition, or by reference to an empirical table. The method can be used for the examination of water from sugar factories, in beer and wine analysis, and for brewery and distillery purposes.—T. A. G.

*Quantitative Estimation of Carbohydrates.* E. Schulze. Chem. Zeit. **18**, 527–528.

ATTEMPTS are frequently made to estimate the amounts of dextrin or similar carbohydrates present in the extracts of various plants by heating these extracts with dilute sulphuric or hydrochloric acid, and determining the reducing sugar with Fehling's solution. The author points out that exact results are only obtainable when the process is carried out under standard conditions; very great errors are involved when the product is a mixture of carbohydrates. The causes which are generally admitted to underlie this matter are as follows:—The conversion of di- and polysaccharides into "glucoses" by the action of hot dilute acids proceeds with different speeds in various cases; even carbohydrates which exhibit the closest similarity in all other properties often show considerable differences in this respect. The hydrolytic decomposition of di- and polysaccharides, which is known as inversion, is invariably attended by more or less action in the opposite direction (reversion). When the "glucoses" are heated with dilute acids for a protracted period, they are decomposed, yielding humus substances and acids (levulinic acid, formic acid, &c.). This latter is particularly true in the case of levulose. Different "glucoses" reduce Fehling's solution to a different extent. When a carbohydrate yields only dextrose on inversion, somewhere near the theoretical amount of the latter is usually obtained; thus:—Meissl obtained 98.6 per cent. of the theoretically possible amount of dextrose from maltose; Winterstein obtained 99.17 per cent. of the theoretically possible amount from trehalose; whilst Allihn (J. prakt. Chem. 1880, **22**, 84) obtained by saccharifying starch with sulphuric acid only 94.5 per cent. of the dextrose indicated by the equation—

Other chemists (Sachsse, Chem. Centralbl. 1877, **8**, 732; Salomon, Jour. prakt. Chem. 1882, **25**, 348; Schulze, *ibid.* 1883, **28**, 311) have obtained larger amounts of dextrose by employing hydrochloric acid. When a carbohydrate yields on inversion levulose, either alone or in conjunction with another "glucose," an amount in any way approaching that demanded by theory is only obtained when, as in the case of saccharose, the inversion is effected by means of dilute acid and short duration of heating.—A. R. L.

*Estimation of Starch by Alcoholic Fermentation.* A. Munsche. Zeits. für Spiritusind. 1894, **17**, 202–203; **17**, 209–210.

ANALYSIS by physiological methods was suggested by Pasteur and used by Delbrück and Petzold (Zeits. für Spiritusind. 1882, 126). Jodlbaur (Zeits. f. d. ges. Brauw.), Hansen (*ibid.* 422), and others using pure cultivated yeasts. It has been shown by Delbrück that starch can be completely fermented in presence of diastase, whilst

Jodlbaur has established the fact that under proper conditions the last traces of fermentable sugars are removed by fermentation, and that the carbon dioxide and alcohol produced are constant quantities.

**The Carbon Dioxide.**—Air-dried potato starch was saccharified with malt extract, heated to destroy any organisms present, and fermented, after cooling, with pure cultivated top yeast. Species II.; Hayduck's solution (50 grms. potassium acid phosphate + 17 grms. magnesium sulphate per litre) and asparagin 0.4 gm. per 100 cc. being added. Fermentation was always completed in about 72 hours, as shown by Fehling's solution, the estimation being made in a control experiment carried on concurrently. The fermentation flasks were connected with a drying vessel containing concentrated sulphuric acid, followed by a calcium chloride tube, to retain any moisture or alcoholic vapour given off. The  $\text{CO}_2$  was calculated from loss of weight, the gas in solution being separately estimated. Tabulated results show that 100 parts of starch yield 51.70 to 51.29 parts of  $\text{CO}_2$ , which agrees well with Pasteur's  $\text{CO}_2$  value for dextrose (51.55). The amount of dissolved gas averaged 0.64 gm. Under equal conditions the same volume of liquid will dissolve the same amount of  $\text{CO}_2$ . In all cases correction was made for the malt extract used.

**The Alcohol.**—This was estimated in the distillate from the fermented liquid by means of a pycnometer, any alcohol retained by the sulphuric acid being separately determined. 100 parts of starch yield 53.43 parts of alcohol, as against Pasteur's figure 53.67 for dextrose, and Jodlbaur's figure 54.08.

The unfermentable extract, after inversion with hydrochloric acid, reduced Fehling's solution strongly. This is due to the gummy matters present which occur in cereals, and have been attributed by Lintner and Döll to galactoxylao, which with acid yields the reducing sugars galactose and xylose.

Briefly stated the results obtained are:—

(1.) The chief products of alcoholic fermentation are, under the foregoing conditions constant, as already shown by Pasteur and Jodlbaur.

(2.) In presence of malt diastase a vigorous fermentation with pure yeast will remove all traces of fermentable, reducing, starch products in about 60 hours.

(3.) 100 parts of dry, pure starch yield on fermentation 51.29 parts of carbon dioxide and 53.43 parts of alcohol.

It is hence possible to estimate starch quantitatively by fermentation in presence of diastase.

The "inversion" method gives too high results with vegetable substances because of the presence of half-soluble gummy bodies which yield reducing substances on inversion. These, being unfermentable, produce no error in the "fermentation" method.—T. A. G.

#### *The Estimation of the Acidity of Malt.* E. Prior, Bayer. Brauerjourn. 1894, 4, 74.

100 GRMS. of the malt are placed in 200 cc. of water or alcohol, and after 12 hours' standing the acid is determined in the filtrate. To prevent acid fermentation during this period through bacteria, chloroform water may be used and 14 hours allowed for extraction at ordinary temperatures. The analysis of a malt gave the following results:—100 grms. of the air-dry malt showed a total acidity requiring for neutralisation 37.0 cc. of  $\frac{1}{10}$  normal caustic soda, of which 3.0 cc. were neutralised by volatile organic acids, 5.9 cc. by non-volatile organic acid, 28.0 cc. by acid phosphates. Calculating the volatile acids as acetic acid, the non-volatile acids as lactic acids, and the acid phosphates as free phosphoric acid, the malt would contain 0.018 per cent. of acetic acid, 0.053 per cent. of lactic acid, and 0.199 per cent. of phosphoric acid.—C. O. W.

#### *Analytical Methods for the Valuation of India-Rubber Goods.* C. A. Lobry de Bruyn. Chem. Zeit. 18, 1894, 329.

1. **Extract Test** (Henriques' method).—3 grms. of the finely cut sample on being boiled for six hours with 50 cc. of a 6 per cent. alcoholic solution of caustic soda should

not lose more than 8 per cent., the loss to be calculated upon the organic substance of the sample only. The extract should contain sulphur and india-rubber resins only.

2. **Dry Heat Test.**—2 grms. of the finely-cut sample are heated to 135° C. for two hours. When cold the sample should not have suffered any alteration and should show a loss of weight not exceeding 1.5 per cent.

3. **Moist Heat Test.**—A small piece of the sample is sealed up in a glass tube filled to about one-half with water, and this tube is then heated to 170° C. during four hours. The sample should not have suffered by this treatment.

4. **Ash.**—From 0.5 to 1.0 gm. of the sample is first fused, decomposed, and partially converted to ash over a small flame. The lamp flame is then increased and the residue cautiously ignited in a porcelain crucible. See this Journal, 1893, 468.

Considering the deficiency of our present knowledge on the influence of the percentage of sulphur upon the durability of an india-rubber article, the maximum quantity of sulphur to be allowed cannot be fixed. The extractive matters allowed in india-rubber are only considered as regards the presence of rubber substitutes, the use of which should be altogether prohibited. The ash should be required to consist of zinc-white only, except in articles which come in contact with acids, where barytes or lead sulphate should be used. Red articles should be vulcanised with antimony sulphide and should not contain any ferric oxide.—C. O. W.

#### *Contributions to the Analysis of India-Rubber Articles, III.*

R. Henriques. Chem. Zeit. 18, 1894, 411.

In extracting india-rubber with a solution of caustic soda the rubber substance retains not inconsiderable quantities of caustic alkali, the weight of which must be determined in order to obtain correct figures for the percentage of extracted matters. The bulk of this alkali can, however, be removed from the extracted rubber by boiling the well-washed residue on extraction repeatedly with dilute hydrochloric acid. The analysis of a sample of india-rubber consisting of a mixture of rubber substitute or oil, india-rubber, and sulphur requires now the determination of the following data:—(a.) Total sulphur. (b.) Total ash. (c.) Weight of substance after extraction with alcoholic soda. (d.) Sulphur in c. (e.) Ash in c. (f.) Sulphur in the fatty acids extracted.

For the estimation of c, from 1.5 to 2 grms. of substance are used and the extraction is twice repeated, boiling each time for from two to three hours. The quantity of india-rubber dissolved by the alcoholic soda is deducted from the weight of the total extract. This correction amounts on the average to 2.5 per cent. From the above figures the percentage of india-rubber (x) and fatty acids (y) in the sample may be calculated by means of the following equations:—

$$x = \frac{100}{97.5} (c - d - e)$$

$$y = 100 - (a + b + x).$$

The quantity of sulphur contained in the rubber substitute is represented by f, assuming that quantity to be about equal to that of the fatty acids in the white substitutes and about 1.5 per cent. larger than the quantity of fatty acids contained in the brown substitutes. The sulphur of vulcanisation is found as the difference between total sulphur and sulphur in the substitute.

The following results were obtained in this manner:—

	I. India-Rubber with Brown Substitute.	II. India-Rubber with White Substitute.	III. India-Rubber with Oil.
	Per Cent. 19.46	Per Cent. 11.38	Per Cent. 21.55

Holde's method for the separation and estimation of oil and india-rubber by extraction with ether-alcohol is impracticable whenever the sample in question contains at the same time india-rubber substitute. This is owing to the considerable quantities of fatty matters which ether alcohol extracts from rubber substitutes. In the analysis of "recovered rubber," which frequently contains asphaltum, the separation of the latter from the india-rubber becomes desirable. This is effected by treating 1 gram. of the finely subdivided sample at ordinary temperatures, with 30 cc. of nitrobenzene. After one hour's standing the mass is filtered, the residue on the filter squeezed with a small pestle and washed with 30 cc. more of nitrobenzene. The washed residue is then boiled with water until all the adhering nitrobenzene is expelled, again filtered, dried, and weighed. The loss of weight thus found, however, is not entirely due to the presence of asphaltum in the sample, but is to about 1.5 per cent. accounted for by the slight solubility of india-rubber in nitrobenzene.—C. O. W.

#### Contributions to the Analysis of India-Rubber Articles.

R. Henriques. Chem. Zeit. 18, 1894, 412.

In estimating the percentage of asphaltum in vulcanised india-rubber articles by the nitrobenzene process, it is necessary to first remove the free sulphur from the sample. This is accomplished by the same means which serves for the estimation of the rubber substitute, *i.e.*, extraction with alcoholic caustic soda. No asphaltum is dissolved by this reagent, although besides the free sulphur all the rubber-substitute and about 3 per cent. of the rubber substance enter into solution. While thus the presence of fatty oils and rubber substitute does not prejudice the estimation of the asphaltum, it is practically rendered impossible by the presence of mineral oils, paraffin wax, and resins. The estimation of lampblack in india-rubber samples containing as further admixtures only oils, rubber substitute, and asphaltum (which are extracted by use of the already-described methods), can be accomplished by a combustion analysis. All reliable analyses of india-rubber indicate the relationship C:H=10:16, so that an admixture of carbon with the rubber can be estimated with satisfactory accuracy from the altered relation of C:H. In applying these new methods to the analysis of some samples of "recovered rubber," the following figures were obtained:—

	A.		B.		C.	
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Rubber substitute and oils.....	56.78	52.24	56.24

Lampblack.....	0.61	0.65	1.38			
India-rubber.....	32.87	36.30	33.40			

The analysis of goloshes (St. Petersburg product) was carried out in the following manner:—

1. One gram. of the finely-ground sample was decomposed in a Geissler apparatus and the total gases ( $\text{CO}_2 + \text{H}_2\text{S}$ )

evolved, were weighed. The contents of the apparatus were then filtered and the undissolved residue repeatedly boiled with dilute acid. The bases (lime, lead, and a little iron) were almost completely dissolved. No sulphuric acid was found in the solution which was used for the estimation of the metals.

2. In the insoluble residue, the sulphur was determined in the manner already described (this Journal, 1893, 467). A small quantity of silica, alumina, and lead sulphate, was obtained at the same time.

3. The total sulphur was estimated in 1 gram. of the original substance. The difference between the percentage of sulphur thus found and that found in 2, represents the sulphur evolved as sulphuretted hydrogen, and by subtraction of the latter from the total gases evolved the quantity of carbonic acid evolved, was obtained; it was found to be equivalent to the quantity of lime observed.

4. Five grms. of the original substance were boiled with acid, filtered, washed, dried, and weighed. Of the substance thus obtained 2 grms. were extracted with alcoholic soda. The extract contained 2½ per cent. of india-rubber; the rest consisted of fatty oils. In the residue from this extraction the asphaltum was estimated by extraction with nitrobenzene, and in the residue thereby remaining the percentages of india-rubber and lamp-black were determined by combustion. The results of the analysis were:—Lead oxide, 8.45; calcium carbonate, 47.81; ferric oxide and alumina, 1.70; silicic acid, 0.44; sulphur, 1.50; fatty matter, 0.95; asphaltum, 8.46; lampblack, 0.39; india-rubber, 30.30 per cent.—C. O. W.

#### Analytical Control of the Vulcanisation of India-Rubber.

R. Henriques. Chem. Zeit. 18, 1894, 701.

The question as to the quantity of sulphur chemically combining with the india-rubber in the process of vulcanisation is still undecided, chiefly owing to the fact of no reliable method being known for the separation of the free sulphur from the combined sulphur in india-rubber articles. Alcoholic soda extracts free sulphur from vulcanised india-rubber, and it appeared, therefore, desirable to test the suitability of this method for the purpose in view. Three samples of best vulcanised Para rubber were experimented upon. Before and after treatment with alcoholic soda they showed the following percentages of sulphur:—

	A.		B.		C.	
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Total sulphur.....	6.44	7.75	8.24			
Combined sulphur.....	3.30	1.86	3.39			

It is evident that a sample of vulcanised india-rubber consists of a really vulcanised compound and possibly an unvulcanised proportion of india-rubber and free sulphur. The two last-named components being readily soluble in various solvents, the isolation of the vulcanised rubber might be effected by treating it with a suitable solvent until

the percentage of sulphur in the undissolved residue remained constant, or until the percentage of sulphur in the latest fraction of the extract is the same as that in the residue. Carbon bisulphide was used for the extraction, the sample being repeatedly treated with the solvent in the cold. Eight subsequent extractions gave the following results:—

Extract No.	Per Cent. of Previous Operation.	Per Cent. of Original India-Rubber.	Sulphur in undissolved Residue.
1	4.39	4.59	4.66
2	3.91	3.72	3.91
3	3.40	3.95	3.77
4	7.79	6.76	3.85
5	6.71	5.37	3.81
6	2.90	2.16	3.70
7	3.92	2.87	..
8	3.71	2.58	3.72

This shows that three extractions are sufficient to remove all uncombined sulphur.

The first two of the above extracts contain chiefly sulphur, with very little organic matter.

The following fractions consist of a grey spongy mass easily soluble in petroleum ether, but invariably leaving a slight residue of sulphur. This indicates a partial dissociation of the vulcanised india-rubber during the process of extraction. On heating the above-mentioned solutions in petroleum-ether for a short time to 100° C. revulcanisation takes place. The composition of that part of the three samples of vulcanised india-rubber, which is insoluble in carbon bisulphide, was found to be:—

—	A.		B.		C.	
	Before	After	Before	After	Before	After
	Extraction.		Extraction.		Extraction.	
Ash	1.16	1.89	2.74	2.81	1.52	1.77
C	76.49	77.70	76.22	80.23	77.50	80.31
H	9.79	10.31	16.73	11.82	11.26	11.47
S	6.44	3.72	7.75	1.82	8.24	3.59
O	6.12	6.47	2.56	3.82	1.48	2.86

This shows the following percentages of free sulphur:—

	A.	B.	C.
	Per Cent.	Per Cent.	Per Cent.
Extr. with alcoholic soda .....	3.39	1.86	3.39
Extr. with carbon bisulphide .....	3.72	1.72	3.59

These figures leave no doubt that, by treatment with alcoholic soda, the quantity of free sulphur in vulcanised india-rubber may be estimated.—C. O. W.

*Contributions to the Analysis of India-Rubber Articles.*  
R. Henriques. Chem. Zeit. 18, 1894, 905.

TERRY and Lobry de Bruyn expressed doubt as to whether the accuracy of the estimation of oils and rubber substitute in india-rubber articles was not affected if no distinction was made between those compounds and the acid resinous bodies which occur naturally in every india-rubber. This

question was tested by submitting various samples of vulcanised india-rubber to the alcoholic soda test. The results were:—

	Sulphur.	Ash.	Residue from Extraction with Soda.	Ash in Residue.	Resins Dissolved.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Para.....	6.43	1.16	91.90	2.92	2.28
Columbian .....	9.17	1.68	91.08	5.04	1.87
Ceara .....	11.69	2.75	91.61	6.16	1.78
Mozambique ..	11.86	2.69	91.27	5.93	2.05
Sierra Leone..	7.44	2.20	97.42	8.38	3.13
Madagascar...	11.77	1.80	90.39	5.82	3.58
Borneo.....	12.21	2.60	92.78	7.90	2.63
Accra.....	11.37	3.30	92.90	9.72	3.86

Particularly striking in these figures is the considerable increase of the ash found in the lower qualities of india-rubber after the extraction. The cause of this is to be found in the formation, during the extraction, of sodium salts of the resinous constituents of india-rubber. These sodium salts are soluble in the alcoholic extract, but after evaporating the alcohol and dissolving the residue in water, these particular sodium salts separate out as insoluble masses, which of course are filtered off and added to the extracted sample with which they are weighed together. This shows that the resinous constituents of india-rubber in no way prevent the correct estimation of the fatty oils and rubber substitute.—C. O. W.

*The Analysis of India-Rubber Articles.* C. A. Lobry de Bruyn and F. H. van Leent. Chem. Zeit. 18, 1894, 309.

See under XIII. C., page 963.

## New Books.

*RASA-RANGA-RAHASYA.* The First and only Monthly Magazine of the Chemical and Tinctorial Trades. Editors: M. G. DESHMUKH, B.Sc., B.A. M.D., and T. K. GAJJAR, B.Sc., M.A. Baroda. Bombay: Printed at the Education Society's Steam Press. 1894. Price Rs. 9 inland, 12s. overland, post free, per annum.

THIS is a new journal, in Hindustani, treating of Chemical Industry; more especially devoted to the tinctorial trades, however. It is issued from Baroda, but printed in Bombay. This the first issue (April 25, 1894) is of quarto size, and the subjects treated of in it are the following:—"A new System of Chemical Notation and Nomenclature." "Elements of Chemistry." "The Manufacture and Industrial Value of Aluminium Alloys." "Manufactures wanted in India." "Removal of mechanically-absorbed Water." "The Causes and Prevention of Spontaneous Combustion." "The most recent Development in Artificial Indigo." "Review of Colours." "New Colouring Matters." "Monthly List of Indian Patents." "Imports, Bombay Presidency; Exports, ditto." "Monthly Price List of Chemicals and Drugs."

**HANDWÖRTERBUCH DER PHARMACIE.** Herausgegeben von A. BRESLAWSKI. Wien und Leipzig: Wilhelm Braumüller, K. u. K. Hof- und Universitäts-Buchhändler, 1894. London: H. Grevel and Co., 33, King Street, Covent Garden.

Is continuation of Vol. II. of this Dictionary of Pharmacy, Parts 17 and 18 now appear. Part 17 commences with "*Pastellfarben*," and ends with "*Polykohleensäure*," which subject is completed in this part. Part 18 commences with "*Polymer*" and ends with "*Rhodium*," continued into and completed in Part 19, yet to appear. Parts 17 and 18 contain 79 pages of subject-matter each.

**DESCRIPTIVE CATALOGUE OF ESSENTIAL OILS AND ORGANIC CHEMICAL PREPARATIONS.** Compiled by FREDERICK B. POWER, Ph.G., Ph.D. Published by Fittsche Brothers, New York, U.S. America. H. Grevel and Co., 33, King Street, Covent Garden, London. 5s.

This little book is strongly bound, of 8vo size, and contains preface and 96 pages of subject-matter. An alphabetical index is unnecessary as the substances described are arranged in the text in alphabetical order.

In PART I. appear the OFFICIAL ESSENTIAL OILS, recognised by the Pharmacopœia of the United States of America, 7th Decennial Revision, 1890. PART II. contains the NON-OFFICIAL ESSENTIAL OILS, not recognised by the U.S. Pharmacopœia, 7th Decennial Revision, 1890. Many of these, however, are stated to be of commercial importance, whilst others are to be regarded at present as possessing chiefly scientific interest. PART III. contains the ORGANIC CHEMICAL PREPARATIONS. An interesting and, for many, a useful feature in the work is the setting in small type and in brackets, under the English names of oils or drugs, &c., the corresponding German names, thus combining the character of a glossary with the other features of the work.

**WATTS' DICTIONARY OF CHEMISTRY.** Revised and entirely rewritten by M. M. PATTISON MUIR, M.A., Fellow and Praelector in Chemistry, of Gonville and Caius College, Cambridge, and H. FORSTER MORLEY, M.A., D.Sc., Fellow of University College, London, and Lecturer on Physics and Chemistry at Charing Cross Hospital Medical School. Assisted by Eminent Contributors. In Four Volumes. Vol. IV., with Addenda. London: Longmans, Green, and Co.; and New York: 15, East 16th Street. 1894. 3l. 3s.

This is the final volume of this Dictionary of Chemistry. It commences with an *Introduction to the Articles on Inorganic Chemistry*, by Mr. Muir, followed by an *Introduction to the Articles relating to Organic Chemistry*, by Dr. H. Forster Morley; these introductions are followed by a List of Special Contributors, and a List of Abbreviations.

The work of the Dictionary itself commences with *Phenyl-Azazole*, and concludes with *Thallium tri-iodide*, the matter within the limits thus indicated, filling 922 pages. The article on "Physical Methods used in Chemistry," alone fills 101 pages. It is the joint work of Messrs. Capstick, W. N. Hartley, and W. Ostwald. Twelve and a half pages are devoted to "Solutions," by Messrs. Arrhenius and Spencer Pickering, and six to "Specific Volumes" by T. E. Thorpe. An important article on "Sugar" (36 pages), appears from the pen of C. O'Sullivan. The Terpenes are treated of by W. A. Tilden in an article occupying twelve pages. M. M. P. Muir has written a full account of Vanadium and its compounds, in a report filling sixteen pages. At the close of the volume, and of the work consequently, is a List of Addenda, referring to descriptive Inorganic Chemistry only. (See this Journal, 1892, 552.)

## Trade Report.

### TARIFF CHANGES AND CUSTOMS REGULATIONS.

(From the Board of Trade Journal.)

#### RUSSIA.

##### Customs Decisions.

The following decisions affecting the classification of various pharmaceutical products in the Russian Customs tariff have recently been given by the Russian Customs authorities:—

Disinfectants known as Britannia and Ichtyolum are exempt from import duty, as provided by Article 112.

The importation of the following pharmaceutical products is, however, prohibited:—

Vaucher anti-choleric pastilles.

P. Florent coen.

Bombelon and Dengel ergotinum.

Sanitas preparations.

P. Florent glycine.

#### SWITZERLAND.

##### Customs Decisions.

The following decisions affecting the classification of articles in the Swiss Customs tariff have recently been given by the Swiss Customs authorities in the period extending from January to August 1894:—

Metallic cement is removed from Category 15 and placed in Category 352, paying a duty of 80 cents per quintal.

Sulphate of barytes, ground, washed, in paste.—Category 45. Duty, 30 cents per quintal.

Antimonic acid (acidum stibiosum, oxide of antimony).—Category 48. Duty, 1 franc per quintal.

Mannocitine (preservative against rust, composed of vaseline and essence of turpentine).—Category 66. Duty, 1 franc per quintal.

Chloride of ethyl (Dutch oil).—Category 72. Duty, 2 francs per quintal.

Polysulphine (substance for bleaching and for lyes).—Categories 76 and 77. Duties, 1.25 francs and 2.50 francs per quintal.

Manganese in a crude state is exempt from duty, under Category 328.

Sulphate of barytes in a crude state is exempt from duty, under Category 332.

#### FRANCE.

##### Customs Decisions.

The following decisions affecting the classification of articles in the French Customs tariff have recently been given by the French Customs authorities:—

Phosphate of lime obtained in the manufacture of gelatine, and commercially known under the name of precipitated phosphate, and used as a manure, is exempt from duty, under Category 281 bis.

#### GUATEMALA.

##### Tariff Changes.

Mr. Audley Gosling, Her Majesty's Minister at Guatemala, in a despatch to the Foreign Office, dated the 18th August, forwards copy and translation of a notice issued by the Guatemalan Government, according to which the import duties on the following descriptions of acids have been reduced from 15 to 5 cents per kilogramme:—

Sulphuric acid, sulphurous acid, carbonic acid, sulphydric acid, phosphoric acid, hypophosphoric acid, fluorhydric acid, hydrofluosilicic acid, nitric acid, muriatic acid, nitromuriatic acid, and any other mineral acids not classified as anhydrous, or in solution at whatever degree of concentration, in any kind of common receptacle, gross weight per kilogramme.

## THE JAPANESE DRUG TRADE AND THE NEW TREATY.

A treaty of commerce and navigation between Japan and the United Kingdom, signed in London on July 16, has only just been made public in this country through being published in full in a British newspaper published in Yokohama. The principal feature of the treaty, from the point of view of our general relations with Japan, is that it removes, so far as British subjects are concerned, the restrictions upon foreigners trading and settling in Japan, and places our countrymen upon a footing of absolute equality with the Japanese with respect to these pursuits. On the other hand, the right of foreign subjects in Japan to be tried by a court composed of officials of their own nationality is abolished, and foreigners will in future be amenable to the native courts of justice, on the same footing with the natives of the country. By virtue of the provisions of the "Protocol" which accompanies this treaty the Japanese Customs tariff undergoes considerable modifications. These changes, unlike the treaty itself, come into operation at once, and are applicable to all goods now imported into Japan. The two countries agree to give to each other the benefit of any advantages which they may hereafter grant

to other countries in the matter of trade, and Japan undertakes that her new provisional tariff, which provides for *ad valorem* duties of from 5 to 10 per cent. upon most of the staple articles of import, is to be replaced as soon as possible by another, with a specific-duty basis. The provisional new tariff makes such articles as mercury, paraffin-wax, saltpetre, and condensed or desiccated milk dutiable at the rate of 5 per cent. *ad valorem*; mercury, paraffin oil, paint in oil, and dry indigo at the rate of 10 per cent. *ad valorem*. There is no mention in the official protocol of any alteration in the duties on drugs and medicines, but it is not unreasonable to assume that it is the intention of the Japanese Government, in the final tariff which is in project, to raise the duties upon several of these articles, on especially such as it is possible to manufacture in the country. Last year Japan imported 446,000*l.* worth of "drugs and chemicals," of which 219,000*l.* worth came from the United Kingdom, 150,000*l.* from Germany, and 30,000*l.* from China; other countries counting for very little in the direct supply of articles of this class.

The following official Japanese statistics, give an interesting detailed view of the respective shares of the principal foreign nations in the Japanese drug market:—

Article.	Total Import into Japan.			Imported in 1893.	
	1893.	1892.	1891.	From Britain.	From Germany.
Acid (carbolic)..... C.	..	..	..	73,781	11,250

Total..... Yen	3,300,451	2,493,556	2,225,766	..	..

The sign C. means cattie, of 1½ lb. English.

The sign Yen means silver yen, nominally 4s. 2d.

\* 2,520 cattie came from the United States.

† 25,174 cattie came from France.

‡ 6,616 cattie came from France.

It will be seen that the great increase in the value of the drug imports into Japan is principally due to her growing requirements of a few heavy chemicals used in manufacturing industries, such as phosphorus and chlorate of potash.

These articles are mainly supplied by this country, but in many varieties of medicinal chemicals Germany has taken the lead in the supply. This is partly due to the fact that increased familiarity with European sources of supply has

enabled the Japanese to go directly to the fountain head for their requirements, instead of, as formerly, giving the whole of their orders to firms in England to place where those houses thought fit. Another reason may lie in the discrimination in favour of non-British goods with which the Japanese Customs officers are sometimes charged. The Japanese Pharmacopœia is framed upon the model of the German one, but in respect to certain articles it is far more stringent than any European work of the kind, and even the best qualities of certain drugs made in Europe fail to reach its extravagant standard. Now, the Japanese Customs law gives to the authorities of the country the right to "restrict or prohibit the importation of adulterated drugs, medicines, food, or beverages," and it is freely said that the Anglo-phobe officials who are charged with the enforcement of this clause have systematically exceeded it in spirit by refusing admittance to British goods which would pass muster in any European country. The prohibition clause, we may add, has expressly been maintained in the new treaty. It is to be hoped that it will be applied in future with more partiality and less excess of zeal.—*Chemist and Druggist*.

#### THE NEW JAPANESE TARIFF.

The following articles of the tariff deal with the metal and allied trades:—

Articles.	<i>Ad valorem</i> Rates of Duty.
	Per Cent.
Cement, Portland.....	5
Glass, window, ordinary:—	
(a.) Uncoloured and unstained .....	8
(b.) Coloured, stained, or ground.....	10
Iron and steel:—	
Pig and ingot.....	5
Rails .....	5
Bar, rod, plate, and sheet .....	7½
Tinned plates.....	10
Galvanised sheet.....	10
Pipes and tubes.....	10
Lead, pig, ingot, and slab.....	5
Mercury or quicksilver .....	5
Nails, iron .....	10
Oil, paraffin.....	10
Paint in oil.....	10
Saltpetre .....	5
Screws, bolts, and nuts, iron .....	10
Tin:—	
Block, pig, and slab.....	5
Plates .....	10
Wax, paraffin .....	5
Wire:—	
Telegraph .....	5
Iron and steel, and small rod iron and steel, not exceeding ½ inch in diameter.	10
Zinc:—	
Block, pig, and slab.....	5
Sheet .....	7½

#### Rule for Calculating *ad valorem* Duties.

Import duties payable *ad valorem* under this tariff shall be calculated on the actual cost of the articles at the place of purchase, production, or fabrication, with the addition of the cost of insurance and transportation from the place of purchase, production, or fabrication to the port of discharge, as well as commission, if any exists.—*Ironmonger*.

#### NEW UNITED STATES TARIFF.

#### *Government Report.*

REPORT FROM THE SELECT COMMITTEE ON PETROLEUM,  
TOGETHER WITH THE PROCEEDINGS OF THE COMMITTEE,  
MINUTES OF EVIDENCE, AND APPENDIX. 214. Price  
10½d.

This is the report of the Select Committee of the House of  
Commons appointed to inquire into and report upon the

law relating to the keeping, selling, and conveyance of petroleum and other inflammable liquids, including the precautions to be adopted to prevent the sale of dangerous lamps for use with inflammable liquids.

The Committee state in their report that they are of opinion that considering the late period of the Session it is not in their power to conclude their investigation; they have therefore agreed to report the evidence already taken to the House, and to recommend that a Committee on the same subject should be appointed in the next Session of Parliament.

The Select Committee was appointed on the 28th of June 1894, and the present report is dated the 27th of July of the present year.

### EXTRACTS FROM DIPLOMATIC AND CONSULAR REPORTS.

#### COTTON-OIL INDUSTRY IN SOUTH CAROLINA.

In a report to the Foreign Office, dated the 10th September, Mr. A. Harkness, Acting British Consul at Charleston, transmits the following information on the subject of the cotton-oil industry in the State of South Carolina:—

The cotton-seed oil business in South Carolina is an industry of comparatively recent growth, the first oil mill established in this State having been a small one built near Columbia in 1868, which was not successful owing to the unsettled business conditions generally prevailing at that time. Later on, however, other mills were established, and they have, with few exceptions, proved to be profitable investments. In the year 1867 there were only four cotton-seed oil mills in the United States, but at the present time there are 253 throughout the country, of which number 27 are situated in South Carolina, 21 being owned by local capital, many of the stock-holders being farmers. The above-mentioned 27 mills now in this State have a capital of over 1,000,000 dollars (200,000*l.* sterling), and last year the Carolina mills crushed about 75,000 tons of cotton-seed, valued at 800,000 dollars (160,000*l.*), producing 60,000 barrels of oil, 26,000 tons of cotton-seed meal, 5,000 bales of linters, and 25,000 tons of hulls. The oil is most sold in northern and western markets, and is much used in the manufacture of compound lard, soaps, and for other purposes.

Part of the shipment to northern markets is exported to foreign countries, and later on some of it comes back to this country under fancy labels as olive oil.

The refined cotton-seed oil appears to be rapidly coming into favour for cooking purposes, either in its natural condition or compounded with other preparations now on the market. It is a sweet and wholesome product—a pure vegetable oil—and is regarded by many persons as being far superior to hog's fat for culinary purposes. The South Carolina farmers also use the cotton-seed meal largely for fertilizer uses, applying it directly to the soil or composting it with acid phosphate. The meal and hulls are also now used by stockmen and dairymen as an article of food for fattening cattle, considerable quantities having been consumed in this manner during the last two or three years.

The cotton-oil industry now gives employment to a large number of business men, mechanics, and labourers, most of the latter being negroes.—*Board of Trade Journal.*

#### THE MEXICAN LEATHER INDUSTRY.

A report on the subject of the leather trade and industry of Mexico has recently been prepared by M. André Beaufils, who is attached to the French Legation in that country.

The raw hides of Mexico are of average quality, and might successfully compete on the European markets with the best South American raw hides, by reason of their solidity, although they are very thin.

An estimate of the cost price of 1,000 Mexican hides delivered at a European port gives approximately the following results:—Cost price in Mexico of 1,000 raw hides at 1.20 *dols.* each, 1,200 *dols.*; carriage to the coast, 50 *dols.*; sea freight, 614 *dols.*; 10 per cent. for other

expenses (loading, unloading, &c.), 25 *dols.*; total, 1,889 *dols.*, which is equivalent to about 20*l.* per 1,000 hides. As the South American hides cost from 20*l.* to 22*l.* there would appear to be great advantage in using the Mexican hides, especially when their superiority to the products of Brazil and La Plata is taken into account. It may be observed that the United States already purchases from Mexico the greater portion of its raw hides.

Speaking of the tanning industry in Mexico, it is stated that it is still in its infancy, both as regards the small number of tanneries met with and the simple processes employed. The largest Mexican tanneries are to be found chiefly in the district of Mexico and in a few of the northern and eastern States.

The tanning of the raw hides may be said to consist of four distinct operations: 1. The washing of the raw hides; 2. Liming; 3. Placing in the bran pit; 4. Tanning properly so-called.

The raw hide arriving from the interior of the country, whether it is salted or dried, is first washed in fresh water, in the opposite direction to the fall of the hair, where it is left for a few days in order to soften and to reject all the substances preserving it from putrefaction. This operation is called the washing.

The washing being completed, the hide is placed in a pit filled with lime-water, water known in Mexico as *pelambre*. It remains in these pits from a week to a fortnight, during which period the hides are stirred several times a day. This operation is for the purpose of removing the hair from the hide. When the hair commences to fall off, the hides are taken out and are scraped on the upper side with a square-bladed knife, so that no hair remains attached to the hide.

The scraped hides are then placed in other pits containing bran-water and called by the Mexicans *salvaderas*. The hide is withdrawn at the end of a few days and is fleshed (*décharné*), that is to say, all waste or fatty matter is removed from the surface of the hide.

All these preparatory operations being finished, the tanning properly so-called commences. The tanning material in Mexico is not represented by tan resulting from oak-bark. It comes from *dividivi*, known by the Mexicans as *cascalote*, a very common tree on the borders of the Gulf of Mexico, belonging to the *cuscalpinia coriaria*, and the pods of which contain an astringent and bitter matter. It is of these pods reduced to powder that the raw material for tanning consists.

The hide thoroughly cleaned and all foreign matter being removed is placed in layers in pits, the hides being separated from each other by a light layer of *dividivi* powder. The pit being piled up, it is filled with water and then closed. Twenty days after, the hide is taken out, cut in two, and placed in other pits, richer in tanning materials. This operation is repeated as many times as may be deemed necessary, the quantity of *dividivi* being increased each time. The raw hide has then become leather, suitable for domestic and industrial uses. Owing to the warmth and the special climatic conditions of Mexico, the process of tanning only lasts two months. Unfortunately, as is always the case with leathers tanned in such a short time, Mexican leathers are of inferior quality; they are spongy, wanting in suppleness and in resisting power. Their use is therefore a very limited one, and is confined to the manufacture of common shoes and cheap saddles.

For the reasons given above, Mexican leather tanned in the country is not of sufficiently good quality to be used for shoes of a superior kind, and leather imported from Europe is obliged to be used. The leathers mostly consumed in native manufacture are calf, kid, and *gamuza*, a kind of badly prepared morocco.

Foreign leathers used chiefly for the uppers of shoes represent about 15 per cent. of the general consumption. The superior qualities come principally from France (about 85 per cent. of the total import), and from England and the United States (about 10 per cent.) for good medium leathers. Germany sends leathers of a very inferior quality, but they meet with little approval on the Mexican

markets. The competition of Germany with France is therefore very insignificant.—*Ibid.*

#### GERMAN MINING INDUSTRY.

Sir C. Oppenheimer, Her Majesty's Consul-General at Frankfurt-on-the-Main, in his general commercial report for 1893, writes that according to official statements the results of the mining industry in Germany for the year 1893 are as follows:—

The total amount of coal produced in 1893 was 73,908,999 tons (1 ton equal 1,000 kilos.), 3.6 per cent. more than in the year 1892, in which 71,372,193 tons were obtained. Notwithstanding this increase in the output, the total value of the coal produced in 1892, viz., nearly 527,000,000 marks, decreased in the year 1893 to 498.5 million marks, as on the average in 1893 only 6.74 marks per ton was received, as against 7.38 marks in 1892. In the coal output of 1893 the share of the district of Dortmund amounted to 52.2 per cent., that of Breslau to 28 per cent., and Bonn to 16.6 per cent., and that of the kingdom of Saxony to 5.9 per cent. The brown coal output was in 1893, 21,567,218 tons, against 21,171,857 tons in 1892; as the total value of this production for 1893 was estimated at 55,000,000 marks, and that for 1892 at 58.5 million marks, an average value of 2.55 per ton in 1893, and of 2.76 marks in the year 1892 was obtained. About three-fourths of the brown coal fell to the district of Halle. Also the production of rock-salt (669,942 tons), kainite (664,986 tons), and other potassic salts (861,162 tons) was greater in 1893 than in 1892, which was 662,577 tons, 548,445 tons, and 842,630 tons respectively; the average price of these products was in the year under report a little higher than in 1892.

The production of common salt has also risen (505,023 tons, against 504,687 tons in 1892), as also of chlorate of potash (137,216 tons, against 123,962 tons in 1892), and for the former product somewhat higher prices, whereas for the latter rather lower prices were obtained in 1893 than in the previous year. As regards the products of the foundries, the production of raw iron (4,986,003 tons, against 4,937,461 tons in 1892) and of zinc (142,956 tons, against 139,938 tons) has increased in comparison with the preceding year; on the other hand, that of lead (94,639 tons, against 97,742 tons in 1892), of copper (24,011 tons, against 24,781 tons), of silver (449 tons, against 489 tons), and of gold (3 tons, against 3 tons 8 cwt.), has not come up to the figures of 1892. The prices of all metals have decreased, in some cases even very considerably.—(No. 340, *Foreign Office Miscellaneous Series.*)

#### THE PRESERVED FRUIT INDUSTRY IN PORTUGAL.

Mr. Honorius Grant, Acting British Consul at Oporto, in a report to the Foreign Office, dated the 17th September, encloses a memorandum on the subject of the fruit-preserving industry in Portugal, in which he says:—

"A certain trade is done from Portugal in the exportation to England of dried preserved fruit, an article the manufacture of which was a kind of speciality of the nuns, but since the gradual extinction of the convents the trade has passed into other hands. The fruit exported consists of plums, peaches, figs, and apricots, and is packed up in round boxes of various sizes and decked with paper lace, silver wire, tinsel, and the like, making up a somewhat showy *tout ensemble* and not unsuitable for a dinner-table ornament.

"Now, considering that better fruit and cheaper sugar are procurable at home, there would seem to be no reason why this article should go from here to England instead of being made by the growers at home.

"The process used here is, I understand, simple in the extreme, and consists, roughly speaking, in boiling the fruit (before complete maturity) with sugar six times in the same water, after which the sugar is allowed to run off, and the fruit is put out on trays to dry in the open air."—*Board of Trade Journal.*

#### PRIZES FOR CHEMICAL RESEARCH.

In addition to the prizes to be offered next year by the Society for the Encouragement of National Industry, an

award of 2,000 fr. is to be given in 1896 for the best paper on the discovery of processes for the synthetic manufacture of useful organic bodies, such as quinine, cane sugar, &c. The prizes will only be awarded in the event of the papers proving of sufficient interest.—*Chemist and Druggist.*

#### GENERAL TRADE NOTES.

##### SOUTH AFRICAN NITRATE FIELDS.

Dalziel's correspondent at Cape Town sends the following account, given by a correspondent of the *Pretoria* (Cape Colony) nitrate fields. The nitrate beds at Prieska present the most valuable and richest deposit of nitrate of potash ever found. It is a most valuable substance, not to be confounded with sodium nitrate or Chilean saltpetre, so largely exported from South America, and sold on the London market at 19s. per ton, whereas the average price of unrefined potassium nitrate is 10s. 10d. per ton. The yield of the farms prospected is virtually unlimited, and, while in many of the large kloofs enormous masses of practically pure salt are found, the average in the soil for the whole area may be calculated at 25 per cent. Attention need only be drawn to the working of nitrates in other countries to prove the richness of the most recent South African discovery. Soils containing nitrate of potash are worked in India and Ceylon when containing only 2½ to 5 per cent., and the richest deposits in those countries rarely contain more than 8 per cent., while in Hungary nitroferous soils containing ½ to 2½ per cent. are worked at a profit. The deposit here is most easily extracted, merely by lixiviation, or hot or cold water decantation of the clear liquor from the soil into shallow tanks, and evaporation by the rays of the sun, when practically pure nitrate crystallises out. By this process, nitrates on a large scale could be produced at less than 2s. per ton, and the cost of transport over 140 miles of country to De Aar, and thence by rail and sea to Europe, is 5s. per ton.—*Engineering and Mining Journal.*

##### THE PRESENT STATUS OF THE CANADIAN ASBESTOS INDUSTRY.

The following particulars of the present condition of the Canadian asbestos industry have been obtained by the writer in a recent visit to the mining district. There is at present no prospecting for asbestos, and with one exception, to be noted hereafter, no business in buying and selling mining properties. After a somewhat prolonged period of dullness in the crude asbestos market, there are now decided indications of a legitimate improvement. Evidently stocks in the hands of manufacturers are running very low, and there is a moderate demand from all parts of the world.

With the asbestos miner it is not now so much a question of finding buyers as of finding a margin on the prices offered. Sales have recently been made at the following prices f. o. b. at the mines: No. 3, a round lot at 40 dols. per ton; No. 2, 65 dols. to 67.50 dols. per ton; No. 1, 115 dols. to 140 dols. per ton.

Nos. 2 and 3 are the grades mostly called for, and these are more largely produced by the mines. No. 1 quality is apparently not as much sought after as in the past, and as a consequence there is a notable stock of this grade in producers' hands. This is doubtless due to the very high price asked for the first quality during the speculative period of three years ago, which caused manufacturers to devise improvements in plant, and methods which enabled them to replace the costly fibre by lower grades. At the same time there is a limited demand for fibre of the very finest quality, as to length and colour, and freedom from impurities; for example, a leading dealer recently was offering 150 dols. per ton for 30 tons that would answer to certain specifications by no means beyond the choice product of our mines.

As a consequence of the improved inquiry for crude asbestos, the large and well-equipped mines, with two or three exceptions, are being worked, not to their full

capacity, but yet to an extent that will make the output of 1894 a decided advance on that of 1893. Fully 3,300 tons have been exported during the first six months of this year.

The old Jeffrey mine near Danville, on the Quebec branch of the Grand Trunk Railway, has long been of geological interest, from the fact that it occupies a knoll of asbestos-bearing serpentine, distant from 40 to 50 miles from any other known deposit of asbestos. This mine, which has also possessed a local interest, inasmuch as it has been owned and actively operated by the oldest miner in the province, a veteran of some four score and seven years, has recently changed hands. It is now being vigorously worked by two of our most enterprising Canadians, who are at present employing 150 hands. These new owners have the great advantage of being in close touch with manufacturers of asbestos goods, and it is probable that this well known mine will become even more prominent than it has been in the past.

The old problem of separating the lower grades of fibre from the enclosing rock is still to the fore. A special feature in this connection has been the installation by Messrs. W. G. Costigan and Co., of Montreal, of their cyclone fiberising machinery in three of the most important mines, viz., the Jeffrey mine, mentioned above, the Anglo-Canadian mine at Black Lake, and the Bell mine at Thetford. In this cyclone machinery the low grade asbestos, which is rock and fibre in intimate association, is introduced in small lumps, which meeting too rapidly revolving discs running in opposite directions have their non-fibrous particles reduced to powder by attrition, while the fibre, by reason of its nature, escapes injury, which is by no means the case when rolls or crushers are used. After leaving the cyclone the grit or gravel is separated by means of a series of screens, which, to a certain extent, also separates the fibre of different lengths.—*Engineering and Mining Journal*.

#### THE MINERAL PRODUCTION OF AUSTRIA.

The "Oesterreichische Zeitschrift fuer Berg- und Huettenwesen" of recent date gives the following statement of the mineral output of Austria for the year 1893, the figures being taken from the returns made to the Ministry of the Interior. The amounts given are in metric tons:—

	Tons.	Percentage of Change.
Gold ore.....	477	I. 190.7
Silver ore.....	18,918	I. 27.2
Quicksilver ore.....	76,215	D. 4.1
Copper ore.....	81,736	D. 0.7
Iron ore.....	1,162,112	I. 11.7
Lead ore.....	101,96	D. 19.4
Zinc ore.....	10,531	D. 10.1
Tin ore.....	26	D. 22.1
Bismuth ore.....	797	D. 6.8
Antimony ore.....	411	I. 353.6
Uranium ore.....	21	I. 19.1
Wolfram ore.....	43	I. 40.6
Chrome ore.....	"	"
Iron pyrites.....	1,959	I. 8.1
Alum and alum slate.....	13,570	D. 31.7
Manganese ore.....	5,111	D. 18.7
Graphite.....	23,807	D. 13.5
Asphalt.....	88	I. 12.7
Lignite (brown coal).....	16,815,955	I. 3.9
Coal.....	9,732,051	I. 5.3

Most of the changes, it will be seen, are not of great importance. The most notable are in zinc ore, and the gain in coal and lignite production.

The metallic output is given as follows, gold and silver in kilogrammes and the other metals and metallic products in metric tons:—

	Tons.	Percentage of Change.
Gold.....(kilos.)	35	I. 171.4
Silver.....(kilos.)	37,311	I. 1.9
Quicksilver.....	512	D. 5.6
Copper.....	944	I. 12.8
Sulphate of copper.....	177	I. 33.1
Pig iron, foundry.....	555,002	I. 4.7
Pig iron, forge.....	108,283	I. 7.5
Lead.....	7,212	D. 0.6
Litharge.....	2,011	D. 4.3
Nickel and cobalt.....(kilos.)	129	D. 21.1
Nickel sulphate.....	8	I. 79.1
Zinc.....	5,879	I. 12.1
Tin.....	66	I. 9.3
Bismuth.....(kilos.)	584	I. 6.6
Antimony.....	175	I. 53.4
Uranium salts.....	5	I. 113.7
Sulphur.....	9	D. 83.3
Sulphur ore.....	1,221	I. 0.9
Sulphuric acid.....	10,248	D. 7.2
Alum.....	837	D. 23.6
Copperas.....	1,129	I. 4.1
Mineral paint.....	3,020	I. 49.3

Most of these show no changes of importance. The increase in iron production is, however, considerable, and indicates a steady growth. The gold and silver output was almost entirely from Bohemia, as in former years. The quicksilver was chiefly from the famous mines of Idria, which supplied 87 per cent. of the total, the rest coming from St. Anna and Littai. The copper was from Bohemia, Salzburg, and the Tyrol.

Nickel, cobalt, arsenic, and chrome ore have disappeared from the list of the products reported in former years, none of these minerals having been produced last year.

#### THE INDIGO INDUSTRY IN BRITISH INDIA.

According to Dr. George Watt's recent report to the Indian Government there are in India 2,762 indigo factories and 6,032 vats, giving employment to 356,675 persons during the working season—a calculation that does not include the agricultural labour necessary to produce the plant. These are instructive figures, but not more so than those which may be shown regarding the history and growth of the industry. In 1782 the total imports of indigo into Great Britain were 495,100 lb., of which South America furnished 161,216 lb., the West Indies 64,309 lb., British Colonies 128,640 lb., and Asia (including India) 23,535 lb. Since then the Asian imports rose rapidly. In a dispatch, dated 1792, the Board of Directors congratulate the Indian Government that, as the British imports of Bengal indigo increased, those from the Spanish and French colonies declined, while at the same time a large export trade from Great Britain to the Continent had been established. It may thus be said that in less than 20 years the East India

Company had restored to India its lost industry. The average for the past ten years was fully 15,000,000 lb. Last year's exports were 126,706 cwt., valued at Rs. 41,412,000.—*Chemist and Druggist*.

#### CINCHONA CULTIVATION IN BRITISH INDIA.

In a recent report of the Indian Government, it is stated that on the Government plantation of the Darjeeling district in Bengal there were, at the end of the year 1892-93, 4,331,000 cinchona trees, or 100,000 less than in the preceding year. Of the existing trees, nearly four-fifths are of the pure quinine-yielding variety, and less than one-quarter belonging to the cinchonine-yielding variety. During the year 466,000 trees were uprooted for their bark, or died, while 181,000 were planted out; all the new plantations have for some years past consisted of quinine-yielding varieties. The harvest of dry bark was 304,000 lbs. The factory produced during the year 3,481 lbs. of cinchona febrifuge, and 5,242 lbs. of sulphate of quinine. Quinine is now sold to public institutions and Government offices at one rupee per ounce, while the febrifuge is sold at ten annas per ounce. The issues from the factory were 3,647 lbs. of febrifuge and 5,518 lbs. of quinine. The sales and issues of medicine during the year yielded a profit, after meeting all charges for maintaining the plantations, renewing plant, and working the factory. As soon as the remaining million of red bark trees are used up, it is intended to manufacture only quinine, and to cease making cinchona febrifuge at the Darjeeling factory. The capital cost of the plantation had been repaid by the sale of cinchona drugs in previous years. During the year 1892, 475 lbs. of quinine were put up in 5-grain doses; each dose is carefully packed, and bears simple instructions in one of the vernacular languages of Bengal. The packets are made up in the jail department, and they are issued to local postmasters, who, for a small commission, retail them to the public at one pie (one farthing) per packet, or dose. As yet, the arrangement has been made for Bengal only; when it is extended to the provinces, the demand for quinine thus brought in convenient shape, and in an absolutely pure state, to the doors of the people, is expected to increase indefinitely. Ample ground has been reserved for extending the Darjeeling plantations. In the Government plantations on the Nilgiri hills, in Madras, the cinchona trees are almost all of the quinine-yielding varieties. Drought, and the absence of sunshine, made the year 1893 unfavourable for cinchona cultivation on the Nilgiri hills. The stock of dry bark in hand at the beginning of the year was 416,000 lbs.; the harvest of the year was 119,000 lbs.; the consumption of the factory was 172,000 lbs.; and 2,000 lbs. were issued in the shape of bark. The produce of the factory during the year was 4,933 lbs. of quinine and 3,139 lbs. of cinchona febrifuge; 3,204 lbs. of the former and 2,600 lbs. of the latter were sold or issued to Government and municipal or local departments. The number of quinine powders issued to the public by collectors of districts rose to 170,000, from 37,000 in the previous year. The area under cinchona on private plantations outside Bengal is returned at 10,862 acres, nearly all of which are in Madras. The exportation of cinchona bark from India by sea, which was 3,074,000 lbs. in 1888-89, and 2,693,000 lbs. in 1891-92, rose to 2,814,000 lbs. in 1892-93.—*Journal of Society of Arts*.

#### CANADA AND THE AMERICAN DRUG TRADE.

Whereas not many years ago Canada imported the largest proportion of its drugs from Great Britain, its imports from the United States have of late increased rapidly, and are now larger than those from England. The total drug imports into Canada from all foreign countries in 1892-93 amounted to 3,408,166 dols. From the subjoined table it will be seen that nearly 50 per cent. was imported from the United States. The Canadian returns of imports and exports for the year ending June 30th, 1894, have not yet been published, but the following is the value of the drugs, dyes, chemicals, and medicines imported into the Dominion

of Canada from the United States during the undetermined years ending June 30th:—

	1890.	1891.	1892.	1893.
Free of duty .....	Dols. 662,504	Dols. 731,332	Dols. 741,267	Dols. 808,165
Dutiable .....	618,963	598,100	626,916	641,437
Totals .....	1,281,467	1,329,432	1,368,183	1,449,602

The value of the total exports of the above descriptions of merchandise from the United States during the year ending June 30th, 1893, was:—

	Dols.
Domestic .....	6,751,068
Foreign .....	628,122
Totals .....	7,379,190

In 1892-93 Canada purchased from the United States a little more than 20 per cent. of all its exports of these articles.—*Chemist and Druggist*.

#### PLATINUM.

The Ural platinum deposits in Russia are the only ones in the world, as this metal is worked nowhere else, and is known simply as a mineral finely disseminated in certain rocks. Platinum occurs in the Ural Government of Perm, where it is found on various private properties and State lands. In the district of Goroblagodat there are 70 allotments for the exploitation of platinum under different private individuals. The metal is found in the form of alluvial deposits or platinum-bearing sands, which frequently also contain gold. These deposits vary in thickness; they are rarely less than three, and often reach seven feet; the grains are usually small in size, but occasionally small nuggets are found weighing one or more kilogrammes. The platinum is frequently accompanied by other rare metals, such as iridium and osmium. At present all the platinum extracted in the Urals is forwarded in the crude state to St. Petersburg, whence it is sent abroad. Although there are two laboratories in the Russian capital for refining platinum ore, the greater quantity is sent abroad in the crude state. The production is subject to a tax of 3 per cent. for leasehold, and 4 per cent. for freehold works. The rapid and variable fluctuations in the price of a product having no definitely fixed exchange value, but indispensable to the arts, reflect upon the production of platinum in Russia. Thus, when the price of the metal is high, it becomes profitable to work the poorer deposits, while it is only possible to work the very richest when the price is low. Although the first platinum deposits in Russia were discovered so far back as 1819, the actual exploitation of this metal began only in 1824, when rich veins were discovered in the Nizhni-Tagilsk district. From 1828 to 1845 platinum money was coined in Russia. The denomination of these coins was three, six, and twelve roubles; the total value of platinum money put into circulation was 4,250,000 roubles. During this period the production of platinum increased considerably, but when platinum coinage ceased the exploitation of the metal was almost entirely stopped, and only revived in 1859. In 1887 the production of pure platinum was 269 poods 4 pounds, in 1890 it was 173 poods 263 pounds. The value of the yearly export of platinum, which goes chiefly to England, is about 1,560,000 roubles. The largest quantity of platinum is now extracted at the deposits of Nizhni-Tagilsk, belonging to Prince Demidoff San Donato, and at the Krestovosvzvensk deposits of Count Schouvaloff. In 1890 there were 6,000 workmen employed in the exploitation of platinum.—*Petersen's Trade Review*.

#### SULPHUR MINING IN LOUISIANA.

A New York syndicate are reported to have purchased the sulphur mines near Sulphur City, Louisiana, for 175,000 dols., and preparations are being made for their development. The sulphur is found at a depth of 180 feet,

and it is estimated that the mines contain a thickness of 100 feet solid sulphur of 98 per cent. purity.—*Chemist and Druggist*.

#### ALLEGED NITRATE DISCOVERIES IN COLOMBIA.

The *Panama Star* reports the discovery, at Magdalena, Colombia, S. America, of deposits estimated to amount to over 7,000,000 tons of nitrates, associated with iron pyrites. The quality of the deposit and its situation are said to be adapted for working in competition with the Chilean trade.

#### THE GERMAN CHEMICAL INDUSTRY SINCE 1885.

*M. Diezmann. Chem. Ind. 1894, 355.*

The progress made by German chemical industry in recent years becomes apparent from the following tabulated statement:—

	1885.	1886.	1887.	1888.	1889.
Imports—Million Marks	220'99	205'23	219'54	242'85	267'45
Exports ..	220'21	214'38	226'35	236'14	259'20

	1890.	1891.	1892.	1893.
Imports—Million Marks	261'87	261'67	266'37	273'1
Exports ..	274'69	277'97	286'04	299'1

Compared with the total trade of the German Empire, the respective percentage values amount to:—

	1885.	1886.	1887.	1888.	1889.
Imports—Million Marks	7'50	7'45	7'06	7'12	6'70
Exports ..	7'73	6'88	7'22	7'37	8'24

	1890.	1891.	1892.	1893.
Imports—Million Marks	6'32	6'38	6'63	6'89
Exports ..	8'26	8'75	9'08	9'67

Some of these changes are, no doubt, due to the incorporation, in the year 1888, of Hamburg and Bremen into the German Customs Union.

In regard to the chemical trade, the value of the raw materials imported amounts to about 55·8—62·4 per cent. of the value of the imports, this considerable variation being chiefly due to *nitrate of soda*, which occupies the foremost and most important position among the imports. Deducting the value of this commodity, there remains an almost constant figure of 92·7 million marks. Raw materials do not figure conspicuously among exports, amounting only to about 12 per cent. The *total trade in the chemical industry* and pharmacy is classified in the following way:—

	Imports.		Exports.	
	Thousand Tons.	Million Marks.	Thousand Tons.	Million Marks.
Raw materials of the chemical industry ..	324'31 up to 683'7	42'15 up to 79'18	148'59 up to 208'43	5'78 up to 8'99
Drugs for medical use .....	9'05 .. 12'68	15'59 .. 23'41	2'55 .. 3'96	5'55 .. 7'89

Among the raw materials of the chemical industry, the following articles may be enumerated, the individual values

exceeding 1,000,000 marks. The data refer to the period 1885—1892.

#### I. A. RAW MATERIALS OF THE CHEMICAL INDUSTRY.

	Imports.		Exports.	
	Thousand Tons.	Thousand Marks.	Thousand Tons.	Thousand Marks.
Nitre .....	153,738 up to 395,653	31,248 up to 69,239	2,430 up to 13,789	523 up to 2,387
Pyrites .....	130,502 .. 238,644	3,092 .. 4,773	8,285 .. 27,940	124 .. 447
Cream of tartar .....	1,331 .. 2,444	1,394 .. 4,346	216 .. 798	471 .. 896
Sulphur .....	11,664 .. 19,518	1,100 .. 2,245	559 .. 1,037	72 .. 150
Kryohite and bauxite .....	3,100 .. 11,782	349 .. 1,922	122 .. 424	45 .. 145
Stassfurt salts .....	125 .. 2,611	.. ..	112,123 .. 175,662	2,803 .. 4,161
Manganese ores .....	6,156 .. 9,662	516 up to 796	3,405 .. 10,620	511 .. 1,538
Not specified .....	11,376 .. 18,332	536 .. 1,411	3,694 .. 8,261	184 .. 445
Total .....	324,314 .. 683,700	42,118 .. 79,977	148,598 .. 208,439	5,784 .. 8,994

Deducting exports from imports the home consumption of *nitre* rose from 154,300 tons in 1885 to 385,000 tons in 1891, and in this respect Germany heads all other countries. The respective figures are:—

	1890.	1891.	1892.
In Germany .....	331,800	385,000	370,000
In France .....	210,500	173,800	215,000
In England.....	100,000	121,000	125,000
In United States.....	32,400	102,000	110,000

The value of nitre varied between *8l.*—*10l.* per ton.

In *pyrites* (including native alum) the chief importing centres were Spain and Portugal; the quantities improved from 123,000 tons in 1885 to 274,000 tons in 1893. The exports of sulphur are decreased from 28,000 tons in 1885 to 8—10,000 tons for the last years, Austria and Switzerland being the chief consumers. In 1893 the exports suddenly rose to 16,000 tons. The estimated average value decreased for imports from 2·3 marks for 100 kilos, in 1885 to 1·8 marks (1893, 1·9 marks), and for exports from 1·6 to 1·3 marks.

The consumption of *cream of tartar* is decidedly on the decrease. The exports consist chiefly of the refined article, hence they are given at an enhanced value (an additional 30—60 marks per 100 kilos.). The trade shows the following figures:—

	1885.	1887.	1888.	1890.	1892.	1893.
Imports ..Tons	2,173	1,646	2,452	2,005	1,391	1,552
Exports... "	216	235	265	498	798	614
Transit ... "	1,220	1,189	467	226	78	..

The importing countries are Italy, France, and Austria. The exports are taken up by England and lately by Australia. The average value decreased for imports from 200 marks per 100 kilos, in 1885 to 99 marks in 1893, and for exports from 230 marks to 145 marks.

The quantity of *Sulphur* imported increased twofold (235,000 tons in 1893), notwithstanding the increased imports of *pyrites*. The values kept fairly constant at 10—12·5 marks per 100 kilos.

The home consumption of *Cryolite* and *Bauxite* amounts for most of the years up to 1891 to 5,000 tons, increasing in 1892 to 14,800 tons, and in 1893 to 9,700 tons. The values average as follows:—

	1885.	1886.	1890.	1891.	1892 and 1893.
Imports .....	M. 9	M. 10	M. 10	M. 30·32	M. 14
Exports.....	80	50	10	42	70

The exports of *Stassfurt Salts* are subject to considerable variations. The chief consumers are:—

	1889.	1890.	1891.	1892.	1893.
United States.....Tons	72,196	119,902	77,751	130,312	162,206
England.....	14,102	38,711	37,179	27,818	58,851
Sweden.....	10,850	12,570	18,744	16,561	50,915
Other countries.....	15,481	10,070	20,526	30,470	66,187
Total.....	112,829	112,123	156,900	115,064	212,259

Since 1885 the values were taken at 2½ marks per 100 kilos.

As regards *Manganese Ores*, the export values show an apparent excess over the import values, the former averaging 7·5—8·5 marks per 100 kilos, for imports, the latter 20 marks in 1885, and since then 15—16 marks. As regards quantities the proportion is reversed. The chief importer is the Caucasus, and in the second line Austria and Belgium. The maximum of the imports was reached in 1893 with 12,000 tons, and the exports fell in the same year to their lowest level (2,700 tons).

#### I. B.—CRUDE DRUGS.

	Imports.		Exports.	
	Tons.	Thousand Marks.	Tons.	Thousand Marks.
China bark .....	4213 up to 6,065	4,122 up to 11,494	22 up to 98	55 up to 226
Sponges .....	260 " 326	3,938 " 8,108	36 " 56	615 " 1,574
Camphor .....	399 " 1,914	119 " 3,133	217 " 581	326 " 2,633
Crude manufactured products not specified.	3,090 " 6,138	2,787 " 5,218	2,025 " 2,845	5,038 " 4,268
Others.....	985 " 1,731	1,892 " 3,265	131 " 411	492 " 1,000
Total.....	9,065 " 14,765	15,594 " 23,414	2,550 " 3,955	7,702 " 7,885

Stocks of *China Bark* accumulated from 1,500 tons in 1880 to 6,000 tons in 1891 and 1892, but the available quantities decreased to 4,230 tons in 1893. The tremendous fall in its value is shown by the following table, in marks per 100 kilos.:—

	1885.	1886.	1890.	1891.	1891 and 1893.
Imports .....	30	10	10	9·32	13
Exports.....	50	50	20	42	70

The use of *Camphor* for the manufacture of smokeless powder was accompanied by a corresponding rise from 110 marks per 100 kilos, to 280 marks in 1890, and since then to 290—300 marks, for imports of the crude and refined stuff. At the same time the exports, consisting chiefly of the refined article, were valued at an increase of 40 marks in 1885, 50 marks in 1886, 55 marks in 1887, 80 marks in 1893 for 100 kilos. The chief producers are China and Japan, and the consumers France, Russia, and Austria.

The imports of *crude products not specified* rose from 3,100 tons in 1885 to 5,000 tons in 1889. They are of a manifold nature, and include laurel leaves from Austria, senna leaves, quassia wood, ipëcacuanha root from England,

vamilla and baldrian root from Belgium, &c. The exports varied between 2,000—2,800 tons, averaging 150 marks for

100 kilos. The principal customers are the United States, Austria, Russia, England, France, and Holland.

### I. C. RESINS, &c.

	Imports.		Exports.	
	Tons.	Thousand Marks.	Tons.	Thousand Marks.
Turpentine resin.....	15,990 up to 76,753	4,984 up to 7,933	4,793 up to 11,371	633 up to 1,285
Gum arabic, &c. ....	1,302 " 2,502	5,674 " 7,790	205 " 627	1,027 " 2,383
Gum lac, &c. ....	1,137 " 1,810	1,705 " 3,205	64 " 225	113 " 430
Other resins .....	2,143 " 3,514	3,840 " 7,029	236 " 1,088	328 " 2,611
Asphalt .....	15,708 " 27,059	938 " 1,488	11,948 " 17,999	584 " 1,009
Refuse for the manufacture of glue.....	4,972 " 6,393	955 " 1,391	2,256 " 5,496	519 " 1,250
Total .....	74,416 " 114,210	19,359 " 28,047	20,234 " 34,839	3,828 " 7,875

Since 1886 there is an increasing tendency in almost all these goods. As regards *turpentine resin* the chief importers are the United States. The exports go to Austria, Russia, Switzerland, and Sweden. Its value for imports is taken at 14 marks in 1880, 11·5 marks in 1885, and 9—10·4 marks since then.

The imports of *gum arabic*, Senegal and tragacanth decreased from 1,746 tons in 1885 to 1,302 tons in 1887, and rose since to 2,502 tons in 1892 and 2,392 tons in 1893. These variations are chiefly due to French imports (Senegal gum), thus : 508 tons in 1885, 98 tons in 1889, 528 tons in 1891, and about 400 tons in 1892 and 1893. The fluctuations are also due to the variations in the value of gum arabic, as evinced by English statistics, according to which 100 kilos, gum arabic are valued for imports :—

—	1885.	1886.	1887.	1888.	1889.	1890.	1891.	1892.
Marks	138	157	185	162	150	122	102	112

and according to Hamburg statistics :—

Marks	202	256	271	226	209	212	226	172
-------	-----	-----	-----	-----	-----	-----	-----	-----

Senegal gum :—

Marks	188	261	263	315	210	..	173	170
-------	-----	-----	-----	-----	-----	----	-----	-----

and tragacanth gum :—

Marks	264	273	294	270	401	..	292	255
-------	-----	-----	-----	-----	-----	----	-----	-----

According to the imperial statistics the three varieties are valued for imports at the following high rates :—

Marks	325	450	450	480	450	350	320	300
-------	-----	-----	-----	-----	-----	-----	-----	-----

which amounts are increased for exports, by 55 marks for 1885, 90 marks for 1886—1889, 50 marks for 1890, and since then by 80 marks per 100 kilos.

One half of the total imports originate from the British East Indies. The difference between imports and exports, which fell between the years 1885—1887 from 1,476 tons to 1,080 tons, has since then increased to 1,875 tons in 1892, but receded to 1,592 tons in 1893. The exports have considerably increased on French and Austrian account.

The home consumption of *gum lac and shellac* remains fairly constant at 1,300—1,600 tons per year, with the exception of 950 tons for 1889 and 1,840 tons for 1893; the prices varied between 120—200 marks per 100 kilos. In *other resins* the consumption varied between 1,820—2,115 tons in 1885—1890, with a minimum of 1,463 tons in 1885. Since then a marked increase of imports over exports has taken place, to 1,933 tons in 1890, 2,371 tons in 1891, 3,025 tons in 1892, and 3,787 tons in 1893, chiefly owing to supplies from England and from the States. No explanation is to be found for this increase, except it be due to incorrect declaration of, say, turpentine resin.

The imports of *asphalt*, including resin and wood-cement, rose from 15,708 tons in 1885 to 29,615 tons in 1893. One half of this quantity comes either direct or via England from Trinidad, and the remainder from Switzerland. The exports amounted to 12,615 tons in 1885, 17,999 tons in 1891, and 12,622 tons in 1893. The chief consumers were, for a long time, the States, but the quantities consumed there decreased in 1893 from 7,350 tons to 2,590 tons. Other consumers are England, Russia, Sweden, &c. The average price was taken in 1885 at 8 marks, and since then between 4·5 and 5·5 marks for both imports and exports.

As regards the *residues for the production of glue* the chief consumer is Austria. The average price for imports was taken at 20 marks for 100 kilos. in 1885, and since then 19 marks; for exports it is taken at 23 marks.

The considerable decrease in the imports of chiefly Austrian and Russian *bone charcoal* from 19,000 tons in 1885 to 10,000 tons in 1892, is no doubt due to the diminished demand for this article in sugar refineries. There is also a corresponding decrease in the exports. The average value of the imports is taken at 20 marks per 100 kilos. in 1885, and at 12 marks in 1893, of the exports at 18—22 marks.

*Yeast*, other than wine yeast, shows a similar decrease in both imports and exports. The imports of *wine yeast*, on the other hand, especially of Italian origin, increased considerably from 710 tons in 1880, to 5,453 tons in 1889; since then it amounted to :—

—	1890.	1891.	1892.	1893.
Tons	3,832	3,812	4,703	5,537

In the same time, the values increased temporarily, from 40 marks per 100 kilos. in 1885 to 50 marks in 1887, and then receded gradually to 25 marks in 1893. The supplies are derived from Italy, France, and Spain.

## I. D. FERMENTING AND CLARIFYING AGENTS.

	Imports.		Exports.	
	Tons.	Thousand Marks.	Tons.	Thousand Marks.
Bone charcoal .....	9,992 up to 19,967	1,204 up to 3,833	2,018 up to 3,538	419 up to 778
Wine yeast .....	2,843 " 5,455	1,137 " 2,245	2 " 33	0 " 13
Other yeast .....	42 " 694	97 " 694	1,327 " 2,128	1,394 " 2,128
Other materials .....	20 " 36	895 " 643	9 " 18	189 " 376
Total .....	13,898 " 23,597	3,207 " 6,120	3,704 " 5,710	1,800 " 3,161

## I. E. CRUDE DYE-STUFFS.

	Imports.		Exports.	
	Tons.	Thousand Marks.	Tons.	Thousand Marks.
Dye-woods .....	48,650 up to 63,326	7,271 up to 10,656	39,960 up to 14,154	1,473 up to 2,281
Graphite .....	7,681 " 13,967	922 " 1,875	1,287 " 3,178	131 " 579
Barytes .....	3,193 " 5,661	369 " 453	21,917 " 31,226	1,563 " 1,561
Dye-earths .....	4,129 " 7,507	495 " 731	8,316 " 10,997	1,175 " 1,510
Others .....	12,314 " 21,937	711 " 2,260	2,382 " 5,622	120 " 669

The German consumption of *dye-woods*, as arrived at by deducting exports from imports, has been decreasing since 1885, with the exception of the year 1893, thus:—

	1887.	1888.	1889.	1890.	1891.	1892.	1893.
Logwood..Tons	38,847	43,085	41,314	42,180	37,446	31,458	35,371
Fustic.... "	6,876	6,129	5,033	4,157	2,836	1,402	4,545
Brazil wood "	4,673	5,518	6,827	1,535	1,826	2,676	1,756

Logwood is imported chiefly from Mexico, Jamaica, and Hayti. Its average value per 100 kilos. amounted to 14 marks in 1885, 17 marks in 1889, then 15 marks, and finally 17 marks in 1893. The English quotations vary between 10·5 and 14 marks. Fustic is valued at between 9 and 12 marks, Brazil wood at 16—18 marks. The trade in dye-woods amounted to:—

	Imports.	Exports.
Logwood .... 1,000 Marks	6,347 up to 8,638	1,697 up to 1,819
Fustic .....	840 " 835	81 " 207
Brazil wood.. "	500 " 1,329	208 " 301

The *graphite* trade resolves itself into transit from Austria to England, and back from England (Ceylon graphite) to Austria. The home consumption is:—

	1885.	1886.	1887.	1888.	1889.	1890.	1891.	1892.	1893.
Tons...	9,519	6,201	6,844	7,602	8,776	11,783	8,086	9,429	10,133

Graphite is supplied chiefly from Austria, and in the second place, and in increasing quantities, from Ceylon:—

	1889.	1890.	1891.	1892.	1893.
East Indies (resp. Tons)	1,669	3,414	3,138	2,864	3,765
England..	1,347	2,119	731	150	?
Holland.....	8694	7,820	7,822	8,450	8,257
Austria.....	324	614	553	639	789
Other States .....					

Whilst dye-woods and graphite are the main imports, *heavy spar* and *dye-earths* are the principal exports. The former is exported to England, Austria, the United States, and Russia. On the other hand, barium carbonate (Witherite) is imported from England and barium sulphate from Belgium. The imports are valued at 8—10 marks per 100 kilos., the exports at 5—6 marks. The exports of *dye-earths* varies between 8,500—9,700 tons, with the exception of the year 1892, when they reached a total of 10,997 tons. The exports are valued at 13—14 marks per 100 kilos., against 10—12 marks for the imports. The latter are increasing, and the main sources are France, England, Italy, Austria, and Belgium.

Among "*others*" crude chalk is the most important as regards quantity. The variations in the values of these articles is due to the circumstance that up to 1887 there were included therein "unspecified dyeing and tanning materials," and which have since been classified among manufactured goods.

The imports of *bark* and *tanning liquid* reached a maximum in 1890, falling off in 1892 to 95,000 tons and in 1893 to 96,400 tons. They are derived chiefly from Austria, France, and Belgium, and their value varies between 9·5—11·5 marks per 100 kilos. The reason of the recent decrease lies chiefly in the competition of uncut Quebracho wood; this Argentine product was imported to the extent of 16,600—21,800 tons a year between 1881 and 1890,

## I. F. TANNING MATERIALS.

	Imports.		Exports.	
	Tons.	Thousand Marks.	Tons.	Thousand Marks.
Bark .....	61,813 up to 103,441	4,778 up to 12,653	2,810 up to 5,207	267 up to 373
Galls, knopperrn, &c. ....	6,132 .. 10,507	4,172 .. 6,578	89 .. 124	84 .. 277
Tanning extracts .....	5,077 .. 8,531	2,285 .. 4,049	171 .. 1,685	85 .. 644
Sumach .....	4,802 .. 8,135	1,123 .. 1,626	222 .. 886	45 .. 195
Quebracho .....	4,339 .. 50,226	284 .. 2,511	7 .. 1,044	1 .. 63
Dividivi .....	1,964 .. 4,708	215 .. 1,224	19 .. 859	5 .. 227
Others .....	2,719 .. 4,205	456 .. 710	205 .. 391	39 .. 83
	91,296 .. 177,130	18,994 .. 25,714	4,582 .. 6,072	684 .. 1,698

50,200 tons in 1891, 27,100 tons in 1892, and 39,000 tons in 1893. The values were:—1886–90, 6·5–9 marks per 100 kilos.; 1891–93, 5 marks. In *galls* distinction is made since 1889 between Knopperrn, Eckerdopperrn, and Valonia. The former are of Chinese and Turkish origin, and their home consumption amounts to 2,000–2,400 tons, valued at 2½–3 million marks. The use of *sumach* is on a steady increase, with the exception of 1893, when a drop to 6,590 tons has taken place. The average value decreased from 25 marks for 100 kilos. in 1885 to 18–20 marks. There was considerable and rapidly increasing demand for *Dividivi*, the values varying between 20–26 marks per 100 kilos. The importing countries were Venezuela, Curacao, Columbia, Hayti, &c. There is a distinct increase in the exports of *tanning extracts*, chiefly for Holland, Belgium, Scandinavia, Russia, and the States. The importing countries are Austria, France, and Belgium.

The average values for 1885–90 were from 45–50 marks per 100 kilos., for 1891 40 marks, and since then 30 marks. An addition of 5 marks may be made for exports.

In summarising the trade in the raw materials of the chemical industry and pharmacy we find that the import values suffered a *decrease* in cream of tartar, china bark, sponges, bone charcoal, beer yeast and pressed yeast, krapp, and cochineal. An *increase* has taken place in sulphur, camphor, drugs not specially enumerated, turpentine-resin, gum arabic, resins not enumerated, graphite, dividivi, and quebracho. The exports of the more important commodities show a considerable decrease in the case of bone charcoal and yeast; an increase in camphor, turpentine-resin, tanning extracts (since 1888), gum arabic (since 1889), gum lac, resins, and residues for the manufacture of glue.

The *manufactured products* show a different picture:—

	Imports.		Exports.

—II. A.

## THE NEW SODIUM NITRATE DEPOSITS OF COLUMBIA.

Through the courtesy of the *Panama Star and Herald*, we have been able to obtain the following additional information concerning the discovery of deposits of sodium nitrate in the Columbian States. The deposits were found in the department of Magdalena, extending over a very wide area, and as regards quality and appearance the Columbian nitrate is said to closely resemble the Chilean. It is asserted, indeed, that the deposits possess certain advantages that will allow of their competing very successfully with the Chilean nitrates.

The discovery was made by M. C. F. Z. Caraeristi, in the neighbourhood of the Sierra Nevada de Santa Marta, and his investigations, of which the results have lately been published, seem to place the value of these new deposits beyond question. So far, it is known that the nitrates extend over a district of seventy-five square kilometres, but it is believed that they will be found to be quite as extensive as the deposits of Chili. The layer of mineral, which has a thickness of from thirty centimetres to three metres, has been cut through at depths varying from 2·40 metres to 6 metres. It is covered by a stratum composed of sulphate of calcium, oxide of iron, and other minerals, while underneath is a layer of sandstone, which has prevented the nitrates from sinking through the lower strata. Being so thoroughly protected, the mineral is found occasionally in a pure state, in the form of crystals, in which the percentage of nitrate is about 24 per cent., the other elements being chloride of sodium and insoluble silicates. These crystals, however, compose a small part of the deposits, and the mineral available for working contains from 11 to 12 per cent. of nitrates. The other constituents are carbonate of calcium, sulphate of calcium, and silicates. It will be seen, therefore, that the mineral is a very valuable agent for fertilising

purposes, and if worked upon an extensive scale is sure to be in large demand.

Of course it is impossible at the present moment to give an accurate estimate of the amount of nitrates available for working, but an engineer, who lately arrived in the country with a view of ascertaining the richness of the deposits, is of opinion that at least 7,380,000 tons of mineral can be produced. Besides nitrates, any country undertaking to develop this territory could make a considerable profit out of the enormous quantities of iron pyrites that are to be found in the adjoining district. These pyrites are said to contain more than 42 per cent. of sulphur. In view of the splendid returns that are likely to result from the investment of money in the nitrate industry of Columbia, these new fields, from which the most satisfactory returns are to be expected, should not fail to attract the notice of American and European capitalists.

One of the principal advantages of the nitrate field of Columbia is its favourable situation for transport. The mineral lies at a distance of about 65 miles from the town of San Juan de la Ciénaga, and some of it is to be found in the basin of the San Sebastian River, which, by means of the Ciénaga Grande Lake, is in direct communication with the sea. Certainly, some work would be necessary to make the waterway navigable the whole length of its course, but it is estimated that this could be done for something like 1,000/. As regards railroad transport also, exceptional facilities will be afforded for the conveyance of the mineral to the port of shipment. When the line from Santa Marta is completed, it will pass within half a mile of the nitrate fields, and, as the railroad is already laid down as far as Rio Frio, it only remains for another 62 miles to be constructed.—*Chemical Trade Journal*.

## BOARD OF TRADE RETURNS.

## SUMMARY OF IMPORTS.

Articles.	Month ending 29th September.	
	1893.	1894.
	£	£
Metals.....	1,687,076	1,605,524

## Monthly Patent List.

\* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

#### APPLICATIONS.

17,666. S. Trivick, P. A. J. Head, and J. Elsner. Improvements in furnaces for metallurgical and other purposes. September 17.

17,836. W. W. Wardle. Improvements in drying apparatus. September 19.

17,848. C. J. Ollagnier. See Class XVII.

18,173. R. Pearson. Improvements in the method of evaporation of liquids, water, brine, &c. September 25.

18,214. H. H. Lake.—From R. Schicht, Austria. An improved method of and apparatus for drying substances which are viscous or semi-fluid in the hot state. Complete Specification. September 25.

18,462. T. W. F. Cherry. Improvements in taps for use with chemical and other fluids. September 29.

18,591. T. Hewitt. Improvements in cooling and freezing machines. October 1.

18,727. G. Krell. See Class VII.

18,828. E. Theisen. Improvements in apparatus for condensing, evaporating, or refrigerating fluids. October 4.

18,992. H. L. Doulton and A. W. Manger. Improvements in the process of and apparatus for softening waters and purifying waste liquors. Complete Specification. October 6.

19,042. J. C. S. McLay. Improvements in heat non-conducting substances. October 8.

19,085. A. Müller. Improvements in apparatus for effecting the absorption of gases by liquids and for cooling gases. Complete Specification. October 8.

19,087. R. Tervet, jun. Improved apparatus for extracting and purifying sulphur, oils, and other substances. October 8.

19,128. W. Hood. Improvements in hydrometers, salinometers, and such like instruments. October 9.

19,169. G. L. F. Edeline. An improved composition for the prevention of incrustation in boilers. Complete Specification. October 9.

19,170. H. Prince. Improvements in apparatus for rowing liquors. October 9.

19,175. A. Gray. Improvements in apparatus used in the manufacture of paper, linen, or other fabrics, coated or impregnated with celluloid, or varnish, or the like. October 9.

19,293. J. L. Mitton and T. J. L. Mitton. Improvements in retort mouthpieces and self-sealing lids for same. October 11.

19,488. T. Scott and The Patent Salt Co., Lim. Improved evaporator for obtaining common salt and for analogous purposes. October 13.

#### COMPLETE SPECIFICATIONS ACCEPTED.\*

1893.

19,618. E. J. Preston. Improvements in apparatus for intensifying fluid pressure. October 17.

22,681. G. Axdorfer and C. F. H. Sass. Improvements in apparatus for mixing gas and air for gas furnaces. September 26.

23,124. G. Dasse and C. Fettweis. Improvements relating to drying and carbonising apparatus for textile and other matters. October 10.

1894

12,880. G. A. Barnard. Improvements in apparatus for cooling or condensing fluids. October 17.

15,413. E. Fudlickar. Improvements in and relating to apparatus for heating liquids, air, and other fluids. October 10.

15,881. W. Oliphant. Improvements in filtering apparatus. October 3.

16,933. E. Herscher. An improved continuous apparatus for the sterilisation of water or other liquid by ebullition. October 10.

### II.—FUEL, GAS, AND LIGHT.

#### APPLICATIONS.

17,679. F. Bremme. Improved mode of treatment and apparatus for the carburisation of gases. Complete Specification. September 17.

17,693. J. W. Scott. Improvements in and relating to apparatus for extracting the solid and gaseous impurities from illuminating and other gases. September 18.

17,759. W. B. Hartridge. An improvement in artificial fuel. September 18.

17,760. W. B. Hartridge. Improvements in apparatus for the manufacture of artificial fuel. September 18.

17,873. H. T. Blake. Dowson gas enricher. September 20.

17,987. S. de la G. Williams. Improvements in and apparatus for the production of gaseous fuel. September 21.

18,078. P. Dvorkovitz. Improvements in and apparatus for enriching gases by liquid hydrocarbons. September 22.

18,991. R. Clough, M. L. Mulholland, and R. Clough, jun. Improvements in apparatus for purifying coal or the like material by the washing process. September 24.

18,237. G. Threlfall and R. J. Hodges. Improvements in gas generating apparatus. September 26.

18,248. C. E. Parker-Rhodes and S. F. St. J. Steadman. Improvements in or relating to the treatment of hydrocarbon oils, spirits, and other highly inflammable materials of a like nature. September 26.

18,369. G. Threlfall and R. J. Hodges. Improvements in and connected with gas-producing apparatus. September 28.

18,440. S. Hersey and Kirkham, Hulett and Chandler, Lim. Improvements in apparatus for washing or scrubbing gas. September 28.

18,441. Kirkham, Hulett, and Chandler, Lim.—From F. D. Marshall, Denmark. Improvements in apparatus for condensing and washing gas. September 28.

18,443. S. H. Terry. Improvements relating to the use of liquid fuel and apparatus for that purpose. September 28.

18,445. B. H. Thwaite. Improvements in gas-generating plant. September 29.

18,510. W. Kemp. Improvements in apparatus for enriching gas. September 29.

18,715. A. W. Summers. Fuel-saving compound. October 3.

18,889. R. Middleton. Improvements in machinery used in process of manufacturing fuel or other dust into blocks for use in furnaces. October 5.

19,003. A. W. Pickering. An improved method of and means for manufacturing gas of illuminating and combustible properties. October 6.

19,127. J. T. Donovan and H. L. Gardner. A new and improved process for the production of ozone. Complete Specification. October 9.

19,130. R. H. Courtenay. An improved method of rendering the combustion of coal-gas more perfect, with appliances for same. October 9.

19,179. F. A. Seigel and F. A. Solbrig. Improvements relating to the protection of the mantles and chimneys of incandescence gas lights. October 9.

19,457. T. Clapham and J. Laycock. Improvements in apparatus for use in the purification of coal or other illuminating gas. October 13.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

#### APPLICATIONS.

17,617. W. R. Hutton. Improvements in apparatus for the distillation of coal, lignite and dross. September 17.

### IV.—COLOURING MATTERS AND DYES.

#### APPLICATIONS.

18,272. L. Lederer. Process for obtaining pure phenols from mixtures. September 26.

18,429. A. Feer. Improvements relating to the preparation of diazo salts, and to the use of the same for dyeing and printing. September 28.

18,516. A. M. Clark.—From A. Edinger and A. Muller, Germany. The manufacture of alkylrhodonates and acid chlorides of chinolin, pyridin, antipyrin, and isochinolin, and their derivatives. September 29.

18,578. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co., Germany. The manufacture or production of colouring-matters. October 1.

18,588. C. D. Abel.—From the Actien Gesellschaft für Anilin Fabrikation, Germany. Manufacture of new condensation products, and colouring-matters derived therefrom. October 1.

18,589. O. Imray. From the Society of Chemical Industry in Basle, Switzerland. Manufacture of basic orange-yellow colouring-matters. October 1.

19,187. J. Y. Johnson.—From C. F. Boehringer and Soehne, Germany. Improvements in the manufacture of the alkyl-ethers of acylized *p*-amido-phenols. October 9.

19,188. J. Y. Johnson.—From C. F. Boehringer and Soehne, Germany. An improved process for the manufacture of lactyl-*p*-phenetidine. October 9.

19,420. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation, Germany. Manufacture of a colouring-matter to dye cotton without mordant. October 12.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

18,769. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik. Improvements in the manufacture of colouring-matters. October 10.

22,741. O. Imray.—From The Society of Chemical Industry in Basle. Manufacture of blue acid colouring-matters of the triphenylmethane series. September 26.

23,310. C. D. Abel.—From the Actien Gesellschaft für Anilin Fabrikation. Manufacture of new bases and their sulpho-acids. October 3.

23,311. C. D. Abel.—From the Actien Gesellschaft für Anilin Fabrikation. Manufacture of colouring-matters, dyeing blue with mordants. October 10.

23,392. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of colouring-matters. October 10.

23,585. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of colouring-matters derived from anthraquinone. October 10.

### V.—TEXTILES, COTTON, WOOL, SILK, Etc.

#### APPLICATIONS.

17,625. A. Stephenson. Improvements in apparatus for scouring and washing wool and the like. Complete Specification. September 17.

17,911. L. Wilson. Improvements in apparatus for drying and otherwise treating yarn in cop or other similar compact form. September 20.

18,463. J. Ingleby. Improvements in the manufacture of linoleum and cork carpets, and apparatus or machinery therefor. September 29.

19,485. A. F. B. Gomes. An improved process for the treatment of textile vegetable fibres, more especially applicable to those of the urtica family. October 13.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

23,052. J. Dawson. Improvements in apparatus for drying wool and other fibres. October 10.

23,324. G. Dasse and C. Fettweis. See Class I.

24,003. F. Lehner. Improvements in the production of and in apparatus for producing artificial silk. October 17.

1894.

15,140. A. Gruschwitz. An improved process for the retting, cleansing, and like treatment of textile fibres. September 26.

16,137. C. H. Arnold. Improvements in the manufacture of waterproof fabrics. October 3.

17,070. E. Hornung and R. Liebl. Improvements in waterproof fabrics, garments, wrappers, and coverings, and in the process and composition for manufacturing the same. October 17.

### VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

#### APPLICATIONS.

18,077. F. Anselmi and The Clayton Aniline Co., Lim. The production of new blue-azo colours on vegetable fibres or fabrics. September 22.

18,218. J. Bolet. An improved machine for printing on textile fabrics and the like. Complete Specification. September 25.

18,249. J. Read. Improvements in machines for washing or scouring textile fabrics. September 26.

18,258. E. Potter and Co., Lim., and J. Barr. Improvements in printing upon calico and other woven fabrics. September 26.

19,226. W. H. Thorpe. Improvements in machinery for mordanting, dyeing, washing, and scouring banks of yarn. Complete Specification. October 10.

19,235. T. Ingham. Improvements in dyeing mixed woven or knitted fabrics. Complete Specification. October 10.

#### COMPLETE SPECIFICATION ACCEPTED.

1893.

22,498. A. J. Boulton.—From P. V. Rennard. Improvements in or relating to the clouding of textile materials in dyeing. October 17.

## VII.—ACIDS, ALKALIS, AND SALTS.

## APPLICATIONS.

17,978. K. J. Bayer. Improvement in the manufacture of chlorine acid potash, or chlorate of potash. September 21.

18,031. G. Millard. Improvements in the art, trade, or manufacture of bisulphide of carbon.

18,206. W. Walker, jun., and F. R. Wilkins. Improvements in utilising residual products obtained in working certain kinds of voltaic batteries. September 25.

18,519. J. Pfleger. Improvements relating to the manufacture of cyanides and to apparatus therefor. September 29.

18,526. J. Hargreaves and T. Bird. Improvements in the manufacture of chlorates of sodium and potassium. October 1.

18,727. G. Krell. Improved apparatus for concentrating and distilling sulphuric acid and other liquids of high boiling point. October 3.

18,791. W. McD. Mackey and J. F. Hutcheson. Improvements in and relating to the production of ammonia. October 4.

18,792. W. McD. Mackey and J. F. Hutcheson. Improvements in and relating to the production of cyanides and ammonia. October 4.

18,940. W. Whitehead and C. Gelstharp. Improvements relating to the separation of arsenic, antimony, bismuth, and other metals from spirit of salt (hydrochloric acid) oil of vitriol, or sulphuric acid and other acid solutions and to apparatus therefor. October 5.

18,995. J. J. Crosfield and K. E. Markel. Improvements in the process of evaporating silicate of soda solutions. October 6.

19,174. D. Levat. Improvements in the treatment of natural phosphates. October 9.

19,189. T. T. Best and J. Brock. Improvements in the manufacture of chlorate of soda. October 9.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

21,239. J. J. Hood and A. G. Salamon. Improvements in the preparation of cyanogen compounds. October 10.

21,451. J. Brock, A. E. Hetherington, F. Hurter, and J. Raschen. Improvements in the manufacture of sulphocyanides, in the recovery of by-products, and in apparatus therefor. October 17.

1894.

4916. A. J. Bonlt.—From E. Warzee, Belgium. Process for the separation and precipitation of salts of iron and zinc from solutions containing both. October 17.

16,067. J. Grossman. Improvements in the preparation and manufacture of hydrosulphurous acid and hydrosulphites. October 3.

16,068. J. Grossman. Improvements in the preparation and manufacture of hydrosulphurous acid and hydrosulphites. October 17.

17,275. T. Craney. Improvements in salt evaporators. October 17.

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

## APPLICATIONS.

18,256. J. L. Wittwe. Glass which consists of spun glass. September 26.

18,397. The Worcester Royal Porcelain Co., Lim., W. M. Binns, and G. H. Hancock. Improvements in the manufacture of decorated fictile-ware. September 28.

19,515. C. Jousset and F. R. Boardman. Improvements in a composition which will adhere to glass, and is for the purpose of diffusing and colouring the light. October 13.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

16,156. J. Gratton. New design for a potter's oven bottom. October 3.

22,637. J. B. Hanquiaux. Improvements in ovens for baking or firing ceramic ware and other refractory products. September 26.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

## APPLICATIONS.

17,621. W. Smith. Improvements in the manufacture of bricks or building blocks. September 17.

17,868. C. Musker and A. Musker. Improvements in or connected with machinery for making paving or building slabs or blocks and other articles. September 20.

17,920. W. Clark and A. W. Rammage. Improvements in fireproof floorings. September 20.

17,947. J. Ryder and Sons, Lim., and J. Ryder. Improvements in the manufacture of red bricks, terra-cotta, tiles, and similar goods. September 21.

18,210. G. S. Cory. An improved composition for roads, pavements, and floors. September 25.

18,233. J. T. Pearson. Improvements in pavements and material applicable thereto. September 26.

19,080. G. Falconnier. Improvements in or relating to the construction of transparent or translucent walls, ceilings, floors, or the like. October 8.

19,180. C. A. Balph and E. P. S. Wright. Improvements in and relating to fireproof floors and ceilings. Complete Specification. October 9.

19,325. T. R. W. Mossman. An improvement in the construction of fireproof floors and roofs. October 11.

19,437. E. Tortora. Improvements relating to the treatment of terra-cotta, wood, clay, gypsum, limestone, and other materials for preserving and other purposes. Complete Specification. October 12.

19,525. J. H. Barry. Improved paving by the utilisation of waste materials. October 13.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

21,292. A. Patrick. Improvements in the manufacture of Portland cement, pigments, and other finely pulverised materials, and in apparatus therefor. September 26.

1894.

5071. G. W. A. Stein. Improved process for manufacturing hydraulic cement. September 26.

14,699. W. Whittaker. Improvements in fireproof and waterproof ceilings and flues. October 17.

15,231. C. Howard. Improved method of vulcanising and drying wood. September 26.

## X.—METALLURGY, MINING, ETC.

## APPLICATIONS.

16,003A. H. Ellis and H. G. Coleby. A new alloy applicable for umbrella fittings, parts of bicycles, and for other uses, where a non-corrodible, strong, and light metal is required. Filed September 17. Date claimed August 22, 1894.

17,666. S. Trivick, P. A. J. Head, and J. Elsner. See Class I.

17,820. W. P. Thompson.—From O. Nicolai, Germany. An improved solder for soldering aluminium, aluminium alloys, and other metals. September 19.

17,961. H. R. Angel. Improvements in the extraction of lead with silver, gold, or other minerals contained in sulphide of zinc. September 21.

17,967. J. Mactear. Improvements in the obtainment of precious metals. September 21.

17,974. A. J. Boulton.—From A. L. Graut and C. G. Richardson, United States. Improvements in the refining of nickel and copper mattes. September 21.

18,003. H. L. Sulman. Improvements in or relating to the obtaining of precious metals from their solutions. September 21.

18,070. J. Mactear. Improvements in the obtainment of precious metals. September 22.

18,146. H. L. Sulman. Improvements in or relating to the recovery of precious metals from their ores. September 24.

18,151. F. C. May. An improved process for the extraction of gold and silver from their ores. September 25.

18,155. J. Green. Improvements connected with the manufacture of iron. September 25.

18,212. G. A. Dick. Improvements in or connected with means or apparatus for treating heated metals under pressure. September 25.

18,264. W. R. Renshaw. Improvements in the treatment for re-manufacture of light scrap iron or steel; machinery and furnace therefor. September 26.

18,279. A. E. Morgans. An improved process for extracting precious metals from their ores. September 26.

18,125. J. Mactear. Improvements in the extraction of precious metals from ores. September 28.

18,529. J. Pfeiffer. Improvements relating to apparatus for use in the manufacture of alkaline metals. September 29.

18,569. J. Harris. Improvements in apparatus for treating ores. October 1.

18,592. H. L. Sulman and F. L. Teed. Improvements in or relating to the extraction of precious metals from their ores. October 1.

18,844. R. Stone. Improvements in the manufacture and treatment of iron, steel, lead, copper, tin, zinc, and similar materials. October 4.

18,919. B. Talbot. Improvements in the manufacture of steel. Complete Specification. Filed October 5. Date applied for March 23, 1894, being date of application in United States.

18,939. J. Y. Johnson.—From N. Basset and W. de Baranoff, France. A process for the treatment of either natural or artificial clays or silicates containing aluminium. October 5.

19,091. S. Trivick. Improvements in and relating to the purification of iron and steel. October 8.

19,303. W. Hammond. An improvement in various fire-bricks and blocks for heating and annealing steel, iron, or copper-wire for special manufacture and mercantile purposes. October 11.

19,394. T. Twynam. Improvements in the utilisation of purple ore and other iron oxides. October 12.

19,510. H. G. Partin. A new alloy of aluminium. October 13.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

13,696. J. B. Torres. A new or improved furnace with fixed crucible for and connected with the metallurgical and siderurgical treatment, reduction and refining of ores and metals. September 26.

21,760. S. O. Cowper-Coles and Sir B. W. Walker, Bart. Improvements relating to the deposition of metals and compounds. October 3.

22,763. G. Fisher. Combined pig-iron moulding apparatus and pig carrier for blast furnaces. October 10.

23,048. F. Watkins. A process for coating iron, steel, or other metallic plates with tin, terno, and other mixtures, by the application or use of hard paraffin or paraffin wax, ozokerite, and earth wax, or a combination of either the above substances, by themselves or in combination with palm oil or palm oil mixtures. October 10.

23,636. T. Hampton. Improvements in the manufacture of armour plates and in ingots therefor. October 10.

1894.

4199. H. W. Gabbett-Fairfax, and W. Beardmore. Improved method of and apparatus for hardening or tempering steel plates and other articles. October 3.

10,478. T. W. Walker. An improved method of preparing iron or steel blooms or billets to be used in guide and other small mills. October 10.

## XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

## APPLICATIONS.

17,741. W. P. Thompson.—From A. Lessing, Germany. Improvements in or relating to galvanic batteries. September 18.

18,172. J. J. Maclean. Improvements in and apparatus for the extraction of gold by electrolysis. September 25.

18,202. H. V. Coad. Improvements in and connected with primary batteries. September 25.

18,288. C. Riordon. Improvements in secondary or storage batteries. Complete Specification. September 26.

18,809. F. King. Improvements in or connected with secondary or electric storage batteries. October 4.

18,814. B. A. Balasny. Improvements in electric batteries. October 4.

19,150. W. H. Beck and C. R. Fletcher, United States. Improvements in the method of and apparatus for the electro deposition of metals. October 9.

19,423. J. H. Dunn. Improvements in the construction of retorts or furnaces for the production of gases by the use of electricity. October 12.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

20,975. J. A. S. Gregg. Improvements in voltaic batteries. October 10.

23,478. A. Coehn. Improvements relating to the electrolytic preparation of oxygen and the halogens, and to the simultaneous production of electrodes. October 10.

1894.

13,377. P. Jensen.—From H. C. F. Stormer. Improvements in processes and apparatus for electrolytically treating salts in solution or in molten state. September 26.

14,634. C. E. Buell. Galvanic battery. October 3.

16,002. H. A. House, H. A. House, jun., and R. R. Symon. Improvements in apparatus for refining metal by electrolysis. September 26.

16,425. D. Young.—From The Hess Storage Battery Co. Improvements in electric accumulators or storage batteries. October 10.

## XII.—FATS, OILS, AND SOAP MANUFACTURE.

## APPLICATIONS.

17,860. J. K. Hill. Improvements in the manufacture of soap and glycerine. September 20.

18,207. A. J. Inston. Improvements in recovering grease from waste suds which have been used in washing wool, hair, or other fibre. September 25.

18,422. S. Rosenblum and F. L. Bartelt. An improved washing powder. September 28.

18,891. R. Armstrong. Improvements in detergent compounds. October 5.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

18,767. F. B. Aspinall, R. W. Hoar, and G. H. Wise. Improvements in bleaching, sweetening, and purifying oils and fats. October 10.

24,556. J. V. Ruymbeke. Process of distilling glycerine and similar liquids, and of treating the residuum obtained after distilling glycerine. October 10.

1894.

9526. A. W. Winter. See Class XVIII. A.

15,228. J. O. Klmsch. Improvements relating to the manufacture of soaps. October 17.

## XIII.—PAINTS, PIGMENTS, VARNISHES, RESINS, INDIA-RUBBER, Etc.

## APPLICATIONS.

17,630. K. Ammann. Improvements in washing blue. Complete Specification. September 17.

17,662. R. Hingston and J. P. Wernegreen. An improved anti-fouling composition for the prevention of marine growth in or on wood or iron. Complete Specification. September 17.

17,740. J. Morris. Improvements in or relating to the production of crystals or formation of oxide chiefly for decorative purposes. September 18.

17,747. E. W. Oliver. Improvements in paint. September 18.

18,269. J. Schmid. Improved mass as substitute for caoutchouc and process for manufacturing same. September 26.

18,906. P. Mercier. A new composition with india-rubber. October 5.

19,363. G. Rockliffe. A new anti-corrosive and non-fouling composition. October 11.

19,469. J. Noad. Improvements in blacking and other leather-dressing compositions. October 13.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

19,115. R. G. Bennett. Improvements in varnish. October 17.

20,234. P. A. Newton.—From A. Nobel. Improvements in artificial india-rubber. October 3.

20,239. J. H. Noad and S. Z. de Ferranti. Improvements in the manufacture of white lead. October 3.

21,292. A. Patrick. See Class IX.

23,028. E. M. Desprez. A new elastic material or manufacture composed chiefly of gutta-percha, india-rubber, or other analogous substances, and the application of the same to various useful purposes. October 17.

24,356. H. H. Lake.—From A. C. Girard and E. A. G. Street. An improved manufacture of writing pencils. October 17.

1894.

9823. D. Coventry. An improved composition or colour for shading glass on conservatories, or for similar purposes. October 3.

## XIV.—TANNING, LEATHER, GLUE, AND SIZE.

## APPLICATIONS.

18,262. J. Baird. A novel process or means for improving the colour of raw or tanned skins, hides, and leathers, and in the employment of an ingredient therewith. September 26.

19,427. R. Ergang. Improvements in machinery or apparatus for dyeing skins. October 12.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

22,849. W. L. Jackson. An improvement in softening and cleansing hides. September 36.

1894.

11,426. P. C. Hewitt. Improvements in processes and apparatus for cooling glue and forming it into sheets. September 26.

13,369. P. C. Hewitt. Improvements in clarifying or removing impurities from glue and other substances. September 26.

## XVI.—SUGARS, STARCHES, GUMS, Etc.

## APPLICATIONS.

17,744. L. I. N. Norman. Improvements in the manufacture of brewing syrup. September 18.

17,976. W. P. Thompson.—From H. A. J. Manoury, France. An improved method of purifying "masses cuites" and raw sugars. September 21.

18,358. H. C. E. Wilnot. Improvements in the treatment of starch or starchy matter, or crystallisable sugar, for the obtainment therefrom of products more especially suitable for use in brewing. September 27.

## XVII.—BREWING, WINES, SPIRITS, Etc.

## APPLICATIONS.

17,712. E. G. Francis. Improvements in the method of and in means for conditioning beer and other similar liquids. September 18.

17,744. L. I. N. Norman. Improvements in the manufacture of brewing syrup. September 18.

17,848. C. J. Ollagnier. Improvements in apple wine and other presses. September 19.

17,964. A. Kinder. Improvements in malt kilns. September 21.

17,965. F. W. Golby.—From J. Puybeyroux, France. A process and apparatus for distilling and rectifying alcohol. September 21.

18,014. F. W. Forbes-Ross. Improvements in or relating to brandy, whiskey, and other spirits or liquors. September 22.

18,435. A. J. Boulton.—From A. Delhaise, Belgium. Improvements in or relating to the purification of beer. September 28.

18,638. T. R. Todd. Improved apparatus for use in brewing. October 2.

19,199. A. D. Currie. Improvements in fermenting apparatus. October 9.

19,338. W. G. Johnston and J. F. Warwick. Improvements in or relating to the treatment or preparation of yeast. October 11.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

19,843. W. S. Squire. Improvements in the manufacture of yeast. September 26.

21,332. J. Heron. Improvements in the manufacture of compounds suitable for the production of ginger beer, herb, or botanic beers, or other fermented beverages. September 26.

23,846. F. Faulkner and J. E. J. Johnson. Improved manufacture or production of extracts from malted grain. October 17.

1894.

2889. G. G. Cave. Improvements in the treatment of yeast. October 10.

### XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

#### APPLICATIONS.

##### A.—Chemistry of Foods.

17,676. J. C. Benit. Improvements in preserving milk and cream. September 17.

18,133. E. Edwards.—From R. Luders, Germany. Improvements in the process of and appliances for sterilising and keeping sterilised milk in infant's feeding bottles. September 24.

18,143. W. Paasch. Improvements in pasteurising apparatus for milk, cream, or the like. Complete Specification. September 24.

18,285. G. Gaertner. Process for reducing the proportion of caseine contained in milk, and regulating simultaneously the proportion of fat. September 26.

18,535. J. Gill. Improvements in furnaces for destroying towns' refuse and the like. October 1.

19,037. J. Pumphrey. Improvements in means for preventing the destruction of food and similar substances by excessive heat. October 8.

19,064. E. Leslie. Improvements in milk sterilizers. October 8.

19,309. T. T. Chard. A new and improved phosphate food for horses. Complete Specification.

19,340. R. G. Nash. Improvements in the preservation of milk. October 11.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1894.

9526. A. W. Winter. Improvements in compound edible fats. September 26.

##### B.—Sanitary Chemistry.

18,765. W. E. Adeney and W. K. Parry. Improvements relating to the employment of aluminium, sulphate, and like clarifying agents in the purification of sewage. October 3.

19,482. H. L. Hinnell. Improvements in the construction of filter beds for the filtration of liquids from sewage sludge, mud, bleachers' dyers', tanners', and manufacturers' refuse, and in apparatus or arrangements for use therein and covering the same. October 13.

#### COMPLETE SPECIFICATION ACCEPTED.

1894.

15,000. R. A. Chesebrough. Improvements in the method of cremating garbage and other refuse. September 26.

### XIX.—PAPER, PASTEBOARD, Etc.

#### APPLICATION.

17,905. J. Baier. Improvement of imitation whalebone. September 20.

#### COMPLETE SPECIFICATION ACCEPTED.

1894.

14,384. H. O. Band. Improvements in the manufacture of parchment. October 3.

### XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

#### APPLICATIONS.

18,509. M. Otto and A. Verley. Manufacture of ethers of the alcohols contained in natural essences and of their corresponding alcohols. Complete Specification. September 29.

19,263. G. Braun. Improved method of recovering solvents used in the manufacture of pyroxylin products. October 10.

19,342. L. Lederer. Production of anilides of phenox-acetic acid and their homologues. October 11.

#### COMPLETE SPECIFICATION ACCEPTED.

1894.

15,171. P. P. Monnet. A process for the manufacture of a scent essence termed "Rhodinol." September 26.

### XXI.—PHOTOGRAPHIC PROCESSES AND MATERIALS.

#### APPLICATIONS.

17,758. V. Mathieu. A process for photographing in colours. September 18.

18,282. C. Beadle. A process for sensitising photographic paper. September 26.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

21,686. W. Fairweather.—From J. Kost. A reflecting and ventilating device or apparatus for photographic exposure by the magnesium light. October 17.

1894.

14,161. J. Joly. Improvements in or relating to photographing in colours. October 3.

## XXII.—EXPLOSIVES, MATCHES, Etc.

## APPLICATIONS.

17,949. H. J. Koster. Improvements in the manufacture of matches. September 20.

17,960. A. Brock. An improved pyrotechnic compound. September 21.

17,994. H. S. Maxim. Improvements relating to smokeless explosives. September 21.

18,156. G. H. Hosie. Improvements in and relating to the manufacture of nitro-cellulose, oxy-nitro-cellulose, and hydro-nitro-cellulose. September 25.

18,496. F. W. Bawden. An improved explosive. September 29.

18,682. H. Maxim. Improvements in fulminating compounds. Complete Specification. October 2.

18,683. R. C. Schupphaus. Improvements in the process of nitrating cellulose. Complete Specification. October 2.

18,921. O. Imray.—From F. C. Glaser and Co., Germany. Manufacture of a new explosive. October 5.

19,098. A. G. Brookes.—From W. J. Smith, United States. Improvements in exploders or fuses for projectiles. Complete Specification. October 9.

19,299. G. Hübner. Improvements in smokeless explosives. Complete Specification. October 11.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

20,467. P. A. Newton.—From A. Nobel. Improvements in fuses for mining and similar purposes. October 17.

23,416. K. C. Edmunds. Improvements in explosives. October 3.

23,579. H. R. von Dahmen. An improved manufacture of explosives. October 10.

1894.

15,887. G. J. Buechert. Explosive compounds. September 26.

## XXIII.—ANALYTICAL CHEMISTRY.

## COMPLETE SPECIFICATION ACCEPTED.

1893.

23,039. R. W. Woosnam and the Dairy Supply Co., Lim. Improvements in apparatus specially suitable for use in estimating the amount of fat in milk and other substances. September 26.

### The Society of Chemical Industry.

#### Past Presidents:

Sir H. E. Roseoe, M.P., LL.D., V.P.R.S. ....	1881—1882.
Sir Frederick Abel, Bart., D.C.L., F.R.S. ....	1882—1883.
Walter Weldon, F.R.S. ....	1883—1884.
W. H. Perkin, Ph.D., F.R.S. ....	1884—1885.
E. K. Muspratt.....	1885—1886.
David Howard.....	1886—1887.
Prof. James Dewar, F.R.S. ....	1887—1888.
Ludwig Mond, F.R.S. ....	1888—1889.
Sir Lowthian Bell, Bart., F.R.S. ....	1889—1890.
E. Rider Cook.....	1890—1891.
Prof. J. Emerson Reynolds, M.D., D.Sc., F.R.S.	1891—1892.
Sir John Evans, K.C.B., F.R.S. ....	1892—1893.
E. C. C. Stanford.....	1893—1894.

### COUNCIL FOR YEAR ENDING JULY, 1895.

*President:* Prof. T. E. Thorpe, F.R.S.

#### Vice-Presidents:

Sir F. A. Abel, Bart., F.R.S.	Sir John Evans, K.C.B., F.R.S.
Horace T. Brown, F.R.S.	E. K. Muspratt.
H. Brunner.	Dr. W. H. Perkin, F.R.S.
John Calderwood.	John Spiller.
Chas. Dreyfus.	E. C. C. Stanford.
Dr. A. Dupré, F.R.S.	Prof. W. A. Tilden, F.R.S.

#### Ordinary Members of Council:

Frank Clowes, D.Sc.	Ivan Levinstein.
Thos. Fairley.	Manning Prentice.
C. A. Fawcitt.	G. N. Stoker.
Prof. G. G. Henderson, D.Sc.	Wm. Thorp, B.Sc.
David Howard.	T. Tyrer.
Prof. A. K. Huntington.	Frank Wilson.

With the Chairmen and Secretaries of Sections.

#### Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

#### Honorary Foreign Secretary:

Ludwig Mond, F.R.S.

*General Secretary:* Charles G. Cresswell.

*Offices:* Palace Chambers, 9, Bridge Street, Westminster, S.W.

### NOTICES.

Notice is hereby given that, in accordance with the alterations in Rule 27 sanctioned at the Annual General Meeting in Edinburgh, all new members elected after January 1st next, and also those elected since the last Annual General Meeting, who do not pay subscription for 1894, will be required to pay an entrance fee of one guinea. In accordance with the same rule the Life Composition Fee will be 20*l.*, instead of 15*l.* as heretofore, after the 1st January next.

## BANKERS' ORDERS.

For the convenience of Members, the Treasurer has arranged with the Bankers of the Society that they shall collect subscriptions from Bankers in town and country; and Members, who have not already done so, are invited to fill up and sign the Banker's Order enclosed with the December number of the Journal, which should then be sent to the Honorary Treasurer, Mr. E. Rider Cook, East London Soap Works, Bow, E.

Authors of communications read before the Society, or any of its Local Sections, are requested to take notice that under Rule 41 of the bye-laws, the Society has the right of priority of publication for three months of all such papers. Infringement of this bye-law renders papers liable to be rejected by the Publication Committee, or ordered to be abstracted for the Journal, in which case no reprints can be furnished to the author.

Notice is hereby given, for the information of members and advertisers, that the advertisement columns of this Journal have been contracted for by Messrs. EYRE and SPOTTISWOODE, the Society's printers and publishers, to whom all communications respecting them should be addressed.

Notice is hereby given that the next List of Members will contain the professions or business occupations of the Members of the Society. Any Member who desires to confirm or alter his description as given before election should communicate with the General Secretary.

Foreign and Colonial Members are reminded that the subscription of 25s. for 1895, payable on January 1st next, should be sent in good time to the Treasurer, in order to ensure continuity in the receipt of the Society's Journal. Any changes of address to appear in the new List of Members now in course of preparation, should reach the General Secretary not later than January 15th, 1895.

## LIST OF MEMBERS ELECTED 23rd NOVEMBER 1894.

Barden, Sam., Far Bank Farm, Shelley, near Huddersfield, glue and size manufacturer.

Bateman, R. W., 90, Cazenove Road, Stoke Newington, N., leather manufacturer.

Brook, G. Bernard, 27, Wostenholme Road, Sheffield, analytical chemist.

Brown, G. E., 79, Disraeli Road, Putney, S.W., chemist to L. & S. W. Railway Co.

Cameron, Alex., Agricultural Laboratory, 4, Lombard Court, E.C., analytical chemist.

Case, W. T., 7, Cedar Street, New York, U.S.A., chemist.

Chaloner, G. W., Niagara Works, Eagle Wharf Road, London, N., manager of chemical department.

Coblentz, Virgil, M.A., Ph.D., College of Pharmacy, 115, West 68th Street, New York, U.S.A., chemical lecturer.

Colquhoun, W., St. Mary's Chambers, Cardiff, engineer.

Coste, J. H., 69, Goswell Road, London, E.C., analytical chemist.

Court, Haywood, 67, Surrey Street, Sheffield, analytical chemist.

Diestel, Wm., 77, William Street, New York, U.S.A., dyestuff importer.

Evans, Jno. H., 71, Lambton Road, Cottenham Park, Wimbledon, analytical chemist.

Ewan, Thos., Ph.D., B.Sc., The Yorkshire College, Leeds, teacher of chemistry.

Fairechild, Sam. W., College of Pharmacy, 115, West 68th Street, New York, U.S.A., manufacturing chemist.

Fischer, Albert, c/o Messrs. Grant, 23, Billiter Street, London, E.C., journalist.

Gane, Eustace H., 79, Ann Street, New York, U.S.A., pharmaceutical chemist.

Gruencklee, Carl, c/o Messrs. Chas. Pfizer and Co., 11, Bartlett, Brooklyn, N.Y., U.S.A., chemist.

Gulliver, Geo. W., Prince Regent's Wharf, Silvertown, E., chemist.

Harden, Arthur, Ashville, Upper Chorlton Road, Manchester, lecturer in chemistry.

Hewitt, A. H., The Green Island Cement Co., Ltd., Hong Kong, China, engineer.

Jarrett, H. T., 90, William Street, New York, U.S.A., chemist.

Jenks, Robt. L., Research Department, Imperial Institute, London, S.W., chemist.

Kebler, Lyman F., B.Sc., 305, Cherry Street, Philadelphia, Pa., U.S.A., manufacturing chemist.

Marten, T. Tremills, 45, Stapleton Hall Road, Stroud Green, N., analytical chemist.

Moszczenski, J. von, 133, South First Street, Brooklyn, N.Y., U.S.A., analytical and consulting chemist.

Oakes, Geo. A., Bloomfield, N.J., U.S.A., woollen mill owner.

Parker, Chas. E., c/o Seabury and Johnson, East Orange, N.J., U.S.A., chemist.

Parker, J. Gordon, Leather Department, Yorkshire College, Leeds, chemist, Ph.D.

Reid, Walter C., 20, Percy Park Road, Tynemouth, manufacturer.

Rettie, Theodore, B.Sc., Cassel Gold Extraction Co., 13, W. Scotland Street, Kinning Park, Glasgow, metallurgical chemist.

Scott-Smith, G. E., 67, Surrey Street, Sheffield, analytical chemist.

Smith, Bernard E., 73, Westmoreland Road, Newcastle-on-Tyne, alkali works inspector.

Taylor, Albert, Technical School, Stockport, lecturer in chemistry and dyeing.

Taylor, G. Midgley, 27, Great George Street, Westminster, S.W., analytical chemist.

Tipler, Fred. C., 7, Richard Street, Crewe, analytical chemist.

Traphagen, Frank W., Ph.D., Montana Agric. Expt. Station, Bozeman, Mont., U.S.A., chief chemist.

Weston, Robt. S., B.Sc., Cinclare Central Factory, Brusley Landing P.O., La., U.S.A., chemical director of sugar factory.

Woltereck, Dr. H. C., 35, Wall Street, New York, U.S.A., consulting chemist.

## CHANGES OF ADDRESS.

Anselm, Dr. F., c/o Manchester; c/o Actien Gesellschaft für Anilin Fabrikation, Treptowerbrücke 33, Berlin, S.O.

Bamber, H. K. G.; Journals to Hill Road, Dovercourt, Harwich.

Barrie, D. McL., 1/o Johannesburg; retain Journals until further notice.

Chadwick, L. N., 1/o Elsham Road; 30, Avonmore Gardens, Kensington, W.

Clark, Dr. Franklin S., 527, Madison (not Madeira) Avenue, New York, U.S.A.

Collins, H. S., 1/o Berners Street; c/o Davy, Yates, and Hucks, 61, Park Street, Southwark, S.E.

Comer, H., 1/o Jersey City; 1, Broadway, New York, U.S.A.

Edgell, G. E., 1/o Queen's Terrace; 2, Gladstone Terrace West, Gateshead.

Elworthy, H. S., 1/o 1; 19, Hill Road, Bandra, Bombay.

Ford, J. B., jun.; Journals to Michigan Alkali Co., Wyandotte, Mich., U.S.A.

Galt, Hugh A.; Journals to Michigan Alkali Co., Wyandotte, Mich., U.S.A.

Greenway, T. J., 1/o 8th Avenue; Harrow Road, East Adelaide, South Australia.

Hall, Jno. A., 1/o Manchester; Victoria Chemical Works, Victoria, British Columbia.

Jones, W. Norris, 1/o Weston; The Lancashire Metal Works, Widnes.

Krause, O. H.; Journals to c/o American Sugar Refining Co., Jersey City, N.J., U.S.A.

Lawson, Dr. T. A., 1/o 15; 111, Alexandra Road, N.W.

Loewenthal, Dr. R., 1/o Steglitzerstrasse; Magazinstrasse 12a, Berlin, O.

McVitie, R., 1/o Malton; The St. Andrew Biscuit Works, Edinburgh.

Paul, Dr. Benj. H.; Journals to Parkside, Kingston Vale, Putney, S.W.

Rae, Geo., 1/o Widnes; c/o Mrs. Dalrymple; 599, Great Eastern Road, Glasgow.

Ramsay, W., 1/o Dolgelly; 15, Lime Grove, Seaforth, Liverpool.

Rhodes, Jos., 1/o Belfast; Glengowan Printworks, Caldercruix, *via* Airdrie, N.B.

Seryngeour, A., 1/o Box 20; c/o African Gold Recovery Co., Box 1283, Johannesburg, S.A.R.

Steel, R. Elliot, 1/o Plymouth; Northampton and County School, Northampton.

Taylor, Ambrose; Journals to Madron, Penzance, Cornwall.

Utsumi, S., 1/o Hakodate; c/o "Gakushikwai," Imperial University, Hongo, Tokio, Japan.

Wade, W. L., 1/o Nine Elms Lane; Staines Linoleum Works, Staines.

Winstanley, H., 1/o Caldercruix; Cale Green Villa, Stockport.

Zinkeisen, Dr. W., 1/o London; 225, George Street, Glasgow.

#### CHANGE OF ADDRESS REQUIRED.

Wood, Jas.; 1/o 22, Plashet Road, Plaistow, E.

## London Section.

THE CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE, W.

Chairman: B. E. R. Newlands.

Vice-Chairman: C. C. Hutchinson.

#### Committee:

E. J. Bevan.	S. Riedel.
W. G. Blauden.	A. Gordon Salamon.
E. Grant Hooper.	A. Shearer.

R. Messel.	T. Tyrer.
H. de Moshthal.	Frank Wilson.
E. O'Neill.	Lewis T. Wright.

Hon. Local Secretary: John Heron.

74, North Side, Clapham Common, S.W.

#### SESSION 1894-95.

Monday, December 3rd.—

Mr. E. W. Kuhn (of Paris). "The Rational Sterilisation of Alimentary Liquids."  
Dr. B. H. Atfield, M.A., D.P.H. "An Investigation of the Natural Sodium Sulphate Lakes of Wyoming, U.S.A."  
"Specimens of India-rubber, and Petroleum Oil, Varnish, and Soap," will be exhibited by Mr. Thos. Christy, F.R.S.

Meeting held Monday, November 5th, 1894.

MR. B. E. R. NEWLANDS IN THE CHAIR.

The Session for 1894-95 commenced on Monday, November 5th.

After some brief opening remarks from the new Chairman of the Section, Mr. B. E. R. Newlands, and the reading of the Minutes of the last meeting by the Secretary, Mr. Watson Smith was called upon to read the following posthumous paper by Dr. C. R. Alder Wright. He said:—

"With regard to the paper I am about to read, when our Secretary, Mr. Jno. Heron, wrote and told me Dr. Alder Wright had promised to prepare one for the autumn session of the London Section, I found that Mrs. Alder Wright was unaware that such a paper existed.

"On looking among Dr. Wright's papers however, relating to his work on the alloys, we found last of all a bundle of papers forming a rough draft, with empty spaces left for references and for two illustrations.

"Mrs. Wright then remembered how that the week before his death our friend had laboured to complete this paper, and so fulfil his promise to our Secretary and to the Section. She recalls that on finishing the paper, he seemed much exhausted, and exclaimed, 'There, I have done all I shall ever do on that subject, and now I shall take some rest.'

"Somewhat remarkable, too, are the words he wrote on the cover of the paper, 'Final Paper for the Society of Chemical Industry.'

"I have filled in the references required, and have discovered one of the figures referred to, in the Proc. Roy. Soc., but I cannot find the second, and must omit it.

"I may perhaps add that it is at the request of his widow that I have undertaken to revise and to read this, Dr. Wright's, last scientific contribution.

"Probably no more fitting memorial of an eminent man of science could be imagined than that now left behind him by Dr. Alder Wright himself, in the presentation of the series of experimental essays to the Royal Society on the scientific aspects of this question of the alloys, now completed in the presentation of the paper before us on the technological and other bearings of the subject."

## THE COMPOSITION AND CONSTITUTION OF CERTAIN ALLOYS.

BY DR. C. R. ALDER WRIGHT, F.R.S.

For some years past the author has devoted a large amount of time to a laborious experimental inquiry into the subject of the relations of metals to one another as regards their mutual miscibility or solubility when rendered fluid, by heat; many of the results obtained have from time to time been communicated to the Royal Society, and abstracted from the proceedings of that Society to the pages of this Journal.\* The present paper has for its object partly to collect together and epitomise the general conclusions that may be drawn from these particular researches, so far as at present completed, and partly to discuss the subject in general; more especially since a good deal of confusion appears to exist in the minds of various writers between certain phenomena which, though allied, are really sharply distinguishable from one another; whilst a number of the statements on the subject, repeated from text-book to text-book till fossilised, are in point of fact considerably inexact.

When two metals are melted separately and the one fluid poured into the other and the whole vigorously stirred, it sometimes happens that more or less complete solidification is brought about on account of chemical action taking place between the two, resulting in the formation of a definite atomic compound which is solid at the temperature of the crucible, and is not wholly dissolved in whatever excess of either constituent may happen to be present. This solidification, however, is comparatively of rare occurrence; in any case it can always be avoided by employing a temperature sufficiently high to keep the mass perfectly liquid, in which case one of two things happens: either the two metals intermix perfectly, mutually dissolving each other so as to form a single permanent homogeneous fluid that remains uniform in character so long as the temperature is maintained high enough to prevent incipient solidification; or, they form two different liquids not miscible with one another, and separating from one another by gravitation on standing molten for a sufficiently long period; these fluids consisting respectively of the first metal containing in solution a saturating amount of the second, and *vice versa*. The two cases are precisely correlative with the behaviour of alcohol and water when intermixed at the ordinary temperature, and that of ether and water employed in proportions not outside of certain limits, *e.g.*, used in equal volumes.

In some cases the separation by gravitation only takes place slowly, notwithstanding that a notable difference in density may subsist between the two binary alloys formed; many hours or even days standing molten at an equable temperature may be requisite before approximately complete separation is effected, the two fluids forming a sort of emulsion, comparable with the minute oil globules suspended in milk, or with the persistent froth formed on shaking up ether with soap-water, or aqueous fluids containing various forms of organic matter. This circumstance has in some instances led to the erroneous belief that a given class of metals could be permanently mixed together in all proportions when molten, forming in all cases a homogeneous liquid, when in point of fact only metallic froths or milks are formed, consisting of two different intimately mixed alloys. In particular, aluminium and bismuth and aluminium and cadmium have been long described as being freely miscible, whereas the contrary is the actual fact.

On the other hand, if a homogeneous fluid mixture of two metals be gradually cooled down, a point is sooner or later arrived at when solid matter begins to form. In some cases, and with certain proportions of the constituents of the mixture, the temperature at which solidification begins, remains constant until the whole has solidified; this only happens when a definite compound of metals in atomic proportions is produced, no excess of either constituent being present. In general, the temperature at which solidification commences is higher than that observed later on, when more solid matter has formed, especially towards the end of the operation, the portions last solidifying often requiring a considerable reduction in temperature before they become solid. The "incipient solidification point,"\* or temperature at which solid matter first begins to form, is sometimes referred to as the "freezing point" of the mixture, but the term is an undesirable one in this connection, it being preferable to restrict the term "freezing point" to that definite fixed temperature (under constant conditions as to pressure) at which a single chemical substance (*e.g.*, water, or a definite atomic compound of metals, *e.g.*, SbAl) passes from the liquid to the solid state, this temperature remaining constant until the whole mass has solidified; whereas the "incipient solidifying point" refers to a variable temperature, *viz.*, that observed at the earliest stage of the passage from the liquid to the solid condition of certain of the constituents of a fluid mixture, leaving still fluid a "mother-liquor" of composition different from that of the solidified portion; this temperature being not only more or less markedly higher than the temperature of solidification of the last portions of the mass, but being also a value which varies even for the same constituents according to their relative proportions. Thus the beautiful experiments of Neville and Heycock (C.S.J. Trans. 1889, 666; 1890, 376; 1892, 888) have shown that when comparatively minute amounts of one metal are dissolved in a large quantity of another, the masses exhibit a series of incipient solidification points higher or lower than the true freezing point of the predominating metal by amounts closely proportionate to the weights of the other metal added; a rise being exhibited in those cases where the two metals are capable of combining chemically together, forming compounds of higher melting point than that of the predominating metal (*e.g.*, Sb dissolved in Bi or in Sn, or Ag dissolved in Cd); whilst in other cases a fall is observed, from the magnitude of which conclusions may be drawn on Raoult's principle as to the molecular aggregation of the dissolved metal. Then the effect of adding a little zinc to a large mass of bismuth or lead, is to produce a depression in the value of the incipient solidification point of the mixture below the fixed freezing point of pure lead (or bismuth) nearly proportionate to the quantity added; so that an "atomic fall" of about 1.5° in the first case and 5.0° in the second is observed; values comparable in magnitude and identical in sign with those observed when metals are employed miscible in all proportions with bismuth or lead, *e.g.*, Cu, Ag, Sn, Cd, Au. Aluminium is so slightly soluble in molten bismuth, cadmium, or lead, as to render it difficult to obtain any reliable measurements; but at any rate nothing abnormal is noticeable in its effect on these metals as compared with that in tin, with which it is miscible in all proportions when molten (Heycock and Neville, *loc. cit. supra*).

\* When a mixture of different substances in the fluid condition is slowly cooled, an immersed delicate thermometer indicates a gradually decreasing temperature until solid matter begins to form. At this point a slight rise in temperature is usually manifest on account of the mixture having become more or less superheated before the solid matter actually separated, the amount of this rise depending on the nature of the mixture, and also on the details of construction of the thermometer, its capacity for heat as compared with that of the mixture, and the amount of latent heat rendered sensible during the separation of solid matter. With a sufficiently large mass of material and proper arrangements to avoid too rapid chilling by radiation, &c., a practically constant temperature is thus indicated for some considerable period (often from 30 to 100 seconds or even more), during which the loss of heat by conduction and radiation is balanced by the evolution of heat during solidification; after this the thermometer begins to fall again. The nearly constant temperature observed during this period is usually taken as the "incipient solidification point"; the method of observation has long been well known technically in connection with the valuation of tallow, &c., as "Dallien's process" (Mon. Sci. Paris, 1868).

The phenomenon of segregation of solid matter from a liquid mass on cooling, such solid matter being different in composition from the portion still remaining liquid, is obviously wholly different from the phenomenon of want of miscibility between two different metallic fluids where no solid matter at all is present; but in many cases the distinction has not been appreciated by writers on the subject, and notable confusion and want of exactitude have accordingly resulted. As an example of this, even in so carefully revised a work as Morley and Muir's dictionary, now just published, this statement is made (article "Copper"), that "copper and lead melted together at a red heat form alloys; but the fused mass tends to separate into two layers, the upper containing much Cu and little Pb, and the lower much Pb and little Cu." On careful examination, however, this statement is found to be incorrect; so long as the temperature is high enough to keep the whole mass fluid the fused mass does not separate into two layers any more than does a mixture of alcohol and water; but at a somewhat lowered temperature solid matter begins to separate, rendering the mass more or less pasty; this solid matter is either copper alone or copper combined with but little lead, forming a difficultly fusible alloy, just as chilled alcohol and water will allow solid crystals to form, consisting either of ice alone or possibly of a cryohydrate of alcohol. In the case of copper and lead the solid matter thus separating floats up to the top of the remaining fluid matter in which the lead is concentrated; the degree of separation depends on the rate of cooling; but the tendency towards segregation is so marked that it is almost impossible to cool a mass of 30 or 40 grms. of mixed metals (in about equal proportions) without finding a measurable excess of copper in the top layers, and of lead in the bottom ones.

The preceding remarks respecting binary metallic mixtures for the most part equally apply to ternary, and more complex alloys. These, when rendered completely fluid by heat, are divisible into two classes, *viz.*, those which form single homogeneous liquids and those which do not, but give rise to two (or possibly more) liquids not miscible together inside of certain limiting proportions. When the temperature is reduced so that solidification commences, as a general rule segregation of constituents takes place, the portion first separating in the solid form having a composition different from that of the portion still remaining liquid.

The spontaneous separation from one another of the constituents of a fluid mixture of metals is obviously a matter of considerable importance in technical operations where alloys are employed for castings, or are prepared by fusing together the constituents; whether such separation be brought about in virtue of the immiscibility of certain metallic mixtures produced on melting together the constituents, or by segregation in the solid form of certain of the constituents or definite compounds thereof in the act of cooling, in either case a want of homogeneity in the cast mass is apt to be developed which may be of serious moment, especially in the case of ingots, &c. intended to be subsequently wrought by mechanical processes. As regards segregation during the act of solidification, it is well known that the larger the mass and the more slowly the cooling is conducted, in general the more likely is the segregating action to come measurably into play; and various devices are in use in foundries to minimise the action in different cases. But as regards the formation of immiscible alloys which separate from one another whilst still fluid, very little accurate knowledge of the limits within which such separative actions occur was extant at the time of the commencement of the author's experiments on the subject; the result of these researches, however, has been to define these limits with considerable precision in the case of a very considerable number of binary and ternary mixtures of the principal metals of ordinary occurrence. In order to distinguish from one another mixtures of metals which remain homogeneous whilst molten even on long standing, and mixtures which divide into two (or possibly more) different fluid alloys on standing molten for a sufficient time, the terms "real alloys" and "ideal alloys" may be conveniently applied to the two classes respectively, this nomenclature having been

originally proposed by Sir G. G. Stokes\* to distinguish from one another certain kinds of ternary metallic mixtures.

In order to examine thoroughly into the general question of mutual miscibility or otherwise of metals, and to decide how far the statements ordinarily found in the text-books are correct or not, it was found necessary to examine in detail the behaviour of each metallic combination separately. This is a somewhat greater task than at the first blush would appear to be the case; for even when the number of metals is limited to the following nine, the total number of possible combinations is a large one. Out of the nine metals Pb, Bi, Zn, Al, Sn, Ag, Cu, Cd, Sb, no less than 502 different alloys may be formed; by taking them two at a time 36 combinations result; if three at a time, 84; if four at a time, 126; and so on, as indicated in the following table:—

No. of Combinations possible.				
No. of Constituent Metals in Mixture.	Constituent Metals miscible together in all Proportions under all Circumstances so long as Temperature high enough to maintain perfect fluidity.	Product divides into at least two immiscible Alloys when Constituents are in Proportions inside of certain Limits.	Total.	
2	31	5	36	
3	55	29	84	
4	55	71	126	
5	31	95	126	
6	9	75	84	
7	1	35	36	
8	None	9	9	
9	None	1	1	
182		320	502	

In addition to the binary and ternary combinations of these nine metals (and some few more complex mixtures), various alloys have also been experimented with to some extent containing other metals, although their peculiar physical qualities more or less interfere with the systematic determination of limits of miscibility where fusion for lengthened periods is requisite; thus the volatility of mercury and arsenic prevents their convenient use at moderately elevated temperatures, whilst the high oxidisability of sodium and potassium renders special appliances necessary in their case. Again, the high fusing points of iron, nickel, platinum, and others, and the costliness of gold and of the rarer metals, prevent their being freely employed in the simple way practicable with the nine above mentioned. In several instances indications have been obtained that interesting results would follow the extension of the systematic experiments made so far, to include a larger number of metals.

#### Binary Alloys.

On systematically examining the 36 pairs of metals obtainable from the above list of nine, from the point of view of forming "real" alloys only under all conditions, or of giving rise to "ideal" alloys when mixed in proportions inside of certain limits, and allowed to stand molten for a considerable length of time, it at once becomes manifest that in several instances the statements current in the text-books are erroneous. For instance, it is ordinarily stated (apparently on the authority of Tissier) that fused antimony and aluminium will not intermix. This, however, is not the case; when fused aluminium and antimony are stirred together in certain proportions a mixture of solid and fluid matter results: the former has been shown

\* Proc. Roy Soc. 49, 1890-91, 179.

by the author to consist essentially of a difficultly fusible\* compound of antimony and aluminium indicated by the formula  $SbAl$ ; whilst the liquid part consists of a solution of this compound in whichever of the two constituents may be present in excess. If, however, the temperature be raised sufficiently high to render the mass fluid, a perfectly homogeneous liquid results which shows no tendency to separate into two different fluids, even on standing at rest molten upwards of eight hours. Again, as above stated, copper and lead are described in various text-books as not mixing together perfectly; but the fact is that so long as the mixture is kept hot enough to be perfectly fluid a single homogeneous liquid alloy is formed. Similar remarks apply to copper and bismuth. On the other hand, according to the text-books, aluminium and bismuth unite together, forming useful alloys.

The following experiments may be quoted as examples illustrating the kind of figures obtained by operating in one or other of these ways, the alloys examined being accordingly regarded as not exhibiting the phenomenon of separation into two different binary mixtures of metals, whilst molten.†

Mixture of about one part ZINC and two parts TIN, kept Fused for Seven Hours and cooled quickly.

—	Zinc.	Tin.
Top layer of compound ingot .....	31.37	68.6
Bottom " " .....	31.13	68.87
Difference $\pm 0.24$		

Mixture of about equal Weights of TIN and CADMIUM, Fused for Six Hours and quickly cooled.

—	Tin.	Cadmium.
Top layer.....	49.37	50.63
Bottom layer .....	49.69	50.31
Difference $\pm 0.32$		

Mixture of about two parts CADMIUM and one of COPPER, Fused Six Hours and quickly cooled.

—	Cadmium.	Copper.
Top layer.....	66.20	33.80
Bottom layer .....	66.35	33.65
Difference $\pm 0.15$		

Mixture of about equal Weights of BISMUTH and COPPER, Fused Four Hours and Sampled by "SPOON and PIPETTE."

—	Bismuth.	Copper.
Top layer.....	49.51	50.49
Bottom layer.....	49.76	50.24
Difference $\pm 0.25$		

\* This Journal, 1892, 349. Prof. Roberts-Austen has subsequently determined the "solidifying point" of this compound by means of the Le Chatelier pyrometer, and found it to be practically identical with that of pure gold,  $1045^{\circ} C$ , or upwards of  $350^{\circ} C$  higher than the melting point of the highest fusing constituent. So large a rise in fusing point is a phenomenon *anterioris* amongst compounds of metals with one another, although not unknown to a lesser extent: thus Roberts-Austen (See also this Journal, 1893, 810) has shown that aluminium and gold combine to form the compound  $Al_2Au$ , which solidifies at  $1,065^{\circ}$ — $1,070^{\circ}$  or upwards of  $30^{\circ}$  above the solidifying point of the least fusible constituent.

† The existence of the atomic compound  $SbAl$  has also been confirmed by D. A. Roche (Monit. Scient., 1893, 269; this Journal, 1-93, 840).

\* The percentages are calculated throughout on the sum of the weights of the two metals found by analysis as 100.

In these instances, as in most others, the differences in composition between the top and bottom layers do not lie outside the limits of experimental error; in some few cases, however, indications were observed of a slight tendency for the lighter alloy to float up and the heavier to descend: thus, for example:—

Mixture of about three parts TIN to one of ALUMINIUM, Fused Six Hours and quickly cooled.

—	Aluminium.	Tin.
Top layer .....	22.36	77.64
Bottom layer.....	21.39	78.61
Difference $\pm 0.97$		

Inasmuch as such differences between top and bottom were never great, and also varied from experiment to experiment, they were considered to be more probably due to incipient segregation during solidification, than to the formation of true "ideal" alloys, incapable of permanent existence, and dividing into two entirely different real alloys.

Operating in one or other of the ways above described, the following 31 pairs of metals were ultimately found to produce "real" alloys, no matter what their relative proportions: *i.e.*, no natural difference was discernible between the uppermost and lowest layers of the mass obtained by melting together, thoroughly intermixing by stirring, and allowing to remain at rest molten for some time (often several hours):—

Aluminium antimony.	Bismuth tin.
" copper.	Cadmium copper.
" silver.	" lead.
" tin.	" silver.
" zinc.	" tin.
Antimony bismuth.	" zinc.
" cadmium.	Copper lead.
" copper.	" silver.
" lead.	" tin.
" silver.	" zinc.
" tin.	Lead silver.
" zinc.	" tin.
Bismuth cadmium.	Silver tin.
" copper.	" zinc.
" lead.	Tin zinc.
" silver.	

In several cases definite atomic compounds of the constituents of the above binary alloys appear to exist, so that when a molten mass containing the constituents in suitable proportions is allowed to cool slowly, the compound tends to separate from whatever excess of either constituent may be present: if the compound fuse at a higher temperature than the constituent present in excess (as, for example, the compound  $AlSi$ ), the solid matter first separating consists of the compound, leaving as mother-liquor a solution of the compound in excess of the more fusible constituent; if, on the other hand, the constituent present in excess have a higher melting point than the compound, this constituent separates first, the mother-liquor consisting of the more fusible compound, together with more or less of the less fusible constituent dissolved therein.

On the other hand, the following five pairs\* were found to yield only ideal alloys when mixed in proportions inside of the limits under-mentioned:—

Aluminium bismuth.
" cadmium.
" lead.
Bismuth zinc.
Lead zinc.

\* The immiscibility of lead and zinc has long been known, notwithstanding that in certain books of reference they are still described as alloying "in all proportions" (*e.g.*, Morley and Muir's dictionary, article "Lead Alloys," Vol. III., 125). More than 30 years ago their limits of mutual solubility were approximately determined by Matthiessen and v. Bose (Proc. Roy. Soc. XI., 430).

As the temperature rises, the limits between which ideal alloys are formed with these five pairs, become narrowed; precisely the same thing is noticed with analogous ternary and more complex ideal alloys (*vide infra*).

#### LIMITS FOR ALUMINIUM BISMUTH.

At near 870° C. between  $\left\{ \begin{array}{l} \text{Bi} = 99.72 \\ \text{Al} = 0.28 \end{array} \right\}$  and  $\left\{ \begin{array}{l} \text{Bi} = 2.02 \\ \text{Al} = 97.98 \end{array} \right\}$ .

#### LIMITS FOR ALUMINIUM CADMIUM.

At near 750° C. between  $\left\{ \begin{array}{l} \text{Cd} = 99.78 \\ \text{Al} = 0.22 \end{array} \right\}$  and  $\left\{ \begin{array}{l} \text{Cd} = 3.39 \\ \text{Al} = 96.61 \end{array} \right\}$ .

#### Ternary Alloys.

Out of the 84 combinations obtainable by taking the nine metals chiefly experimented with, three at a time, 55 are "real" under all circumstances, but the remaining 29 form "ideal" alloys when mixed in proportions lying outside of certain limits which are conveniently expressible as the boundary of a particular area inside a triangle (*vide infra*).

Theoretically, three different classes of ideal ternary alloys may be distinguished; but as regards the particular metals examined, one of these classes is unrepresented amongst the various combinations thence derivable. The three classes may be distinguished thus: let the three constituents be respectively A, B, and C; then, by taking them two at a time, three pairs are obtainable, A B, A C, and B C. In the first class only one pair, A B, is incapable of mixing in all proportions. In the second class two of the pairs, A B, A C, are incapable of mixing in all proportions. In the third class all three pairs are similarly incapable. The three classes may accordingly be thus tabulated:—

	Immiscible Pairs.	Miscible Pairs.
Class 1	A B	A C, B C
Class 2	A B, A C	B C
Class 3	A B, A C, B C	Nil

The class of which no representative is found amongst the 29 combinations as above, is the third; 23 combinations of the first class, however, and six of the second class, can be formed from the nine original metals, *viz.*:—

#### CLASS I.

A.	B.	C.
Pb	Zn	Either Sn, Ag, Sb, Cu, or Cd (5)
Bi	Zn	Do. do. (5)
Pb	Al	Either Sn, Ag, Sb, or Cu (4)
Bi	Al	Do. do. (4)
Cd	Al	Either Sn, Ag, Sb, Cu, or Zn (5)
		Total 23

#### CLASS II.

A.	B.	C.
Either Zn or Al	Bi	Pb (2)
Either Bi or Pb	Al	Zn (2)
Al	Either Bi or Pb	Cd (2)
		Total 6

[1861]; at the same time the corresponding limits for bismuth and zinc were also approximately deduced. Deville showed many years ago that aluminium and lead were immiscible. As previously stated, the immiscibility of aluminium and bismuth and of aluminium and cadmium was apparently unknown until recently pointed out by the author (Proc. Roy. Soc. 52, 19; this Journal, 1892, 492).

Ternary ideal alloys of the first and second classes, in practice, always divide into pairs of real alloys. A ternary alloy of the third class, however, might, under certain conditions, divide into three real alloys; thus if A could dissolve but little of B or C; B only small quantities of A or C; and C only a little of either A or B, a mixture of A, B, and C, in approximately equal quantities would necessarily divide into three different ternary alloys; *viz.*, A containing a little B and C; B with a little A and C; and C containing a little A and B; so that the fused mass would divide into three layers according to the relative densities of the alloys formed.

Although mixtures of three metals possessing this peculiar feature have not been obtained so far, still it is possible to prepare analogous mixtures of non-metallic fluids. Thus, a mixture of approximately equal volumes of castor oil, petroleum (kerosene), and water, when well shaken up, forms a sort of emulsion, which, on standing for some time, separates into three distinct layers.

#### Determination of Limits within which Ideal Ternary Alloys of Class I. are formed.

In order to deduce accurately the limits for a given trio of metals, a somewhat lengthy series of experiments is requisite, all made at the same temperature. With alloys of the first class this is best effected by taking suitable quantities of the immiscible metals A and B, and fusing them with gradually-increasing proportions of the third metal C (termed by Sir G. G. Stokes the "solvent" metal). The relative quantities of A and B requisite for any given experiment should be approximately calculated from the results previously obtained, which is readily done at sight when the values are graphically represented as described below; the quantities should be such as to develop approximately equal volumes of the two alloys produced, since experience indicates that if one alloy be formed in very much larger quantity than the other, abnormal results are more likely to be produced. By-and-by the result is arrived at that the limit within which an ideal alloy is produced, is passed, so that a real alloy results, the two ends of the compound ingot formed being of practically identical composition; but before this is attained, pairs of "conjugate" alloys are produced with each mixture employed. To represent these results graphically, Sir G. G. Stokes has suggested the following method:—A triangle is drawn to scale (preferably equilateral), and the centre of gravity deduced (by a simple process of plotting) of three weights placed respectively at the three corners of the triangle, and in the same ratios as the percentages of the three constituents of the ternary alloy to be delineated. Conveniently the solvent metal is supposed to be at the apex of the triangle, and the other two at the respective ends of the base. This point then represents the alloy in question; so that, by finding the two points representing the two real alloys into which a given ideal alloy divides, and joining them by a line ("tie-line" or "tie"), a visible representation is given of the mode of division of the ideal alloy employed.\* A series of alloys with gradually-increasing proportions of "solvent" will then give a series of tie-lines uniting the pairs of conjugate points respectively obtained from each mixture. By drawing a line through all the points thus deduced for the heavier alloys, and another through those similarly obtained for the lighter ones, two branches or portions of a continuous curve ("critical curve") are deduced, the gap between the ends being the smaller the more nearly the series of mixtures employed approaches to a particular limiting composition, indicated on the diagram by a point towards which all the ties continually approach, and at which they vanish. The exact position of this "limiting point" is calculable with a considerable degree of approximate accuracy from the relative positions of the various pairs of conjugate points, by one or other (or both) of two methods ingeniously devised by Sir G. G. Stokes for the purpose.†

\* The ideal alloy itself is necessarily represented by some point situated in the tie-line between its ends.

† Proceedings Royal Society, 49, 1890—1891, 174—178.

The annexed figure, for example, illustrates the critical curve deduced by means of 14 tie-lines (each the result of several concordant experiments averaged) with mixtures of

lead, tin, and zinc at near  $650^{\circ}$  C. The point *L* is the "limiting point," calculated as above; *a*, *b*, *c*, *d*, *e*, *f*, and *g* represent seven different real alloys (actually prepared and found to be such) all lying slightly outside the space enclosed by the critical curve and part of the base line, forming approximately a segment of a circle or of a parabola. Any alloy represented by a point lying *inside* this space is an ideal alloy; whilst, if the point representing an alloy lie *outside* (like *a*, *b*, *c*, &c.), it is a real alloy. In this particular case the configuration of the tie-lines is remarkable: the lower ties slope downwards to the left (lead side), showing that tin predominates in the heavier alloy, as compared with the lighter one; but the upper ties slope in the opposite direction, indicating that the opposite is the case when the original mixture contains larger proportions of tin. The upper ties converge towards a sort of central point; the middle portion of that part of the right-hand side of the critical curve where this is manifest corresponds with a mixture of metals containing tin and zinc close to the ratio represented by  $\text{SnZn}_4$ , suggesting that the tendency towards the fraction of the definite atomic compound thus indicated is the cause of the convergence. The tie-line exhibiting the maximum amount of slope (No. 5) represents a point on the left-hand branch of the curve, where the tin and lead are approximately in the ratio  $\text{SnPb}_3$ , suggesting the possibility of the existence of this definite atomic compound being the cause of the direction of slope being different for the lower ties from that found for the upper ones, a notion strengthened by the facts that a precisely similar double-sloping configuration of ties is observed with lead-tin-aluminium mixtures, the maximum slope of the lower ties also corresponding with  $\text{SnPb}_3$ , whereas no double-sloping sets of ties are observed with any alloys not containing simultaneously lead and tin. In similar fashion the systems of tie-lines and the critical curves thence deduced for the other 22 ternary alloys of the first class have been more or less minutely determined and delineated.\* From these experiments, as far as at present completed, the following general conclusions may be drawn as regards alloys of Class I. :—

1. With each ternary combination of metals the position of the critical curve varies with the temperature in such fashion that the curve for the higher temperature lies *inside* of that for the lower temperature. Towards the base of the curve (i.e., for those mixtures containing smaller proportions of "solvent" metal) the effect of variation of temperature is but slightly marked; but nearer to the limiting point (i.e., for mixtures containing quantities of "solvent" approaching the maximum possible consistent

with the alloy remaining ideal) the effect is much greater; in some cases a comparatively small variation in temperature makes all the difference whether a given mixture of metals forms an ideal alloy dividing into two real alloys exhibiting a considerable amount of difference in composition, or produces a real alloy not dividing at all.\*

2. The position of the limiting point corresponds with a ratio between the two immiscible metals which is not constant, but varies widely with the nature of the solvent metal.

3. In most cases the contour of the critical curve exhibits no marked sinuosity or irregularity; but in a few instances it shows a marked bulge outwards or notch inwards, which reaches its maximum development when the ratio between the solvent metal and one of the immiscible metals approaches towards that indicating some definite atomic compound. The atomic compounds  $\text{AgZn}_5$ ,  $\text{Ag}_4\text{Zn}_5$ ,  $\text{Bi}_2\text{Sb}_3$ , and  $\text{CuZn}$  are thus pretty clearly defined by bulges and notches.

4. In some few cases, although no irregularity of outline of the critical curve is noticeable, yet the configuration of the tie-lines exhibits some peculiarity, leading to the idea that an atomic compound of some of the metals, which affects the relative distribution of the metals in the two conjugate alloys, is formed: e.g., the above-described double direction of slope with  $\text{ZnPbSn}$  and  $\text{AlPbSn}$  alloys suggesting the compound  $\text{SnPb}_3$ , and the convergence towards some central point of a number of tie-lines with  $\text{ZnPbSn}$  alloys, suggesting the compound  $\text{SnZn}_4$ . The existence of the compound  $\text{Pb}_3\text{Cd}$  is clearly indicated by a convergence of this kind. In the majority of cases, however, no change in direction of slope of tie lines is noticeable throughout the entire series, all sloping either to the right or to the left. No fixed law regulating the direction of slope has been arrived at: with silver or copper as solvent, when the results are plotted, the heavier of the two immiscible metals being towards the left, the ties invariably slope downwards to the left (i.e., the heavier alloy formed contains less solvent than the lighter), whether the immiscible pair be  $\text{PbZn}$ ,  $\text{BiZn}$ ,  $\text{PbAl}$ ,  $\text{BiAl}$ , or  $\text{CdAl}$ . With tin as solvent, on the other hand, the ties invariably slope to the right, except those obtained with smaller tin proportions in the case of  $\text{PbZnSn}$  and  $\text{PbAlSn}$  alloys, when the slope is towards the left, probably on account of the effect of the formation of a definite compound  $\text{Pb}_3\text{Sn}$ , as above described. With antimony as solvent, however, the ties all slope to the left with the certain immiscible pairs ( $\text{PbZn}$ ,  $\text{PbAl}$ ,  $\text{BiAl}$ ), but to the right with others ( $\text{BiZn}$ ); similarly, with cadmium as solvent, the ties all slope to the left with the immiscible pair  $\text{PbZn}$ , and to the right with the pair  $\text{BiZn}$ . With zinc as solvent in the alloys of  $\text{CdAlZn}$ , the ties slope to the left. It would thence seem that whilst the nature of the solvent metal obviously influences the direction of slope, and whilst the ties slope to the left in the larger number of cases out of the 23 possible ones, it cannot be deduced that one given solvent always gives a slope to the left, and another one to the right, and so on.

5. As regards the dimensions of the segment-like areas within which real alloys are not formed in different cases, it is noticeable that on comparing the critical curve obtained with a given trio of metals, of which lead is one, with that obtained with the corresponding trio, where bismuth is used instead of lead, the latter always lies *inside* the former. In similar fashion, when zinc is displaced in a given trio by aluminium, the curve obtained with the latter metal lies *outside* that obtained with the former. Similar relationships also apply (but not invariably) to certain pairs of solvent metals, the temperature and the two immiscible metals being the same; thus, whether these two metals be lead and zinc, lead and aluminium, bismuth and zinc, bismuth and aluminium, or cadmium and aluminium, the curve obtained with silver as solvent metal always lies *outside* that formed with

\* Fluids other than melted metals exhibiting the same characters as to mutual miscibility or otherwise, behave in precisely the same way: thus a mixture of water, chloroform, and acetic acid behaves in a fashion exactly parallel with that observed with a molten mixture of zinc, lead, and tin. Near the limiting point the sensitiveness to temperature variation is very great.—Proc. Roy. Soc. 50, Part V.

copper; and apparently the curve with antimony always lies inside that observed with tin. On the other hand, although the curve with tin as solvent lies inside that with Ag (and a *fortiori* inside that with Cu) in the four cases where the immiscible pairs are respectively PbZn, BiZn, PbAl, and BiAl, yet this is not the case when the immiscible pair is CdAl; the Sn curve then lying outside both the Ag curve and the Cu curve.

### *Ternary Ideal Alloys of the Second Class.*

In order to depict graphically the results arrived at by the analysis of the real alloys into which ideal alloys of the second class divide themselves, the same triangular system may be conveniently adopted, with the difference that the two miscible metals are placed at the ends of the base line, and the third metal (not miscible completely with either of the others) at the apex of the triangle. The limits within which ideal alloys only are formed, are traced out by plotting the conjugate points and connecting tie-lines as before, the result in all cases being a space of very different shape from that deduced with alloys of the first class. Instead of this space being bounded by part of the base line and a curve approximating more or less to the arc of a circle or part of a parabola, it is a quadrilateral, two of the sides of which are parts of the sides of the triangle, whilst the other two are curved lines running more or less horizontally, and consequently cutting off from the triangle a three-sided portion at the top, and a four-sided part at the bottom. Mixtures corresponding with points lying in either of the upper or lower areas are real alloys, and do not divide into two on standing molten; whilst mixtures corresponding with points lying inside the intervening quadrilateral figure are ideal alloys, and divide into two real ones, one situated on the one line and the other on the other line.

### *Quinary Alloys.*

Of the 126 quinary combinations obtainable from the nine metals employed (95 of which are capable of forming ideal alloys), obviously a yet larger number of classes and subdivisions may be *a priori* formulated, many of which have representatives amongst the combinations deducible from the nine metals used: thus the alloys—

Zn, Pb, Cd, Sn, Ag

Al, Cd, Sn, Ag, Cu

contain *one* ideal binary pair, A B; whilst the following—

Zn, Pb, Bi, Sn, Ag

Al, Pb, Cd, Ag, Cu

contain *two* such pairs, A B, A C: and so on.

### *Sexenary Alloys.*

Of the 84 sexenary alloys obtainable, only nine are real; *viz.*, the seven formed by taking each six out of the series—

Pb, Bi, Sn, Ag, Cu, Sb, Cd

(*i.e.*, by omitting each one in turn); and the two following:—

Al, Zn, Sn, Ag, Cu, Sb

Zn, Cd, Sn, Ag, Cu, Sb

### *Septenary, Octenary, and Nonary Alloys.*

Of the 36 septenary combinations deducible, only one is real; *viz.*:—

Pb, Bi, Sn, Ag, Cu, Cd, Sb.

None of the nine combinations obtained by taking the metals eight at a time, is capable of giving a real alloy, excepting when the constituents are mixed outside of certain limiting proportions; and the same remark is true of the mixture obtained by putting together all nine metals; thus a mixture, of which the great bulk consists of any one of the five ideal binary alloys PbZn, PbAl, BiZn, BiAl, CdAl, together with small admixtures of the

remaining metals, will divide into two different alloys, consisting, for example, of—

1. Chiefly Pb, with small quantities of the other eight metals.

2. Chiefly Zn, with small quantities of the other eight metals.

The CHAIRMAN said that the paper just read had an interest far exceeding the interest of the subject, it being the last work of their dear friend Dr. Alder Wright. Nearly every member of the Society knew him, and to know him was to admire him and revere his memory. The paper now before them was an illustration of the thorough manner in which Dr. Wright did all his work. It was monumental in character, covering the whole history of the subject. Probably few members would wish to discuss the matter that night, but he was happy to say that there was present with them a fellow-student of Dr. Wright, one who had known him from his boyhood, namely, their worthy President, and he would ask him to say a few words, if not on the paper itself, at any rate on the author.

The PRESIDENT: I do not propose, in the very few words that I shall say to the meeting in response, sir, to your invitation, to utter anything in the way of contribution to a discussion on the matter of Dr. Wright's last paper. Indeed, I am quite incapable of contributing anything which would be worthy of being listened to on that subject. But I should not like this opportunity to pass without saying something on the merits of a man whom I have known intimately for 30 years, and who is now no longer to come amongst us. Dr. Wright, his friend Mr. Watson Smith, who has just read to us his last paper, and I, began our chemical careers together, working shoulder to shoulder in that laboratory in the rear of Richard Cobden's old house in Quay Street, Manchester, which was the place in which the now palatially-housed Owens College had its humble beginning. As you have said, sir, to know Wright was to admire him, but I will say more: to know Wright well was to love him. For beneath the surface-aspect of the man—beneath all his eccentricities and peculiarities—there was a great substratum of genuine worth and high personal character. There was a certain large-heartedness about the man without the least trace of malice or uncharitableness. He was often misunderstood; people occasionally said harsh things of him; but no unkind word of retaliation—no word which could be misconstrued to his quondam opponents' demerit—was ever uttered by him. The very directness and straightforwardness of his speech and manner was indeed the keynote to his character. There is in the paper we have just heard the melancholy interest which springs from the circumstance that it is the last contribution which this or any other Society will ever receive from him. That of itself gives the paper a peculiar importance to us on this the first night of a new year in the existence of our Society—a night upon which we might have reasonably hoped to see Wright once more among us, and to hear his voice again: for, as the minutes just read to you show, it was actually raised among you at your very last meeting. Indeed, we should have had from him the very paper which our editor has just read, and its reading would have been accompanied by a wealth of illustration and by an amount of exposition which were characteristic of him. A man of clear ideas, with a very considerable vocabulary, and power and felicity of expression, Wright was, indeed, one of the very best expositors I have ever heard. This charm we have missed to-night—the charm which comes from the personal interest which the writer would himself have thrown into his communication. There is an aspect of the paper which struck me forcibly, as no doubt it did many here—namely, the indication it affords of the extraordinary versatility of its author. That versatility, that remarkable receptivity and power of adaptation to all sorts of fresh ideas, was characteristic of Wright from his student days. The ease and rapidity with which he accomplished his collegetasks always appeared marvellous to his fellow-students. It was so not only in chemistry, but he excelled

equally in every other department of knowledge which he took up as a student: physics, mathematics, classics—even in such subjects as Hebrew and the Greek Testament—in all he gained distinction, as the old prize lists at Owens College testify. His published papers range literally over every department of chemistry, pure and applied. Now he treats of the constitution of whole groups of the alkaloids, and was, as you know, concerned in discovering one of the most important and valuable of the artificial members of the series—apomorphine. Now he deals with a most difficult branch of organic chemistry—the nature of the essential oils, and the very minute differences to be observed in the physical characters of the isomeric terpenes. Then he passes to various sections of inorganic chemistry, and from them to industrial applications of both organic and inorganic chemistry. He was as much at home in discoursing upon the intricacies of the manufacture of alkali and sulphuric acid as in discussing the characters and constitution of the opium alkaloids. In physical chemistry, too, he finds a field for his energy. The existence of hydrogenium is established, and Wright is concerned to determine certain of its physical properties. Indeed, his first published paper was on a section of physical chemistry—the action of light on silver salts, and in re-reading that paper a few days ago I was greatly struck with its power and promise—the precision of its statements, its orderly arrangement, and literary merit. He did not think that the whole of chemistry was concerned with the study of carbon compounds—he was not merely a benzological man. In this his last paper we have one more instance of the catholicity of his tastes and the range of his acquirements. For it is to my knowledge the condensed expression of many years of thought and a great amount of experimental work. I could say much more about Wright's personal character—about his worth as a man and his staunchness as a friend. One indication of his qualities you have gleaned from the circumstances which led up to the reading of this paper. He gave his word to our Secretary that this paper should be prepared; and under the most trying conditions, while suffering from pain and great physical prostration, he fulfilled his promise. This trustworthiness was eminently characteristic of him, and was thoroughly in accord with my lifelong experience of his character and qualities. Those who were best acquainted with him, and knew the circumstances under which much of his work was done, regarded the amount and quality of it as nothing short of marvellous, and the only solution I can offer is that he found in work itself solace and comfort under the physical pain and consequent mental depression from which he had for many years suffered.

The CHAIRMAN suggested that under the circumstances it would not be fitting to discuss the paper itself, but he would suggest that the members should confine their remarks to expressing their feelings concerning the author.

Mr. THOMAS TYLER, while feeling unable to add materially to the eloquent tribute to Dr. Wright's character and work which had fallen from the lips of the President, yet wished, as one of the oldest officials of the London Section, to add his testimony to the worth, integrity, and high character of the friend they had just lost. The qualities which the President had referred to were by no means confined to important matters, but were equally noticeable in the smallest details with which Dr. Wright was concerned. He had had many proofs of this in the course of his long acquaintance with Dr. Wright, and as a consequence he held his friend's judgment in such esteem that he could confidently accept it, even if, as sometimes happened, it differed from his own.

Mr. WATSON SMITH wished also to express his high opinion of Dr. Alder Wright as a friend and as a man, apart from his conception of him as a scientist. As the President had said, they were trained together at Owens College, but his acquaintance with Wright went further back than that—almost even to his infancy. Throughout their lives Dr. Wright had been a most sincere friend, and he never could forget the help and kindness which Dr. Wright had extended to him when he came from Manchester to take up his duties

in London, which went even to the extent of placing his house at the disposal of himself and wife, until they found a house of their own. He would also like to speak of the tender way in which Dr. Wright had spared his wife the knowledge of the terrible complaint which was the cause of his death. It appeared from the wording of the paper that he never expected to be alive to read it, for it was carefully written (as it now appears in the Journal) in the third person throughout.

## NOTE ON OXIDISED LINSEED OIL.

BY WALTER F. REID, F.I.C., F.C.S.

NEARLY the whole of the linseed oil which is manufactured in this country or imported into it is finally converted into the oxidised form; in fact, the large and growing consumption of this material is mainly due to the facility with which it absorbs oxygen from the air, and, in so doing, is changed from a liquid into a solid body. The paint which embellishes or disfigures our dwellings, the floorcloth or linoleum which covers our floors, and the pictures which adorn our walls—all owe whatever stability and cohesion they may possess to this oxidised modification of linseed oil.

In some industries, such as the manufacture of linoleum, and, to a small extent, in that of india-rubber, the linseed oil is first oxidised and the solidified product is afterwards mixed with other substances. In the majority of cases, however, the oil is used in its liquid state, as in paints and varnishes, and solidifies when exposed in a thin film to the action of the air.

Where the oil is oxidised as a preliminary process, two methods are employed on the large scale. In the first and oldest the oil is heated to temperatures varying from 350° F. to 500° F., with a small quantity of litharge or red lead. The operation is sometimes accelerated by blowing air through the oil, and samples are taken from time to time to test the progress of the oxidation. If a small portion of the oil becomes "stringy" when cooled and tested the oxidation has reached a stage which is sufficient in some industries; but in others, such as the manufacture of printer's ink, the operation is pushed a little further and the surface of the oil is sometimes ignited. The product is a dark-coloured, viscid mass of disagreeable odour and sufficiently fluid to take the shape of any vessel into which it is placed.

In the more modern process of oxidising oil for the manufacture of linoleum, the linseed oil is first boiled with the usual quantity of litharge, or red lead, or a mixture of both, and the boiled oil is allowed to flow over sheets of a light cotton fabric technically known as "serim," which are suspended vertically in sheds heated to 80° F. to 100° F. Every time the "serim" is flooded by the oil, a film of oxidised oil is formed on each side, varying in thickness from  $\frac{1}{16}$ th to  $\frac{1}{8}$ th of an inch. When these accumulated films, now termed a "skin," reach a thickness of about  $\frac{1}{2}$  inch they are cut down and ground between rollers preparatory to the next process. In this transverse section through a "skin," you may be able to detect some of the daily films, and you will observe that the colour deepens considerably towards the centre. Oxidised oil made in this manner forms, as you will see by the sample shown, an amber-coloured mass of considerable elasticity, but very deficient in tensile strength. It is heavier than water, while the original linseed oil is, as you are aware, much lighter. In this process of oxidation there is an increase of about 10 per cent. in weight; but the actual absorption of oxygen is greater because considerable quantities of volatile substances, including much acrolein, are given off at the same time. The fibre of the cotton "serim" has been much weakened, for linseed oil during oxidation has a powerful action not only upon textile fabrics, but also upon wood and even iron. The preliminary oxidation of the oil in this state is by no means complete. If ground between rollers and placed in a heap the solidified

oil absorbs oxygen from the air with such avidity that ignition of the heap sometimes takes place. For making linoleum the ground oxidised oil is heated with kauri gum and resin, forming an elastic, sticky cement which, if dissolved in a suitable solvent, would form a varnish; it is, in fact, almost identical with the film left by a kauri varnish after evaporation of the solvent and oxidation of the oil contained in it. You will notice that this linoleum cement is somewhat darker in colour than the oxidised oil; but seen in section by transmitted light it appears much lighter than in bulk. It is tougher than the solidified oil which forms its main ingredient, although not quite so elastic.

The oxidised oil which you have seen in bulk is practically identical with the substance produced by the spontaneous oxidation of linseed oil when mixed with pigments to form paints. After observing the facts which I am about to bring before you, I carried out a number of experiments, extending over many years, with films of both raw and boiled linseed oil alone and also mixed with various pigments. The results showed that the product obtained was almost identical with that which you see here.

Both in the case of paints and varnishes this solid, elastic substance has hitherto been regarded as the ultimate product of the oxidation of linseed oil when exposed to the air. Mulder, whose researches have thrown much light upon drying oils, and who termed it "linoxyn," says of it:—

"It is the important basis of all linseed oil paints and the product of the drying of linseed oil."

Schaeffler repeats this, and adds that linoxyn is probably the product of most drying oils. The same opinion is generally held with regard to varnishes containing linseed oil, and is well expressed by a technical writer in the following words:—

"After an article has been varnished the process of solidification, to which we unphilosophically apply the term drying, is carried on by the absorption of oxygen gas from the surrounding atmosphere, and when the varnish is thoroughly hardened it has absorbed all the oxygen it is capable of, and the result is a beautiful, transparent glaze." Von Pettenkofer, again, who made many interesting researches on paints and varnishes and published a work on the restoration and preservation of pictures, assumes that the elastic film produced by the oxidation of linseed oil is permanent in its chemical properties.

If, however, we examine carefully the behaviour of linseed oil for a period longer than that over which the investigations of these and other observers extended, we find that the properties of the oxidised oil are profoundly modified in the course of time; so profoundly, in fact, as almost to destroy the foundation upon which our theories on this subject have been based. If a surface of pure oxidised linseed oil be exposed to the air for about two years it becomes sticky and softens somewhat. In about three years, if the surface be vertical, part of it will run down as a semi-fluid mass, and in the course of five years a layer of oxidised oil 1 centimetre thick will be completely liquefied. You will see here the product which has resulted from the gradual oxidation of a "skin" of oxidised linseed oil which was, in 1878, identical in all its properties with the fresh one which I have just shown you. It is an extremely viscid, semi-fluid mass of a much darker colour than the oxidised oil from which it is derived. Raw linseed oil produces a similar substance; but both the preliminary oxidation and subsequent liquefaction require a longer period of time than the boiled oil. The properties of this substance, which we may term super-oxidised linseed oil, differ very materially from the initial linoxyn, and possess great interest in connection with nearly every industrial application of linseed oil. By studying it carefully we may find an explanation of many phenomena which have hitherto remained obscure. Like the solid oxidised oil it is heavier than water; but it has also become to a considerable extent soluble in that liquid. In this property may be found the explanation of the necessity for the renewal, at comparatively short intervals, of all oil-paint which is exposed to the weather, while similar paint protected from the rain will last very much longer.

Linoxyn is but slightly acted upon by alcohol, while the product of its subsequent oxidation is almost completely

soluble in that solvent. Von Pettenkofer invented a process for the restoration of oil paintings by exposing them to the vapour of alcohol at ordinary temperatures; and in his work on the subject he ascribes the action of the alcohol to the restoration of the molecular contact of the pigments. He was unaware that alcohol was an almost perfect solvent for the medium by which these pigments were fixed. In this, as in other directions, there is a remarkable resemblance between linseed oil and india-rubber. The first preparation of the india-rubber by warming a thin film of the liquid from which it is derived, much resembles the oxidation of the oil. Then follows what can only be regarded as an intermediate stage of solidity and elasticity, after which comes a final, or perhaps we had better say a further, stage of oxidation. During this stage the india-rubber also becomes soluble in alcohol. There are further analogies, such as partial solubility in water, to dwell upon which would exceed the limits of this note.

In the facts which I have placed before you may be found the explanation of many phenomena which will be familiar to you. In old prints and books, for instance, you will frequently have noticed a brown stain on the paper adjoining the print, or on pages opposite dark woodcuts. From such stained paper I have extracted a substance identical with this super-oxidised linseed oil. As the oil contained in the printer's ink liquifies, it is absorbed by and spreads through the paper, producing those stains which are too familiar to lovers of old books.

Again, some of you may have been vexed at the too rapid deterioration of articles made of patent leather, especially boots. The glossy surface of such leather is composed of a mixture of oxidised linseed oil and Prussian blue, and this will explain why the surface becomes sticky or cracks long before the leather itself shows signs of wear. So well known is this defect that dealers of repute refuse to hold themselves responsible for the wear of patent-leather goods. American cloth, which is a cotton fabric dressed with a composition similar to that used on patent leather, acquires a disagreeable adhesiveness when packed away for a few months in contact with other articles.

One of the most useful articles in the chemist's laboratory is india-rubber tubing. Many of us, no doubt, have met with samples of tubing which, while new, were apparently of excellent quality, soft and supple, although, perhaps, slightly deficient in elasticity. In about a year's time such tubing, should it contain solidified oil, will be unfit for use, while pure india-rubber will show hardly any signs of decay. The india-rubber itself will, of course, eventually become unserviceable; in fact, all elastic substances with which I am acquainted, except one, are very prone to decay. That one is the curious mineral elaterite, of which I have brought a specimen with me, in the hope that it may be of some interest. This piece is from Derbyshire, and has been exposed in the open air for 13 years, without the least deterioration. You will observe that it possesses considerable elasticity under compression, although its tensile strength is not very great.

It is found in the carboniferous limestone impregnated with a dark brown mineral oil of the consistence of gas tar. The other substances which I have noticed associated with it are iron pyrites, galena, and the sulphates of iron and lead. I believe that many years ago attempts were made to distil a mineral oil from this substance, but the progress of industrial chemistry has since been such that the problem has been reversed. A process for converting the heavier mineral oils into elaterite would enrich us with a substance which might find many useful technical applications.

Those of you who take pleasure in visiting a picture gallery—and who does not?—must have remarked with regret the condition of so many of the oil paintings. The colours of the pictures of comparatively modern date are far inferior to those of the frescoes on the walls of Pompeii or in the chambers of the Egyptian tombs, and it would be an insult to the memory of the artists to suppose that they ever laid on their colours in the sombre shades which we now see. It has been supposed that some special virtue lay in the pigments used in Greece and Egypt; but analytical chemistry, together with the records which have been handed

down to us, enables us to reproduce with accuracy almost any pigment known to the ancients. Aniline colours are of very recent origin, and we must look to the medium used for an explanation of the deterioration which has undoubtedly taken place. Two main causes have co-operated in producing the alterations which are but too evident. One is the liquefaction and darkening of the medium upon which the artist has relied to cement the particles of pigment to each other and to the canvas. The substance produced being extremely viscid retains permanently any dust or dirt with which it may come into contact. The other cause of alteration in an oil painting is traceable to a more purely chemical action. Linosyn itself is an inert substance, difficult to dissolve and to bring into combination with other substances. The product of its further oxidation, however, has a strongly acid reaction and forms solid compounds with most pigments of a basic nature. With white lead, for instance, a solid compound is produced which, though very friable and brittle, is quite solid and prevents the liquefaction of any point of which that pigment forms a substantial part. Those who have attentively examined the darker portions of pictures will have noticed that cracks and flaws are there much more frequent than in the lighter portions of the same pictures. Most of the dark-coloured pigments are but slightly basic in their nature, and they require a very much larger proportion of oil than the lighter colours. While white lead gives a good paint with but one eighth of its weight of linseed oil, ivory black cannot be used with less than its own weight of oil, and lampblack requires even a greater proportion. The larger the quantity of oil present, therefore, the less basic is the substance which alone is available for maintaining it in a solid condition. When lamp-black, or any finely divided variety of carbon, is used as a pigment, the occluded oxygen in its pores has a most injurious effect on the consistence of the paint, and it is well known that such black paints have a great tendency to remain sticky or "tacky." I have known a manufacturer to prepare a special quick-drying oil for black paint with the inevitable result that the paint was worse than before. This defect of black paint has frequently been attributed to the pigment alone. John Smith, who wrote a curious treatise on the art of painting about two centuries ago, says:

"In the substance of the colour is contained a certain greasy fatness that is an enemy to drying, to remedy which, burning in the fire till it be red hot and cease to smoke, will consume that fatness, and then it will dry much sooner."

This treatment would no doubt improve the drying qualities of the paint because the oxygen contained in the pores of the carbon would be driven off at a red heat.

The surface to which oil paint is applied must necessarily exercise an important influence upon the conservation of the film. If it contain a basic substance or a carbonate the effects of the liquefaction of the linosyn may be partially neutralised. Miniatures painted in oil upon ivory no doubt owe their generally good state of preservation to the combination of some of the mineral constituents of the ivory with the organic acids as these are generated during the oxidation of the oil.

Many other similar instances might be given; but I think after what has been said you will agree with me that it is a matter for deep regret that most of the talented artists of our generation are embodying the creations of their genius in a material which is anything but permanent, however pleasing its appearance may be for the moment.

#### DISCUSSION.

The PRESIDENT said he gathered from the paper that Mr. Reid considered the process of drying or coagulating india-rubber to be similar to the process of oxidising linseed oil.

Mr. REID replied that they found no oxygen in the finished rubber, but there was a similarity in the conditions under which it solidified.

The PRESIDENT, continuing, said: of course all dried rubber contained a certain amount of oxygen. He might

say that many years ago he was in Grão Para, and had the opportunity of seeing the process of making india-rubber as carried on by the Indians and half-breeds who tapped the Seringa. That the process was not altogether one of oxidation was obvious from the fact that the finished rubber, though containing a certain amount of oxygen, was not equal in weight to the juice that had gone to make it. It was clear therefore that a considerable amount of moisture was given off in the process of coagulation. With respect to the remarkable capacity of oil for absorbing oxygen, he might mention a curious experience of his own. Some years ago he was consulted by a blanket manufacturer at Huddersfield as to the extraordinary way in which the blankets, after being drawn from the bleaching house, where they were treated by the fumes from burning sulphur, fell here and there into holes. He went carefully over the whole process, but for a time could get no clue to the mystery. Eventually, however, it was discovered that while the blankets were in the centrifugal machines after removal from the fulling mill, the engineers, in oiling the bearings, would sometimes inadvertently spatter some of the blankets with drops of oil, and when these blankets were afterwards exposed to the sulphur fumes the oil brought about the rapid oxidation of the sulphurous acid, and so effected the tendering of the fabric.

Mr. IVES observed, with reference to the extraordinary way in which the colours used in Egyptian decorations retained their brilliancy, that the vehicle employed was a wax, not an oil, and consequently did not oxidise so readily.

Mr. T. CHRISTY thought that the tendency of the paper was to convince one that the linseed oil trade was no longer one of our greatest industries, and that, in fact, it was doomed. There was another reason for coming to that conclusion, namely, that very good oil, and varnish too, could now be obtained from petroleum; so good in quality that the use of linseed oil was likely to be superseded. A case had recently come under his notice in which a city restaurant had been completely painted and varnished by means of these products, with an entire absence of the disagreeable smell which always accompanied the use of oil paints. He hoped during the session to bring these products before the Society. Curiously enough, Mr. Reid had brought to their notice that night an earth which might be utilised for their manufacture, as well as for rubber, and he had no doubt many members would turn their attention to this new earth.

The CHAIRMAN enquired whether the petroleum varnish required the admixture of a gum.

Mr. CHRISTY replied that he believed it did not.

Mr. C. G. CRESSWELL observed that a soap was usually supposed to be formed by the action of white lead on linseed oil, and asked Mr. Christy how he would produce such a soap with the aid of petroleum. It was all very well to talk of new varnishes, but the merit of the paints used by our fathers lay chiefly in the fact that they did really contain white lead, whereas the paint used by the speculative builder of to-day had so little lead in it that it could be easily rubbed off with a clothes brush, and was therefore utterly unsatisfactory as a protective covering for wood. The blue pigment referred to as having been discovered in the tombs of Egypt was described in a memoir to the Académie des Sciences, and there was an abstract of it in the Society's Journal (Feb. 1889, 142). The pigment was metallurgical in character.

Mr. CHRISTY observed that he had seen specimens of soap actually made from the petroleum products he had referred to, and works were now being erected for its manufacture. He had tried it in his greenhouse, and found it the best insecticide he had ever employed.

Mr. W. J. HORN asked whether Mr. Reid had experimented with poppy oil in the same way as with linseed oil as to its oxidising qualities.

(Continued on page 1024.)

Mr. W. F. REID, in reply, said that the non-increase in weight of india-rubber sap by oxidation, was due to the fact that the juice contained only a small portion of the active substance, just as linseed only contained a certain percentage of linseed oil; but if one could obtain the pure substance contained in juice in its liquid state, and treat it by heating, one could find out whether there was a sensible increase or not. He hardly thought there would be, seeing that the percentage of oxygen in india-rubber was very minute. In fact, it was not a process of oxidation, but it might be one of polymerisation. If linseed oil were heated in a closed vessel, it solidified, shewing that internal molecular changes took place which were not due to oxidation. Possibly, it was so with india-rubber. Mr. Ives had asked if the Egyptians did not use wax as a vehicle. He believed they did not, but the Greeks certainly did, and had a peculiar way of preparing it. They used punie wax, mixed with volatile oils as a medium. The wax was kneaded with sea water, and exposed to the light; and modern experiments proved that the punie wax so treated possessed qualities quite different from those of wax bleached in the sun without the use of salt water. He could not agree with Mr. Christy that linseed oil was doomed. It had many and increasing uses, and no doubt its defects would be neutralised by the methods of using it; as in the case of linoleum, in which a large percentage of ground cork was used, and this absorbed the liquid oxidation products of the linseed oil as they were generated. With regard to the petroleum varnish referred to by Mr. Christy, he would like to know if its basis was similar to the elaterite, of which he had shown specimens; if so, it might be a permanent varnish.

Mr. CHRISTY could only say that it was a petroleum product, and that Mr. Reid's specimen closely resembled it.

Mr. REID, continuing, said: with regard to the blue pigment which had been referred to, that he had derived his information from the article cited by Mr. Cresswell, which proved the value of the Society's Journal in gathering notes together that might otherwise be lost. As to petroleum, he hardly thought it necessary to turn it into a soap, as it was an excellent cleansing agent naturally. He had tried experiments on a small scale, not only with poppy oil, but with nut oil also. Both oxidised much more slowly than linseed, but both eventually liquefied, and Schaedler was quite right in saying that all drying oils possessed the same property, though they contained less linoxyn.

Meeting held Wednesday, 7th November 1894.

## CHAIRMAN'S ADDRESS.

### THE INVASION OF THE INVENTOR.

BY EUSTACE CAREY.

As I spoke to you last year of "the multitude of inventions, mostly bad ones, which beset us on every side, and of the trained skill and knowledge which is required to sift the good from the bad, to winnow out the few grains of wheat from the almost interminable mountain of chaff," I thought I might do worse than take the inventor, his methods, and his fair remuneration, for my subject, as it is one which is interesting to all of us.

The genus inventor may be divided into three or four well-marked species or groups.

The practical manufacturer, who, with command of capital, experience and the assistance of experts, works out an invention to a finish, ending in the adoption or definite abandonment of a new process, belongs to a class of inventors, who, when they possess capacity and perseverance, cannot fail to be of great service to the community.

But even celebrated men of this class have not been able always to restrain themselves from the weakness of inventors of a commoner type, they have, parenthetically as it were, run to the Patent Office to secure the protection of immature notions and half-fledged ideas which have occurred to them during their work on the main and particular invention which they have had in hand; in fact the very best of inventors, however practical and experienced they may be, seem to be sometimes victims of a disease which we may call inventor's mania, the spirit of invention invades them, ideas good, bad, and indifferent seize upon them, and writing specifications and paying patent fees, becomes an almost daily excitement, without which life seems to them flat and uninteresting.

But as to those inventors whom we may place in the front rank, what is their method? They begin like everybody else, by having an idea; a new method of making an old material occurs to them, or a new use for an old product. Whatever their invention may be their first step is probably to try a laboratory experiment—the laboratory experiment succeeds—instantly visions of the potentialities of the new process fill their thoughts and glorious castles in the air at once appear to charm and allure them forward. On the other hand there are many processes which work well on the large scale and could not be made to work at all on the small, at all events good working on the small scale would be a matter of great difficulty.

Those manufacturers and capitalists, even who belong to this first and best class of inventors, are not always an unmixed blessing to their partners and the firms to which they belong. They are apt to pursue will-o'-the-wisps and neglect steady attention to what I may call every-day improvements. A manager or managing partner of a works who has his eyes open to perceive the small additions or alterations which may improve or cheapen production and has the openness of mind to accept suggestions from his colleagues and his workmen as to the never ending improvements which can be made in details, is frequently a wiser man than the manufacturer who has a genius for revolutionising everything. An inventive partner often gradually becomes a perfect terror to his friends who have every cause to lament the invasion of that inventor.

Among those who are not engaged in manufacture there are also inventors, some of them men of good chemical knowledge, and some of them men of some technical experience, but who cannot afford themselves to make a large scale experiment or they cannot create a value for invention by the expenditure of sufficient capital, so what do they do? They call in an expert. Their best course

Notices of Papers and Communications for the Meetings to be sent to the Local Secretary.

SESSION 1894-95.

December 5th.—Mr. Eric E. Watson. "The Calculation and Composition of Blast-Furnace Charges, as applied to the Smelting of Lead and Silver Ores."

would be to procure the aid of the best expert of all, the practical manufacturer, but that in their opinion would not pay them sufficiently well. They want a large sum for the invention, and so after they have seen an expert they go to a company promoter. The company promoter's first and immediate business is to get up a prospectus, and one of the essentials to a good prospectus is to have the favourable opinion of a well-known scientific expert, who gives it as his solemn opinion that "from the interesting and successful experiments which he has been permitted to witness, and from a careful examination of the reactions which are quite feasible under proper conditions, and that if the large scale results bear out the experimental trials, which he sees no reason to doubt, then the prospects of the new company are brilliant in the extreme."

But I may say the value of an invention increases as the scale on which it is demonstrated increases. The full value can only really be estimated when the working expenses have been demonstrated for some considerable time, so as to give a correct idea of the wear and tear of the plant. It is proverbial that most inventors estimate the costs of their processes at too low a figure. To make a proper estimate of the cost of a new process is an exceedingly difficult problem.

One great difficulty which presents itself at the outset to the practical manufacturer is that a great many inventors are unwilling to take any further risk of their invention, but demand to be at once remunerated to the full value of their own estimated profit, to be made in the unexpired portion of the 14 years' life of their patent. Now, while it is difficult to fairly guess the possible saving or profit to be gained by an invention, it is still more difficult, well nigh impossible, to capitalise it, to make such a venture, except at a very short purchase, say two or three years, is almost equivalent to gambling if a company be formed to acquire new patents and large amounts are paid in cash.

If, in a manufacture, finality could be reached and a certainty thus arrived at that the patent to be acquired would not be superseded in the course of a few years, such payments to the inventors might be justified, but when we remember that a money-making invention is just the one which is sure to attract the attention of inventors all the world over the payment of a large sum is highly dangerous. Yet most inventors insist on a payment of a certain amount of cash down.

The most prudent are those which are satisfied with a small amount, though the most numerous are those who demand at once a large fortune.

One class of inventors—the dealer in secret processes—is a power in the world, too, since it is a common weakness of human beings to be charmed by the unknown almost in a direct ratio to its approach to the impossible, as witness electric sugar. Whenever a process is to be kept a secret until a purchaser has satisfied himself that it will work we might almost at once dismiss the invention, for if a patentable invention there is no secret necessary, but if not patentable there is no guarantee to the purchaser that the invention may not be worked by others. But without saying more about dishonest inventors we are attacked more than sufficiently by those who are honest and straightforward to lead us in conclusion to consider if any fair, though, perhaps, rough-and-ready method of procedure may be suggested, whereby the reasonable claims of the inventor and of the practical and established manufacturer may be harmonised. I will put out of our reckoning members of our first group of inventors who are capitalists and manufacturers, and who work out their own inventions in their own way and for their own profit, and confine myself to those cases which are more numerous and more troublesome, where the inventor is either an outsider altogether, or at the most an employé of the manufacturer.

It appears to me that when an invention has been practically worked out and fairly put upon a manufacturing basis, a royalty of from 10 per cent. to 20 per cent. of the ascertained saving might in many cases be fairly charged. But certainly it appears to me that half of this royalty is due to the manufacturer who first works out the process on a large scale, the other half may reasonably fall to the

inventor who first gets the idea, and who by preliminary laboratory or small scale experiments shows its theoretical feasibility. I have taken a simple case of an invention where it is clear who is the originator of the idea, and who is the first to work it out practically on the large scale, but if a general support may be given to the foregoing in a comparatively simple and typical case it may not be insurmountably difficult to arrange a fair *modus vivendi* in other cases not so simple, and where the rival claims may vary in one direction or another from those just now described. Let me say, then, by way of suggestion, that a royalty of from one-tenth to one-fifth of the ascertained saving may in many cases be fairly charged, and that this royalty should be divided equally between the man who has the idea and shows by preliminary laboratory experiment and scientific calculation that the idea is worth pursuing, and the man who first demonstrates on the large scale that the new process can be successfully worked. I would name only one addendum, and that is that the works at which the large scale experiments are carried out and brought to a successful issue should enjoy complete immunity from royalty, and I consider that this privilege will in the vast majority of cases be richly deserved. You may ask, "What do you mean by ascertained saving?" and "Why fix the royalty at 10 or 20 per cent., why not any other figure?" I will endeavour very briefly to answer each of these questions.

In ascertaining the saving effected by a new process it is not sufficient to calculate the actual saving in material and wages, but in the case of an established manufacture due allowance must be made for the capital required to replace the old plant by new, and for the risks to be encountered in respect of the validity of the patents connected with the new process. With regard to the amount of royalty I admit at once that 20 per cent. may be an extreme figure; I have put it as the limit beyond which my experience licenses are not often accepted. Let one instance suffice:—The Weldon Manganese recovery process was generally supposed to effect a saving of about 2*l.* per ton on the bleaching powder made by that process; the royalty was at first fixed at 10*s.* per ton, but this was found impracticable under the circumstances, and subsequently 5*s.* per ton was accepted, the pioneer manufacturers obtaining a considerable concession. Here we have a royalty of say 12½ per cent. of the generally admitted saving, but we must remember that this royalty was only obtained after the process had been thoroughly established at more than one large works. I need not multiply instances; each case as it arises will have special points of its own which require adjustment, which adjustment will be the result of bargain; but the proposition which I wish especially to submit for your consideration is not the actual royalty charged which will vary and be the result of bargain, but that the claim of the manufacturer who first works out a process is generally speaking as good as that of the inventor himself who first brings the idea to light after preliminary laboratory trial. This doctrine may not be a very welcome one to hopeful inventors, especially to young ones, but I venture to think that on consideration and in the light of experience some such rule as this will be found to be just and to work well.

With regard to the inventor who has an idea, and nothing more, and who does nothing in the laboratory or out of it to demonstrate the probable feasibility of his invention, I have nothing good to say or to suggest! I think that he may be quietly dropped out of our calculations; at all events, his contribution to sound progress is usually infinitesimal.

I should have liked to be able to allude to some of the many electrolytic processes which are fighting for supremacy, and threatening a terrible invasion of the old. That there are scores of busy, clever, and eager brains working away, endeavouring to bring these processes into successful operation, is patent to us all, and it behoves us to prepare for the invasion of this inventor as for that of all other inventors, and when he has won his spurs and proved his case, to welcome him with open mind, and by timely enterprise to show that we willingly accept and can promptly profit by the invasion of the true and real inventor.

## DISCUSSION.

Mr. E. K. MISPRAIT thought that Mr. Carey, when speaking of what might make an invention succeed or not, did not allude at all to the commercial conditions. It was perfectly possible that an invention might be really very admirable, and, from the technical point of view, be perfectly successful; at the same time, the commercial conditions might be such that it was not profitable; but that same invention, if the commercial conditions were changed, might become, and often did become, very valuable and profitable. As an illustration, he called attention to Mr. Longmaid's process for the calcination of copper ores with common salt, in order to extract the copper as soluble cupric chloride, then precipitating the copper with iron. This process, as worked by Mr. Longmaid, did not succeed; but some years later, when Spanish pyrites replaced Irish pyrites, the process, as applied by Mr. Henderson to the burnt ore, was profitable. But now the commercial conditions had again changed, and since the purple (iron) ore obtained in the process was not so valuable as previously, the commercial success of the process was naturally not so great. He was not quite sure that Mr. Carey had given the layman his full due, and he instanced Mr. Weldon as not originally a practical manufacturer. With respect to the payment of inventors, he entirely agreed with Mr. Carey, remarking that he himself had suggested a somewhat similar system, when giving evidence before the Patents Committee of the House of Commons. He thought it would be desirable that there should be a clause in any patent act, that the patentee should be bound to give his invention to the public on payment of royalties assessed by some impartial tribunal, and that, for chemical patents, at any rate, the royalty ought to take the form of Mr. Carey's suggestion.

Mr. W. P. THOMPSON agreed that patentees ought to be only too glad to arrange a free licence with the manufacturer, who was the first to give their patents a trial. But one effect of the clause for compulsory royalties was, that if a man gave a licence to anybody whatever, that was considered a precedent by which the Board of Trade adjudicated royalties. Almost every great master patent in the mechanical and chemical world had been brought out by laymen.

Professor CAMPBELL BROWN said that while he was delighted to see Mr. Carey sitting upon the false inventor with all the weight of his authority, he might say a great deal in favour of the true inventor if he needed any defence. The manufacturer and the world at large could not get on without him; the law of progress was of course a law of nature, and all they could do with wisdom was to put a brake upon the wheels, sufficient to see that each bit of progress rested upon a safe and sure foundation, and the next important thing to do was to take care that the inventor had as prolonged and thorough an education as could be obtained. The inventor would always exist, and he (Prof. Campbell Brown) did not think that his remuneration could be regulated by Act of Parliament.

Mr. CAREY, in reply, said that he was much inclined to agree with Mr. Misprait in calling Mr. Weldon a layman; but he could not quite agree with Mr. Thompson, when he stated that most of the great inventions had been made by laymen.

## Manchester Section.

ROOMS OF THE CHEMICAL CLUB, VICTORIA HOTEL.

Chairman: R. Forbes Carpenter.

Vice-Chairman: Edw. Schunck.

Committee:

G. H. Bailey.

Sir H. E. Roscoe, M.P.  
W. Thompson.

Hon. Local Secretary:

J. Carter Bell.

Bank House, The Cliff, Higher Broughton, Manchester.

SESSION 1894-95.

The second meeting of the Session will take place on Friday, December 7th, 1894.

Mr. Wm. Thomson, F.R.S.E., will show some new forms of chemical apparatus.

Mr. Peter S. Gilchrist (U.S.A.). "Pine Columns for saving Chamber Space in the Manufacture of Sulphuric Acid."  
Dr. Carl Otto Weber. "A new class of Lake Pigments."

Meeting held Friday, 2nd November 1894.

MR. R. FORBES CARPENTER IN THE CHAIR.

## CHAIRMAN'S ADDRESS.

SINCE our last meeting in this room Mr. Levinstein has felt it incumbent upon him to resign the chairmanship of the Section to which the Committee unanimously re-elected him in April last, and all the members of the Section will, I am sure, endorse the regret felt by the Committee that the pressure of other business engagements has been felt by Mr. Levinstein to be so great that he desired to be relieved of the duties of chairman while still remaining a member of the Committee. We shall long remember his zeal and energy in promoting the interests of our Society in general, and of our Manchester Section in particular. During our eleven years of existence as a section (since February 1883) there have been only three chairmen, Sir Henry Roscoe, Dr. Schunck, and Mr. Levinstein. The last has borne by far the larger brunt of the work, and we all know how indefatigable have been his labours in the interests of chemical industry; while the part he took in organising the chemical section of the Exhibition of 1887 is fresh in our minds and will always be gratefully appreciated. Let us hope that at no distant date Mr. Levinstein may feel able to re-assume the duties of chairman, to fulfil which for the current session your Committee have chosen my unworthy self as his successor.

I must claim your indulgence in the short address that I have prepared to open our session, for I have found some difficulty in selecting suitable material.

I have no intention or desire to obtrude my official personality upon you to night, for is not all that I have to say concerning my professional work contained in the Annual Report made to the Local Government Board by the Chief Inspector under the Alkali, &c. Works Regulation Acts. And yet there are some points that come under my notice which could claim no mention there that may be worthy of attention to those in this room, though my observations will not have the merit of novelty or originality.

Most of those present here, I daresay, had occasion to peruse and to criticise the rules issued by the Home Office under the Factory and Workshops Amendment Act of 1891 for the protection of those employed in various classes of industry, especially the chemical industries. In the case of the latter the rules embody the recommendations of a small committee, of which the chief inspector under the Alkali Acts was a member. On similar lines other committees for the pottery works and lead industry were constituted and reported to the Home Office.

I think I am not wrong in stating that the immediate stimulus to the Home Office in this matter was given by the publication of a work by Dr. J. T. Arlidge, "On the Hygiene, Diseases, and Mortality of Occupations," and it is to this book I desire to direct your attention by giving you some idea of its scope, of the careful judicial spirit in which Dr. Arlidge has approached his subject, and of the conclusions as regards some of our chemical industries at which he has arrived. I hope you have not been already prejudiced in respect to it by reading or hearing of a highly coloured review in the columns of the *Daily Chronicle* at the date of the appearance of the work, followed by a still more highly coloured series of articles entitled "Death in the Workshop"—to the writer of which any kind of physical toil seems a subject for lamentation and commiseration.

Let Dr. Arlidge speak for himself. "The problem to be solved is not merely the mortality and relative prevalence of particular diseases in the several occupations, but to discover what, if any, pathological consequences are rightly assignable to them, and what, when such are found, are their causes. It is not sufficient to analyse the returns of sickness and mortality. To arrive at a correct estimate of the effects positively attributable to an occupation it becomes necessary to eliminate all factors of disease not truly incident to it, a proceeding of great difficulty even when practicable."

Dr. Arlidge goes on to observe that physicians in France and Germany have for a long series of years directed their attention to industrial diseases and have collected a mass of observations. In France extended codes of rules and regulations have been framed to govern factories and to give security to the public against noxious trades, but they are, he says, to a serious extent, inoperative, because there exists no consolidated system of supervision by a distinct body of factory inspectors and medical men. But, as regards the comparative value of foreign statistics in the opinion of Dr. Arlidge, owing to the very dissimilar condition of life and work on the continent, and to the fact that some races of men (for instance the Celtic, Irish, and Welsh) have unfavourable racial health characteristics, the vital statistics of occupations pursued in England are only to be obtained from English sources.

In turning over the pages of the book, I find how frequently the author has to lament the deficiencies and lack of intimate knowledge caused by the absence of observations on the particular trade or occupation under notice. For instance, in speaking of the textile industries, he says: "In my search for facts relative to the changes wrought in lung tissue by the presence of dust arising from textile materials, silk, cotton, wool, and linen, I have been unsuccessful in finding any placed on record by medical men practising in the numerous and large manufacturing towns wherein those substances are in daily use, and in some of which there are medical schools with professors of medicine and pathology"; and again "Returns of the prevalent diseases of dyers and bleachers, of the ratio of mortality and of average age reached by those artisans are greatly needed, and ought to be forthcoming from the extensive works in Lancashire and Yorkshire. We are left to surmise what bodily ailments are likely to arise among bleachers, for, regrettably, no medical man has thought it worth while to determine what they actually are."

To conclude with one more example. "There is unfortunately a complete lack of statistics that might show the effects of high temperature upon workmen exposed to it, and nothing exists to help us in forming an opinion than records of individual cases of suffering; something beyond the general conviction that stokers and furnacemen on board ship are sickly and short-lived should be arrived at from opportunities for investigation possessed by the medical officers of our immense steam fleet." So much for the negative side; let us see a few of the positive conclusions. The impression I receive is that exposure to inhalation of dust, whether mineral or vegetable, is a more potent factor in reducing vitality and in producing distinct degradation of tissues than inhalation of acid vapours, speaking generally. In the latter case, personal qualities and idiosyncrasies and the principle of accommodation seem to count for more

than in the former, where inevitably, as time goes on, deteriorating change of tissues sets in. To come to more purely chemical manufacturing operations, the only table of comparative statistics Dr. Arlidge is able to give was contributed by Dr. Robertson, Assistant Medical Officer of Health at St. Helens, who had tabulated the cases of 503 labourers under two types—chemical and ordinary labourers; and under two death causes—diseases of lungs and all other diseases.

Diseases.	Mean Age at Death.	
	Ordinary Labourers.	Chemical Labourers.
Disease of lungs.....	40	35
All other diseases.....	50	44
Mean age at death, all causes..	49½	48

Unfortunately, says Dr. Robertson, these observations are made from an insufficient number of cases, 503, to do more than give a general indication of the fact that while there is a difference of 1½ years in the mean age at death from all causes, there is a difference of six years between the two classes from diseases of the lungs. "It may be added," says Dr. Arlidge, "as the mean age of chemical labourers is greater than that of ordinary labourers, as far as the mortality from diseases in general is concerned, we have an additional proof of the influence of occupation, on the one hand augmenting chest diseases, whilst on the other showing a less ratio for all other forms of sickness." Dr. Robertson, the compiler of these statistics, expresses his belief that the furnace labourers, by needless exposure to cold in a half-clothed state on their way home, are themselves in no small degree contributory to liability to bronchitis and disease of the respiratory tracts.

It is for this reason that, in my opinion, before these statistics could be accepted as conclusive that further differentiation should be made and comparison be instituted between, say, salt-cake furnacemen and workers at the glass furnaces at St. Helens (not "blowers," for here a fresh form of disease comes into play). Mr. Cooper, Medical Officer of Health at Widnes, has discovered no ill effects from the same vapours as at St. Helens, not even in the intensification of maladies. Children are remarkably healthy, contrasting favourably with those of Liverpool. The estuarine situation of Widnes is favourable for the dissipation of the vapours produced, and accounts, in Dr. Arlidge's opinion, for the difference in vital statistics noted in the two towns. Perhaps the most serious and weighty statement in regard to any chemical products is the following:—

"The comment is unavoidable that when we examine in detail the phenomena of poisoning with nitro-benzol, bisulphide of carbon, and various explosives, we cannot fail to recognise the existence of a series of maladies having certain common features, but which have no place in our accepted nosology. In other words, we are in the presence of a group of trade diseases unlike any ordinary group of every-day maladies which pathologists recognise and study, but upon which careful research may well be expended, and, in short, is in the interests of science demanded."

In describing, as he has to do, a very great variety of technical operations it is not unnatural that error has crept in, but I have come across none of any very serious moment. Dr. Arlidge wrongly attributes the dangers attendant on cleaning out sulphuric acid chambers to the sulphurous acid evolved on stirring up the bottom acid and sulphate of lead, instead of to the acid nitrogen oxides. The extremely deadly nature of exposure to these has a little escaped his notice. The only deaths with which I am acquainted directly due to being "gassed" are from this cause. Let me remind you of the lamented death of Mr. Woolley in this city, of the five (I think) deaths from the breakage of a carboy of nitric acid at Newcastle, near Messrs. Mawson and Swan's warehouse. These were of

persons not accustomed to work among acid vapour; but the danger of nitrous acid to those who are not strangers to its inhalation needs all the more to be insisted on, as exposure to it does not produce the feeling of suffocation or of spasm of the glottis to the same extent as do sulphurous, sulphuric acids, or chlorine, while the damage to lung tissue by absolute formation of chemical substitution products is not felt till perhaps the next day. I know of two deaths attributable to this cause in vitriol works.

Time does not allow me to go further in the examination of Dr. Arlidge's work, into his discrimination between the factors of town-made and trade-made diseases, or into the influence of the nature of occupation in rightly construing vital statistics, a subject in which he proceeds with the utmost caution and perspicacity. I must refer you to the first 60 pages of the work for instruction on these points. Before leaving this portion of my subject I should like to draw your attention to one of the recommendations of the Chemical Works Committee before mentioned, viz.: that at works where outbursts of dangerous gases are liable to occur, a bottle of compressed oxygen should be readily available. The first mention of the use of the "oxygen bottle" that I remember, was by an officer of the Royal Engineers in charge of some balloon experiments, when, in the discharge of the gas from the balloon at the ground level, one of the men got enveloped in the folds of the balloon and was found unconscious, on search being made for him: the poison was no doubt carbonic oxide; but the restoration of an apparently dead man on inflating the chest by artificial respiration and at the same time cautiously turning the tap of the oxygen bottle between the man's teeth was most extraordinarily rapid. In a recent number of the *Chemical Trade Journal*, I see that similar good results have followed in the case of asphyxiation by producer gas. The remedy is so simple and so easily

applied and is so instantaneously effective that I have no doubt many a valuable life will be saved by its means in the future.

And now, knowing how close is the connection of engineering with the existence and development of our chemical industries, I should like to direct your notice to a lecture delivered by the President of the Society of Mechanical Engineers, Professor A. W. Kennedy, F.R.S., at the Royal Institution as long ago as April 1893, on "Possible and Impossible Economics in the Utilisation of Energy," a subject that as treated by him may point the moral for chemists as well as engineers and the illustrations of which are so lucid and striking that he who runs may read. "Half our possibilities," says Professor Kennedy, and this I may call his text, "indeed far more than half our possibilities are of improving up to the best—it is infinitely harder to improve up from the best." For instance, plenty of room exists for raising the general efficiency of boiler work (Fig. 1), for if the average working all over the country were brought up to the standard of the best, there would probably be one-third less coal used every year than is now actually burned. But looking at Fig. 1, and knowing that of the 20 per cent. loss, we must lose something in radiation and pay a price for draught in heating the chimney gases, we cannot look for any very astounding increase of economy in boiler-work over the best that has been done. "No doubt any saving is possible," Professor Kennedy shrewdly remarks, "if one only starts with a bad enough example." In the next diagram, Fig. 2, are represented the theoretical

FIG. 1

FIG. 2

possible efficiencies of the engine cycle of transformation of molecular into mechanical energy calculated from the familiar ratio  $\frac{T_1 - T_2}{T_1}$  where  $T_1$  represents the highest temperature above absolute zero at which the working fluid receives its heat, and  $T_2$  the lowest temperature above zero at which it parts with its heat—the numerator is the working difference of temperature, and the ratio, a limiting number that falls tolerably short of unity. With steam, apart from superheating the temperature  $T_1$  is dependent upon and limited by considerations of pressure and consequently of safety, with ammonia it is similarly limited, but the engine lies much further down the scale both as to

$T_1$  and  $T_2$ . But confining our attention for the moment to steam, in any actually possible steam engine, the process differs so much from the ideal that not more than 20 or 25 per cent. efficiency could be attained, even if the process were carried out perfectly, but in practice only 5 to 15 per cent. of the whole heat of the steam is ever turned into work. By further demonstration Professor Kennedy points out that the possibility of improvement is of doing *twice* as well as at present. In diagrams 3 and 4 is a graphic representation of this. In Fig. 3,

FIG 3

100 per cent. is taken as representing the whole energy of the steam, the area under A represents what might be turned into work by an ideally perfect engine working in an ideally perfect cycle (the left-hand side being a bad, the right-hand a good machine). The area under B represents an ideal engine working in actual cycle and under C the proportion actual engines turn into work. In Fig. 4, the ordinates of A are taken as 100 per cent., and the other two drawn in the relative places, the spaces showing the possibility of improvement in its real proportion. Professor Kennedy indicates that steam being in its working condition a vapour and not a gas, its temperature cannot be raised without at the same time raising its pressure. Considerations of safety and strength of materials become here very important, but even leaving these out of account, if you raise the maximum working pressure from 10 to 20 atmospheres, the theoretical maximum efficiency is raised only 10 per cent., clearly not a promising direction in which to work. The raising of the theoretical efficiency by the superheating of the steam is the direction in which Professor Kennedy seeks for improvement to be made, though it is only recently that the use of mineral lubricants has made it practicable. He mentions the fact that a little ordinary 4-h.p. engine, one cylinder, late cut off, moderate pressure, worked by steam

superheated 200° F., gave positively better results than a fine 100-h.p. Lancashire engine of the best Lancashire make, used with the same steam pressure and no superheating; under ordinary circumstances he would have expected the little one to use four times as much steam as the big one. Turning our attention now to gas engines, their theoretical efficiency is very high, about 80 per cent., the temperature of combustion in the cylinder may be as great as 2000° F. (so says Professor Kennedy, but 1800° C. was reached in Mr. Dugald Clerk's research experiments), yet the actual amount turned into work is less than in the steam engine (compare the lines C in Fig. 4, and B in Fig. 6).

FIG 4

notwithstanding this, the actual energy utilized per thermal unit of combustion heat in a gas engine is very considerably greater than in a steam engine. The area above C in Fig. 6 represents the heat taken by the water surrounding the cylinder in the necessary water jacket. It is quite possible therefore for a gas engine of new type to appear in which only half the present quantity of gas will be needed. Possibly a reduction of initial temperature may be attended by economy and the use of producer gas with its lower thermal efficiency as compared with coal gas as may prove to be a step in the right direction, as many engineers (Messrs. Tangye, for instance) already declare to be proved. "A solution of the whole matter," says Professor Kennedy, "a solution which would also greatly help the steam engine problem, would be the discovery of some non-conducting material which was at the same time suitable for use in the construction of engines. Chemists have done much for us, but we still wait for our non-conductor, something as strong as iron and as easily machined, with the conductivity of sawdust is what we want, a material which at the same time must remain sensibly unaffected by very high temperatures and which will stand rubbing to any extent."

In Figs. 7 and 8 are contained a history of the gradually regenerative process by which the chemical energy of combustion is converted into electric light in a central lighting station; similar letters are used in each section of the figure, reading the transformations from left to right, for similar quantities of energy; in each section the losses of the section before are written off, and the quantity of energy actually carried forward is called 100 per cent.

FIG. 5

In Fig. 7, K represents the losses in the boiler, H condensation in steam pipes and driving of pumps and other such losses inevitable in a central station. G is the part unavoidably lost from thermo-dynamic limitations; F the portion wasted by the engine, the remainder being turned into work; E the amount of heat-energy required to drive the engine itself, doing no work on the dynamo; D are the dynamo losses, C is expended in mains, transformers, &c., and of the energy reaching the incandescent lamps, B is heat and A only is light. Fig. 8 is drawn similarly for a gas engine worked by producer-gas; as regards the latter Professor Kennedy observes: "There seems no doubt the combination, although it does not much reduce the number of transformations, gives, under certain conditions, a very high economy of fuel indeed. I do not think the evidence before us is as yet sufficient, although I hope it shortly will be, to enable us to say how far under ordinary working conditions the actual combined efficiency of the whole plant will be distinctly greater than that of existing systems; the theoretical maximum efficiency is of course much higher." "To sum up," he says in conclusion of the examination of this subject: "the whole matter of possibilities and impossibilities, there does not seem to be anything very startling before us in the way of possible economies, except in the two directions of lamps as light producers, and of bringing up gas engines to their theoretical maximum."

We have heard much from enthusiasts during the last two years of the utilisation of town refuse in the generation of electric energy, the popular theory being that each urban community makes enough refuse with economical combustion to supply heat-energy enough to light the district with electric light. Our newspapers bear testimony to the judicious manipulation of the journalistic representative by the enterprising process promoter, and it is human nature to be enthusiastic about the conversion of dust-bin refuse into electrical energy under the soothing influence of a sumptuous lunch. But, looking at what can be reasonably expected of attainment, we must always bear in mind that the first essential in the disposal of town refuse is that the heat of combustion be so great, and the destructor or cremator be of such construction that all noxious gases have time as well as temperature for their final resolution into carbonic acid and water. This means steady feeding of the destructor through the 24 hours, while the demand for electric light is for a very limited proportion of the day. To charge the material into tubular steam boiler furnaces with the primary object of directly raising steam, and making the cremation of everything noxious the secondary consideration, is to run counter to all the advance that sanitary engineering has made in this department of recent years. I am very glad to be supported in this view by Professor Kennedy from engineering and thermal considerations, "of course," he says, "the stuff (town refuse) has the vast advantage that it costs nothing, even for cartage, but I cannot help fearing that like most things that cost nothing, it will be found to be worth very little more than it costs. I schemed sometime ago the boilers at a station in the north to try the experiment of using waste gases from a town destructor, but have not been sanguine enough to hope that I can do more in this way than save some of the cost of banking fires or running at very low load; I shall be delighted if I am mistaken in my estimate. In any case it has to be remembered that the

FIG. 6

dust destructor works on uniformly day and night delivering a uniform amount of heat, while the boilers of a lighting station want heat non-continuously in most variable fashion. If, therefore, more than a very small fraction of the destructor heat is to be utilised arrangements must be made for storing that heat somehow, so that it can be drawn upon as wanted; with thermal storage there is at least a

theoretical possibility of using most of the destructor's heat without storage. 70 per cent. of it is probably the largest amount that can possibly be utilised." With this quotation I take leave of one of the most suggestive, wise, and witty discourses that I have had the good fortune of recent years to come across in my reading. Those who have access to a file of "The Electrician" will find a good report of the

lecture in the numbers August 4, 11, and 18, 1893. I take this opportunity of expressing my thanks to the author for his kind permission to me to make use of the diagrams that so much aid in understanding the subject.

The question of possibilities and impossibilities in the development of electrolysis has received striking illustration by the publication by Mr. H. Y. Casner in the columns of *Engineering* and later of *The Chemical Trade Journal* of details of his electrolytic process for production of caustic soda and chlorine which has been continuously running at the works of the Aluminium Company, Oldbury, since August. It may be of interest to dwell for a short time on the developments that have taken place since 1888. In every paper that Dr. Hurter has communicated to our Society you will find the same high scientific qualities, and certainly his address to the Liverpool Section in November, 1888 (this Journal, Vol. VII. p. 719-726) is no exception to his high standard. The possibilities of electrolysis as they presented themselves to his mind at that time are there dealt with, and we are enabled now to see what amount of advance has been made in electrical efficiency since then. Taking the simplest electrolytic process known where the electrolyte does not change its constitution—the operation of copper refining—he found a loss of efficiency of 50 per cent., from Messrs. Siemens and Halske's statement of results. It is necessary to proceed with great caution in comparing the statements of electrical efficiencies obtained in different electrolytic processes as often entirely different meanings are attached to the word "efficiency." Dr. Hurter by his context takes the minimum voltage demanded by theoretical considerations and deduces his percentage loss by measuring decomposition per watt. By the custom of electricians, electrical efficiency is determined by the yield per ampère, a very different matter. Mr. Casner inclines to the latter view, he says, apropos of his process—"the electromotive force being 2.3 volts, it is evident any extra voltage is due to the internal resistance of the cell. As the amount of this internal resistance increases relatively to the

quantity or volume of the current passing, the whole matter resolves itself into one of cell construction, so as to arrange a cell that will be commercially practical by taking a large current without materially increasing the extra internal resistance. With almost any cell it is quite possible to pass a few amperes at almost theoretical voltage, but in attempting to increase the volume in order to obtain a practical result, the resistance increases so rapidly in proportion to the volume of the current as to necessitate the use of enormous cells which at best have a comparatively small output. If it is theoretically possible to pass one ampère of current through a cell at 2.3 volts, it certainly cannot be said that it is theoretically possible to pass 550 amperes at the same voltage, entirely irrespective of what is or is not the technical meaning of electrical efficiency."

And yet to my mind all this is a little academic, for the question of yield per watt, or, what is the same thing, its equivalent in mechanical energy or horse-power, is what will decide the investment of capital in trying a process.

It speaks, however, well for Mr. Casner's process that his actual voltage should be only 4, and ampère efficiency 88.5 for, this brings the watt efficiency of a decomposition admittedly far more complex than that of copper refining to somewhere approaching 50 per cent. of the power utilised. It is generally admitted that in the present state of the industry no electrolytic soda process would pay in this country at a higher voltage than 4.

The Greenwood and Le Sueur electrolytic processes described by Messrs. Cross and Bevan (this Journal, 1892, Vol. XI. p. 964, and 1894, Vol. VIII. p. 453) show ampère efficiencies of 80 to 85 per cent. working at 4.5 volts. These, I understand, are working in commercial scale in the United States. Mr. Hasenclever in his report on German chemical industry in 1892, described the remarkable progress of electrolysis of potassium and magnesium chlorides. Some processes therefore are practical.

Few of us realise the small amount of decomposition one ampère produces. Dr. Hurter states it in this way: "It

takes a current of 10,000 amperes day and night every day for three years to produce in one electrolytic cell one ton of hydrogen gas or its equivalent of any other substance. At the (1888) works of Messrs. Gaskell, Deacon, & Co., about four tons of 95 per cent. salt are decomposed per hour. To do that work with the theoretical amount of electricity

engine power equivalent to 5,728 horse power would be necessary, and it would require 100 large boilers to supply the necessary steam."

There is nothing in this statement to be modified by the light of to day except that the basis of the calculation was for the products that appeared H and Cl, 1.65 volts for the

FIG. 2

back electromotive force, and 0.35 volts for resistance. This is correct. Dr. Hurter now states when no current is passing, but, while the current is passing the back electromotive force is 2.25 volts, without resistance, or 2.60 with —Mr. Castner's basis of decomposition (theoretical) is 2.3 volts.

You will notice that Dr. Hurter's remaining figures almost hold their own to-day, first the loss of heat during its conversion into mechanical energy, 90 per cent. (Kennedy, 85 per cent., Fig. 7, losses K. to F.). Second, a loss of conversion of mechanical energy into current of 26 per cent. (corresponding closely with Professor Kennedy's E. and D., Sec. V.). The only place in which I think, from my point of view, Dr. Hurter fell into somewhat serious error was, when speaking of the prospects of electrolysis ousting the Leblanc process. He says, p. 723: "I find that it would cost nearly 1/2 to decompose one ton of salt (electrolytically) and to obtain therefrom chlorine as gas, and a solution of salt containing caustic soda and other things for it could not be anything else. The Leblanc process sells the whole of the products of from 1 ton of salt for less than 6/."

The basis of Dr. Hurter's calculation was  $\frac{1}{2}$  ton of caustic, 70 per cent., and  $\frac{1}{2}$  ton of bleach; the former at 7/., the latter at 5/ per ton. But while electrolysis at that time had not done better than this the theoretical possibilities showed approximately,  $\frac{1}{2}$  ton of bleach and  $\frac{1}{2}$  ton caustic of 70 per cent. Surely in forecasting the future these possibilities should have been taken into account. As regards the Leblanc process no startling improvement is to be expected in the manufacture of caustic, but in that of bleach much has been done since 1888, especially by the Deacon-Hasenclever process to increase the yield of bleach per ton of salt, the limit of attainment is however by now pretty well known.

The only possible rival type in Mr. Castner's mind to his own process is the fusion type of process of which Mr. Vautin's is an example. (This Journal, 1894, 448—455), shortly to be in operation in Lancashire. Mr. Vautin found

in an experimental trial the voltage at which the current will pass 4 amperes to be 2 only, as compared with 1.4 amperes at  $3\frac{1}{2}$  volts in an exactly similar experiment in the wet way, and this is a marked feature in its favour, but the cost of maintenance of the chloride in a state of fusion, and the wear and tear of the carbon anodes are matters which only trial on working scale can prove. Mr. Castner appears to have been well aware of the rocks on which other electrolytic processes have broken down, of the necessity of getting a large number of amperes, or current of large volume, to pass at low voltage, necessitating the abandonment of diaphragms, of the accumulation where no diaphragm is used of hypochlorites and other impurities in the solution necessitating these being rejected from time to time, of the disintegrating effects of these on the carbon anodes (the hypochlorite itself electrolysing with evolution of oxygen from the carbon) and to have skilfully devised his plant so as to turn the flank of one and all these difficulties. Whether the introduction of mercury as a cathode involves a loss at this point by mercury passing into solution remains to be proved. This is the solitary point on which he is silent after the criticisms the process has received, and it is one to which working the process for a considerable time is the only answer. The voltage 4 at which the process is worked is as low as that of any working electrolytic process, if it is not lower, considering the number of amperes passing at that voltage, a very important point for commercial success. The future of the process will be watched with very great interest, and while the horse power necessary for an extensive work, if raised by boiler power, is large, yet, if the water power available at Niagara can allow the electrical syndicate formed to utilise it, to supply 1 e.h.p. for 5 dols. per annum,\* the cost will come to about 1/10 of the cost in England to day of 1 i.h.p. (viz.,  $\frac{1}{10}$  d. per hour), and we might expect great developments of

\* The latest advices I receive show this estimate to have been inaccurate, the actual figures at which 10,000 e.h.p. have been contracted for being 18 dols. per annum per e.h.p., equivalent to  $\frac{1}{10}$  d. per hour.

the process under conditions such as these at Niagara or elsewhere.

For those of us with a sufficient knowledge of mathematics Dr. Hurter's inaugural address to the Liverpool Physical Society in October 1893 on electrolysis will well repay study. The phenomena of conductivity of solutions, of secondary reactions, and the curious disturbing influence known as "migration of the ions" are passed in review and the results of a large number of most interesting and patiently conducted experiments are there recorded and explained.

It seems ungracious to envy the prosperity and efficiency of societies formed like our own for the promotion of technical knowledge and interchange of ideas among its members, but I sometimes entertain these sentiments towards the various district Societies of Gas Engineers, as chemical subjects connected with their industry would find ample scope for discussion amongst ourselves, and these papers tend naturally enough to go to the engineers rather than to come to our Society. I hope this session will not pass without our receiving one or more papers on chemical points connected with the gas industry, for this was never at a stage of development more interesting to the chemist than at the present time. Two movements opposite in principle are dividing the gas world; let me try and shortly summarise the position. In view of the tendency of parliamentary demands for increase of candle-power, and of the limitation of supplies of candle, coupled with the cheap price of petroleum oils, several processes which you will find described in our Journal have come more or less into vogue for increasing the illuminating power of gas; among others I might name the Peebles process, and the Tatham or oxyoil process. In others carburetted water-gas, as in the Lowe process, is adopted as an adjunct. I learn on the authority of Professor Vivian Lewes that last winter 10 per cent. of the gas supplied by the Gas Light and Coke Company, of London, was derived from this latter source, where the ordinary gas of 14 to 15 candles was enriched with the 22 candle water-gas and sent out at 17 or 17.5 candles to ensure getting the required 16 candles at the testing stations. That gas engineers should be alive to the advantage of having a plant that can be so rapidly put into operation as the one I mention is not to be wondered at when we remember the demands upon their plant that are sure to arise on the advent of fog lasting perhaps a week. It is impossible to heat up beds of retorts quickly enough for the requirements. The sanitary drawback, however, will at once suggest itself to you, it is not desirable to increase the percentage of carbonic oxide in our burning gas, as the increase of danger of accident by escape and use rises in direct proportion. I will do no more than mention this feature that should not be lost sight of. But there is another feature of greater interest to us as chemists. In proportion as the percentages of carbonic oxide and hydrogen are increased in such degree does the height of the flame of the gas lessen when burned, and to this cause more than any other does Professor Vivian Lewes attribute the complaints by consumers of defect of illuminating efficiency that have arisen. The following are some figures obtained by him in burning 5 ft. of different gases per hour in a standard argand:—

Gas.	Height of Flame in Inches.
Hydrogen.....	0.985
Carbon monoxide.....	2.206
Carburetted water-gas.....	2.5
Methane.....	1.25

This statement prepares us now to appreciate the argument of the other school of gas engineers that contains the eminent names of Mr. George Livesey and Mr. Thomas Newbigging, and receives the weighty support of Professor Vivian Lewes. Mr. Newbigging is perhaps the most recent exponent of the view that the enrichment processes are all

tendencies in the wrong direction. He distinguishes between illuminating power and illuminating effect, the former, of course is the photometric measurement and comparison of the light with that of standard candles, in which process the eye of the observer is carefully shielded from all direct sight of the flames. A light of high illuminating power may not have by any means so great a proportionate illuminating effect (take the arc light as an instance of this familiar to every one). As one passes from the south of England to Scotland the illuminating power of gas rises from 16 candles in London to 18 to 19 in Manchester and Salford, and to 22 and 24 in Edinburgh; will any one, says Mr. Newbigging, contend that it is possible to obtain proportionate increase of illuminating effect. The natural illuminating power, without enrichment, given by the Durham coals in use in London is about 14.5 candles, and Professor Vivian Lewes found hardly any difference in candle units per foot of gas consumed in No. 1 and No. 5 flat flame burners (which form 85 per cent. of those in domestic use) between 14.5 and 16-candle gas. The absolute figures of candle unit efficiency being No. 4, 1.74 and No. 5, 1.87; when I tell you that the maximum candle unit efficiency per foot of gas when burned in regenerative burners is 10 you will see that there is plenty of room to improve up to the best in the department of burners, and that it is quite arguable that the great cost of enrichment is so much money wasted. As an experiment the South Metropolitan Gas Company sent out for the period of a fortnight unenriched gas of about 14.5 candles without receiving complaint from a single consumer. The point I have previously mentioned as to size of flame has a distinct bearing on this question of illuminating effect. A natural coal-gas, containing its due proportion of methane will give a larger flame than an enriched one, and the illuminating effect of the larger flame will be as great as that of a smaller and more intensely brilliant surface of flame obtained from an enriched gas of higher candle power. In addition there are physiological reasons supporting the contention of this school, the eye automatically and involuntarily closing against admitting too many rays from a highly brilliant flame. It will be most interesting to watch the progress of the newer ideas. If, in Manchester, some of the money spent in enrichment were only diverted to purification from sulphur impurities we should (with all due respect to Professor Lewes, who is still unconvinced by the arguments this Section has brought forward) be deeply grateful to the authorities. Those of you who feel interested enough in the subject to make further acquaintance with it will do well to read the paper of Mr. Thomas Newbigging at the meeting of the Gas Institute this summer, and the discussion thereon to be found *in extenso* in that most excellent technical publication, "The Journal of Gas Lighting," July 1894. One drawback to the enrichment processes I have not named, the fact that the gas is the carrier of hydrocarbon vapours. This leads to stratification in the gas holders, and when the gas passes along the mains with the friction against the skin of the pipe, tendency to condensation and deposit of liquid hydrocarbons arises, so that to reach the consumer gas of proportionately higher candle power must be sent out from the works. We had some years ago, in Salford gas, during the period when the Hawkins process was in use, sufficient evidence of this phenomenon.

In covering so much and such varied ground this evening I have necessarily been able to touch but lightly on each subject. If my remarks have been at all suggestive that is all the merit that I hope for them to possess.

MR. GEO. T. FRANCE IN THE CHAIR.

### PRACTICAL RESULTS OF THE LUNGE-ROHRMANN PLATE-TOWERS FOR CONDENSING HYDROCHLORIC ACID.

BY G. LUNGE.

AS ONCE of practice is better than a pound of theory—this, I think, everybody will admit, without in the least depreciating the immense services theory can render to practice, services which the writer is the very last person to hold cheap. After some tilting between Dr. Harter and myself in the pages of this Journal, in which theoretical reasoning played the greater part, and which I did not care to continue at the time, fearing that it might appear tedious, it will be appropriate to relate something about the *practical* results obtained with plate-towers (sometimes called "Lunge towers") on a large scale.

An opportunity for this arose in the following way. A little more than a year ago, Mr. Richard Curtius, managing partner of one of the oldest German alkali works, Messrs. E. Matthes and Weber, of Duisburg, had his attention drawn to the plate-towers. I believe principally through my friendly polemics with Dr. Harter. He made up his mind that he would go in for their use as hydrochloric acid condensers, not in a half-hearted way, which might very easily have led to an erroneous result, but as thoroughly as possible. He fitted up one of his salt-cake furnaces with a condensing plant based on that system, and almost at the outset obtained the most encouraging results. This furnace has been running ever since with plate-towers, and, as we shall see, produces a better yield of acid than any system which has been hitherto known. Most other manufacturers would have been contented with such a result, and would simply have continued to work on in the way in which they had succeeded from the first. But Mr. Curtius, with an enterprise and a zeal for technical chemistry which cannot be sufficiently praised (seeing that he is not in the least interested in making propaganda for other people's inventions), made it his task to try various modifications of the first system, in order to completely elucidate that subject, and he has not yet finished his experiments. But, as the works' manager, Mr. Lasche, with the consent of his chief, is about to publish the results hitherto obtained, and as I have had an opportunity of seeing his report before it goes to the press, I think it will interest English and American chemists to get a short summary of it several months before it would be otherwise accessible to them, together with some explanatory remarks of my own.

It is hardly necessary to point out that I give Mr. Lasche's results in an absolutely unvarnished form. The reader is therefore not to be treated to an *ex parte* statement, but to absolute *facts*, established at a first-class works, and to be published by its responsible manager, whom I had never seen or communicated with in my life before the termination of the experiments to be reported upon.

The salt-cake furnace in question is a muffle furnace, decomposing every 24 hours 10 charges, amounting in all to 4 tons 5 cwt., or 30 tons per week. The pan-gas and muffle gas travel separately through about 30 ft. of 16-in. pipes, and then enter into two small towers, 3 ft. wide and 10 or 13 ft. high, one of them empty, the other one filled with coke. Here a little impure acid, with much sulphuric acid, is condensed. The second tower was intended to serve as a wash-tower, by being fed with water or weak acid, but this was not done during the experimental period, both towers only working as air-coolers. The gas then enters an empty receiver, and then passes through six ordinary earthenware receivers, holding 66 gallons each, the connections being made by high bends, to increase the cooling action. In all, the gases travel over a distance of 130 ft. (reckoning horizontal and upright way) before entering the plate-towers. These consist of nine cylinders, 3 ft. wide and 3 ft. 3 ins. high. The bottom cylinder is empty; the next three cylinders contain 60 Lunge-Rohrman plates; the fifth cylinder is again empty; the sixth and seventh contain coke, resting on an earthenware grating; and the two top cylinders are again empty. The plates are held in the grooves of annular bearers, 2 in. high and tightly ground upon one another, so that a second column is formed within the first, the space between them being filled with pebbles. The diameter of the plates themselves is 2 ft. 2 in. The 15 bottom plates have holes of 12 mm. diameter; the next 35 plates, holes of 7 mm.; the last 10 plates, holes of 6 mm. The top of the tower is provided with an ordinary water-spreading arrangement, and just below there is an exit pipe, slanting a little upwards, and then leading downwards to the chimney flue, a "sight" being interposed, which at the same time serves for regulating the draught.

The acid formed in the towers flows through the six receivers and runs off from the first receiver. At first it was attempted to work without these receivers, which not merely aid in the condensation, but also serve for equalising the unavoidable variations of work. This attempt, as was to be expected, failed; the strength of the acid and its temperature varied within wide limits. But after the six receivers had been interposed, the specific gravity of the acid, when both that coming from the pan and from the muffle were united, varied only between 1.161 and 1.167, and averaged 1.164 at 15° C. All following specific gravities are also reduced to that temperature.

The temperature of the gases on entering the pan-set was from 15° to 55°, average 34° C.; in the muffle-set 15° to 59°, average 49°. It was always highest towards the end of an operation. On entering the plate-tower in the pan-set it was 14° to 37°, average 24°; in the muffle set 16° to 38°, average 28° C. The acid running from the first receiver in the pan-set showed sp. gr. 1.141 to 1.170, average 1.160; in the muffle-set 1.152 to 1.175, average 1.163; between the tower and the nearest receiver in the pan-set 1.136 to 1.162, average 1.168; in the muffle-set 1.132 to 1.162, average 1.145. During October 1893, for instance, there were made 181 charges of 8½ cwt. rock-salt each, or 119 tons 8½ cwt., which yielded 218 tons 16½ cwt. of hydrochloric acid of sp. gr. 1.162, or 183.2 parts of hydrochloric acid for every 100 parts of rock-salt decomposed. This is a yield not attained by *any* other condensing plant in any part of the world, as far as my knowledge goes. I have taken some trouble in collecting information on this point, for use in my treatise on Sulphuric acid and Alkali, and the highest yield I have heard of from anywhere is only 180 parts acid of sp. gr. 1.16 (20° B.) on 100 rock-salt.

The temperature of the exit gases in the pan-set was 30° to 40° C. Mr. Lasche also tested their acidity, but his figures admit of no comparison with those given by the English alkali inspectors, as he only tested for the total

acidity including  $\text{SO}_2$  and  $\text{SO}_3$ , and took his tests immediately behind the towers, whilst the alkali inspectors test the condensers only for  $\text{HCl}$ , and the total acidity in the chimney outlets, where the condenser gases are diluted with other gases, before issuing into the outer air. So much is certain that, tested in the English fashion, the Duisburg towers must have shown themselves to be equal to the very best of English condensing plants, since the acid really escaping from them into the air is notoriously less than in any other known case.

At the plant in question an arrangement had been made for taking samples of the acid coming down from the small coke column, before reaching the top plate of the plate-tower proper. This acid, very remarkably, at the pan-tower showed sp. gr. 1.108 to 1.158, average 1.133; at the muffle-tower 1.067 to 1.121, average 1.094. It seemed from the outset hardly possible that a corresponding quantity of  $\text{HCl}$  should have escaped condensation on the plates, and quite impossible that it should have been all condensed by a coke-column 2 ft. wide and 6 ft. high. That must be from the first the conclusion of people not prejudiced at the outset against the plate-towers, but inclined to give them a fair chance. Mr. Lasche indeed came to the conclusion that very much liquid acid must have been carried away mechanically by the draught from the plates, and mechanically retained by the coke. The experiments to be described anon, where the coke was left out, and it was tried to avoid the mechanical loss in other ways, did not yield as good results as the original plan, with a little coke at the top; but, as we shall see, the yield even then was so good that it is utterly out of the question to attribute to the coke much more than the mechanical part above mentioned.

The Duisburg condensing plant, as above described, had given such excellent results that it could not be expected to improve them further. Mr. Curtius, however, in the interest of technological science, resolved to try some modifications of the plant, in order to completely elucidate the working of the plate-tower system, and in particular the part played by that small column of coke. The work was stopped, the coke was taken out, and work was recommenced with the plates alone. The draught was regulated by means of the "sights" in such manner that the anemometer in the exit pipe showed an inward pressure of 6 mm. water; this draught was found to answer best, and to obviate any escape of gas at the furnace doors. It was at once found that the distribution of the water on the top had to be improved, and even then the yield of acid was now only 169.6 per cent. of sp. gr. 1.157. Such a yield is still superior to that of a very large number of works, and some years ago it would have been considered first-class at most places, but they could not think at Duisburg of leaving matters at that point, since after removing the coke nearly 8 per cent. less acid than before had been obtained. The aim was now to see how many additional plates would be required to attain the same yield as with the coke. The first trial was made by putting three additional plates on the top of the others, with holes of 5 mm. diameter; but this would not work at all, as the draught was too much interfered with. Still this experiment was very valuable in settling the lowest limit for the size of holes for this purpose. Evidently holes 5 mm. wide are too narrow to allow the passage of the gas at the same time as that of the comparatively large quantity of water running down in a hydrochloric acid condenser, although long experience has shown that such holes are most suitable for apparatus employed for recovering nitric acid from the lower oxides of nitrogen, in which case only a very small feed of water is used. Hence the minimum size of holes for  $\text{HCl}$  condensers must be placed at 6-millimetre holes, and this may be the proper size altogether, but plates with 7-mm. holes are also doing very good work. Any width above this is decidedly objectionable, whilst for sulphuric acid apparatus, owing to the greater viscosity of even chamber acid, the minimum size of holes has been ascertained by experience to be 8 mm. The 15 plates at the bottom of the Duisburg towers, with 12-mm. holes, evidently did practically no condensing work at all; this part of the towers always remained quite cold, the heating only commencing where the plates with 7-mm.

holes started. This is no matter of surprise; the 12-mm. holes leave hardly any margin for the acid to stand on the plates, which is one of the guiding principles in the construction of the Lange plates; they act merely like sieves, with hardly any condensing power, so that the space occupied by these plates has very little more efficiency than if it were empty.

The plates with 5 mm. holes were now taken out, and 11 other plates were put in, 10 with 7-mm. and one with 6-mm. holes. The draught had to be increased to 12 mm. water pressure on the pan-tower and 14 mm. on the muffle-tower. The yield now rose to 177.7 parts acid of sp. gr. 1.160, the specific gravity varying from 1.144 to 1.161 on the pan side, and from 1.150 to 1.164 on the muffle side. This yield most assuredly exceeds that obtained at a great majority of works, but it is about 3 per cent. less than that obtained with the original plant, that is, with the small coke-column at the top of the plates. The acidity of the gases was also decidedly greater than before. Mr. Lasche points out that the yield would probably have entirely equalled that obtained before, if the 15 plates with 12-mm. holes had been replaced by such with 7- or 6-mm. holes, and that in this case the coke would have been found quite unnecessary.

Even if it should be found that by some such arrangement the coke could be entirely dispensed with, I am at the present inclined to advocate retaining such a small column of coke at the top of the plates. The additional two cylinders and the few cubic feet of coke cost very little indeed; but although they may not, and indeed cannot, exercise any essential condensing action in the proper sense, they are evidently very useful in perfecting the equal spreading of the water before it reaches the top plate (which is very important), and in mechanically retaining the liquid acid drops carried upwards by the draught; also in counteracting the tendency of the feeding water to be drawn towards the exit pipe, which is placed just below the cover.

I must point to a drawback of the plate-towers as erected at Duisburg (and elsewhere) which will not occur in future. I have explained above that the annular earthenware bearers form a complete inner cylinder within the outer shell. The space between was loosely filled with pebbles, but formed, of course, a non-conducting air-jacket. This, together with the double earthenware envelope, must be very prejudicial to the dissipation of the heat produced within the tower by the action of  $\text{HCl}$  upon water, and must decidedly lower the efficiency of the tower. In future the towers will be constructed with a new form of cylinder, provided with projections for bearing the plates, the present annular receivers being entirely done away with. The cooling action of the air will then be much more complete, and it may be expected that the same excellent results as hitherto will be obtained with a smaller number of plates.

The experiments at Duisburg are now being continued, to try the action of towers of larger diameter with different kinds of plates, and so forth, and we shall in due time hear more about it. But already now, as Mr. Curtius states, the Duisburg trial has absolutely established the success of the plate-tower system for condensing hydrochloric acid. This small apparatus has shown itself more than equally efficient with either the ordinary huge coke-towers, with or without the addition of some cast-irons, or else the 100 stoneware receivers, followed by small coke-towers, as usual on the Continent. These trials have also fully justified my assertion, formerly impugned on theoretical grounds by the high authority of Dr. Hurter, according to which a plate-tower possesses from 10 to 20 times the condensing power of an equal space of coke-tower (compare this Journal, 1893, 330 and 421). Even if we comprise in our calculation those inefficient 15 plates with 12-mm. holes, the inner space of the Duisburg towers, so far as it is filled with plates, is only 2 ft. 4 in. wide and 10 ft. high, equal to just 74 cub. ft., for both towers together. With a decomposition of 30 tons per week this is = 2.46 cub. ft. per ton per week. In well-conducted English works the condensing coke-tower space averages about 50 cub. ft. per ton per week. It is true that this comprises the empty spaces above and below the coke, but these are more than allowed for by our taking in on the other side the 15 plates with 12-mm. holes. For the sake of this comparison we

must deduct from the 50 ft. the space occupied by the sturdy coke-column in the plate-towers, to which we must of course assign neither more nor less efficiency than to an equal space in an ordinary coke-tower. The small coke-column in the plate-towers amounts, for both of them together, to a space of 19.3 cub. ft., or 1.61 cub. ft. per cent per week. Deducting this on both sides, we find 2.46 cub. ft. of plate-tower space equivalent with 48.36 cub. ft. of coke-tower space; that is, a ratio of 1 to 20. If due allowance were made for the 12-mm. hole plates, and for the present insufficiency of cooling action in the Duisburg towers, the comparison would be even more favourable to the latter. They furnished not merely a better yield of acid than the most gigantic coke-towers, but even the variations in the strength of the acid were no greater in the former than in the latter case. This result at the same time amounts to a distinct proof that the preliminary cooling of the gases, before they reach the condensers, really plays the very important part assigned to it by the late Dr. E. Angus Smith, and that the unavoidable rise of temperature, caused by the absorption of HCl in water, can be coped with much more easily and in a much smaller space than both some modern theories and the practice of some Widnes alkali-makers have allowed. Just in this particular respect, as we have seen, the Duisburg towers were decidedly not quite as efficient as they might have been, and as their successors will be in future, and yet they have completely attained their purpose.

#### DISCUSSION.

Dr. HURTER writes as follows:—Professor Lunge has given in his paper a number of facts from a similar paper by Mr. Lasche; and draws sweeping conclusions from facts, which, if they prove anything, prove the failure of the Lunge plates as compared with coke.

Usually the conclusions of a paper are the only part which most readers look at, leaving the tedious details to be studied by those whom it may concern. The concluding paragraph of Dr. Lunge's paper will undoubtedly lead the readers to think, that at Duisburg they have managed to condense the hydrochloric acid from 30 tons of salt per week in the very small space of 74 cub. feet, and that this result had been accomplished solely by the aid of the great efficiency of the Lunge plates, which, he states, are proved to have been twenty times as efficient as an equal space filled with coke.

The plant consisted, for a decomposition of 30 tons of salt per week, of a pan and muffle furnace and the following condensing systems, of which there were two sets, one for the pan, the other for the furnace-gases.

The two sets were identically alike, and comprised between them the following parts:—

- (1.) Cooling pipes, about 80 yards of 16-inch pipes.
- (2.) Two empty towers (one for each system) 2 feet 8 inches diameter and 10 to 12 feet high.
- (3.) Two towers filled with coke, but not fed with water (one for each system), same diameter, 17 feet high.
- (4.) Four large Bombonnes kept dry to collect all acid condensed up to this point (two for each system). No water was allowed to flow through these.
- (5.) Twelve large Bombonnes (six in each system), through which all the water from the following towers was flowing. These were found to be indispensable; without them the system would not work.
- (6.) Two Lunge plate towers (one for each system) 2 feet 8 inches diameter, about 30 feet high. The lower part of these towers contained at first 60 plates, and above them about 6 feet of coke; later on the coke was removed, and still later 11 plates were substituted for the coke.

The acid condensed in these towers flowed through the Bombonnes.

It is impossible for me to give the accurate cubical capacity of this compound system, but approximately I take it as about 1,100 cub. feet, 1,000 of which are in front of the Lunge towers. It is surely idle to talk of the wonderful results obtained with 74 cub. feet of plate room when these are preceded and assisted by 1,000 cub. feet of

space in front of them, unless indeed absolute proof were furnished that the space in question really does the greater part of the work.

The results we have at our disposal (as found in Mr. Lasche's paper) give, however, the direct contradiction to the statement that the 74 cub. feet of space filled with plates have contributed any extraordinary amount to the condensing power of the system.

We are told that the acid obtained at the outlet from the Bombonnes tested on an average 32.8° Tw. As the gases arrived at the Bombonnes with an average temperature of only 93° F., most of the steam had already condensed, and we may take it that the amount of water flowing from the Bombonnes was also the water flowing down the Lunge towers. Acid of 32.8° Tw. contains 32.3 per cent. of HCl and 67.7 per cent. water. Thus for every 32.3 parts of HCl condensed 67.7 water were flowing down the towers.

In the tower, above the plates, there was a layer of coke of 6 ft. depth, placed there probably to catch the last traces of hydrochloric acid which might escape from the plates, and also for the better distribution of the water.

Mr. Lasche had wisely made provisions for testing the strength of the acid flowing from the coke on to the plates. The result seems to have surprised him, for he says:—

"*Marvellously* the following strengths were obtained: at the pan condenser the acid flowing from the coke had on an average 26.6°, as minimum 21.6°, as maximum 31.6° Twaddel."

The acid from the tower, at the bottom, flowing into the Bombonnes, had an average strength of 29.6° Tw., minimum 27.2° Tw., maximum 32.1° Tw.

With these data it is easy to calculate that the 67.7 of water flowing down the tower absorbed in the coke space 21.2 parts of HCl, in the plate space 3.8 parts of HCl, and in the Bombonnes 4.3 parts of HCl.

The work of the system may thus be represented as follows:—

	Per Cent.
Acid condensed in the coke space .....	74.9
" " plate space .....	11.8
" " Bombonnes .....	13.3

It would be incorrect to draw the conclusion from these results that about 50 cubic ft. of coke space had done six times the work which was done by 74 cubic ft. of plate space.

The fact is that the work done by any part of a condensing system is not measurable at all, either by the acid condensed therein or by the changes of temperature which occur therein, but solely by the number of units of heat which the particular part of the system can disperse. In every condenser, as far as I know, without exception, the large bulk of HCl gas disappears just near the entrance of the condensing fluid. But the liquid acid there formed cannot be strengthened to the required degree, unless the heat of condensation be dispersed and the temperature of the acid lowered. It is the function of the other parts of the apparatus to do this.

For this reason the Duisburg system did not work at all without the Bombonnes; the Lunge tower was not able to cope with this task. Again, if on the top of the six feet of coke another six feet had been placed, the disappearance of the large bulk of HCl gas would have occurred in the upper six feet, and the condensation in the lower six feet of coke would have been a very small fraction, and not, as before, 75 per cent. After the removal of the coke the work done by it now devolved on the plates, and they were unable to cope with the work, as the results clearly prove.

The results after removal of the coke were very bad indeed, but they will not serve as a correct basis for the calculation of the comparative efficiency of coke and Lunge plates. None of the results detailed in Mr. Lasche's paper will serve that purpose, and until the managers of Duisburg will permit the whole of the plates of the Lunge towers to be removed and to be replaced by a rational coke packing we shall not be in a position to know that comparative efficiency. I devoutly hope the managers of the Duisburg works will in the interests of technical science make that most interesting experiment, and prove once for all the truth of Professor Lunge's assertion that the same space will do 20 times more work with plates than with coke.

As far as the managers at Duisburg went in the substitution of plates for coke, the results are decidedly in favour of coke, and they are alive to that fact.

The following comparison of results obtained (1) while working with coke, (2) while working without coke, (3) while working with 11 Lunge plates instead of coke, show the very marked superiority of coke over the plates:—

One hundred parts of rock salt yielded in form of liquid acid—

	Pure HCl.
(1) when working with coke.....	58.8 per cent.
(2) " " without coke.....	39.6 "
(3) " " with plates instead of coke.....	55.6 "

The exit gases contained free acid, which was expressed as  $\text{SO}_2$ , and which I give in grains per cubic foot. It will be seen that the substitution of 11 plates for the 6 ft. of coke caused the exit-tests to be doubled.

#### Pan Gas Exit-Tests (Average).

(1) When working with coke.....	1.24
(2) When working without coke.....	?
(3) With 11 plates instead of coke.....	2.44

#### Furnace Gas Exit-Tests.

(1) With coke.....	4.5
(2) Without coke.....	?
(3) With 11 plates instead of coke.....	12.7

It is a great pity that we are not in possession of sufficient data to calculate exactly in what part of the system the great loss of hydrochloric acid happened after the removal of the coke and before the introduction of the additional 11 plates in its place. There is little doubt, however, that most of this loss occurred in the furnace condenser. Even after the coke had been replaced by plates the production was bad, and the following results obtained from Mr. Lasche's figures by a calculation similar to the one already made, show that it is the furnace condenser where this loss occurs. Pan gases are comparatively easily dealt with, while the furnace gases frequently give trouble.

While the furnace condenser was working with coke in the upper six feet, the condensation of the hydrochloric acid was distributed as follows:—

	Per Cent. of Total condensed.
Condensed in Lunge towers.....	31
Condensed in Bombonnes.....	9

After 11 plates had been substituted for the six feet of coke the distribution was as follows:—

	Per Cent. of Total.
Condensed in Lunge tower.....	69.9
Condensed in Bombonnes.....	30.1

As the alteration in the tower could affect the condensing power of the Bombonnes but little, the acid flowing from them being of the same strength, there must have been quite an appalling state of affairs in the tower after the substitution of plates for the coke.

It is in the condensation of the furnace gases that the great value of coke will always make itself felt, and there no Lunge plates will ever compete with a rational coke packing.

Mr. MARTYN thought that a careful comparison of the relative merits of the two systems of condensing hydrochloric acid must result in a pronouncement in favour of the coke condensers. The points for comparison in each case were, firstly, the original cost of the plant; secondly, the relative efficiency of the systems; thirdly, the expense of maintenance and depreciation; and lastly, the cost of the supervision. As four plate towers were required to do the work of one coke tower, the first cost of the system could be but slightly in favour of the plate towers. With respect to efficiency, he (Mr. Martyn) thought that coke towers would be hard to beat. As a coke tower would last some 30 years, the item for maintenance and depreciation would naturally be less than in the case of the plate towers, subject, as the latter would be, to very great variations in temperature. Naturally also four plate towers would

require more supervision than the single coke tower, and though for some purposes plate towers might be found to be peculiarly suitable, yet it was unlikely that they could be generally substituted in this country for the coke condensers.

Dr. BRIDGES pointed out that the large cooling space through which the hot gas had to pass before reaching the plate tower must contribute largely to the efficiency of the system. He should like to know whether the effect of externally cooling the gas by a water spray had ever been ascertained.

The CHAIRMAN, replying to Dr. Bedson, said that though the effect of a water spray in actual contact with the hot gas had been tried and was known, he had never heard of the external application of water merely as a cooling agent.

Dr. LUNGE replies by letter as follows:—

An advance copy of Dr. Hurter's criticism on my paper on Practical Results of the Lunge-Rohmann Plate-Towers having been sent to me by the Hon. Secretary of the Newcastle Section, I beg to reply to it herewith.

Dr. Hurter estimates the gas space in front of my towers at 1,000 cub. ft. for pan and muffle combined, and he contrasts this with the "wonderful results" alleged to be obtained with 74 cub. ft. of plate room, hinting that the space in question really does the greater part of the work. I can satisfy him on this point. The pipes, empty towers, and bombonnes in front of my towers (except the last six for each set) were provided by the desire of the owners of the works, and acted entirely as cooling space, such as the great majority of English and other alkali works provide in front of their proper condensing apparatus. I never asserted that this cooling space could be diminished when adopting my system; I always thought it very irrational to neglect a thorough preliminary cooling of the gases, in full accordance with the views of the late Dr. Angus Smith, although perhaps not with some modern theories and practices which I cannot profess to refute on this occasion (it is done in Vol. II. of my "Sulphuric Acid and Alkali," which is to be published shortly). This cooling space at Duisburg condenses most of the sulphuric acid, but only a few per cent. of the HCl.

The six bombonnes (66-gallon receivers) in front of the plate-tower, as is clearly proved in my paper, served almost entirely for equalising the unavoidable variations of work. I quote the absolute figures from my paper, only converting the specific gravities into degrees Twaddell: acid running directly from the pan-tower 29.6° from the muffle-tower 29° after having passed through the six bombonnes, 32° and 32.6° respectively. That is all the work they did in connection with my towers, whereas Dr. Hurter knows very well that those continental works which condense in bombonnes generally use a hundred such for a pan and furnace with a coke-tower at the end. I have from the very first demanded that a few such receivers should be placed in front of my towers: 1st, to equalise the variations of work; 2nd, to bring up the strength of the acid to that required for sale; 3rd, to serve as an acid store, exactly as is done in the case of ordinary coke-towers; the only novelty in the Duisburg apparatus being that as few as six receivers of 66 gallons each have been found to be sufficient, whereas I formerly thought a few more were required for the above purposes.

Mr. Lasche's paper shows that the coke can be entirely dispensed with by providing a better dividing apparatus at the top of the tower.

Dr. Hurter makes a calculation according to which—judging from the strength of the acid flowing from the coke on to the plates—the coke, amounting to about 50 cub. ft. for the pan and muffle together, would have done 74.7 per cent. of the whole condensing work, the plate space 11.8 per cent., and the bombonnes 13.3 per cent.

My explanation was originated by Mr. Lasche, and proved to be at least partially correct: that the result obtained after removing the coke was not, as Dr. Hurter says, "very bad indeed," but 170 parts acid of 32° to 100° of salt, which is probably superior to the majority of works; that by adding a few more plates the yield, without any coke, rose

to 17.8 acid of 32, which is probably superior to the *bona fide* results of nearly all other alkali works, although Dr. Hurter composedly still calls it "bad"; that the 15 bottom plates in my towers, with 12-mm. holes, were practically inactive, and Mr. Lasche considered that if, in lieu of them, plates with 7-mm. holes had been present, the coke would have been entirely useless; that the exit pipes were only a few inches wide, and any gas tests taken in them cannot for a moment have been compared with the English alkali inspectors' chimney tests; that the owners of the Duisburg works are extremely satisfied with the results obtained, and have put up another plate-tower set, undaunted by the "appalling state of affairs" which Dr. Hurter says must have existed.

1. Dr. Hurter says: "As far as the managers at Duisburg went in the substitution of plates for coke, the results are decidedly in favour of coke, and they are alive to that fact." That sounds, and evidently is intended to sound, as if the Duisburg people had generally convinced themselves that a coke-tower is superior to a plate-tower, the truth being that they do not dream of employing more than that trifling quantity of coke space (about  $\frac{1}{3}$  of an English coke condenser) above the plates, as is distinctly said in Mr. Lasche's paper, and that the managing owner at the last meeting of the German Society of Chemical Industry, loudly declared it would be simply foolish not to apply my system in future.

2. Dr. Hurter says: "100 parts of rock-salt yielded in the shape of liquid acid—

	Per Cent. of pure HCl.
(1) When working with coke.....	58.8
(2) " " without coke.....	32.6
(3) " " with plates instead of coke..	55.6

The first and third figure are right: the first representing an actual yield by my system of 96.2 per cent. of the theoretically possible yield from 98 per cent. rock-salt. But for No. 2 Dr. Hurter has chosen the figure obtained at the very first trial after removing the coke, and he glides over the fact that the yield at once rose to 52.4 per cent. pure HCl by simply improving the distribution, exchanging some plates for others with narrower holes, and adding one plate for the better distribution of the water, but before putting in the additional ten plates intended to replace the coke.

3. Dr. Hurter says: "If on the top of the 6 ft. of coke another 6 ft. had been placed, the disappearance of the large bulk of HCl would have occurred in the upper 6 ft., and the condensation of the lower 6 ft. of coke would have been a very small fraction, and not as before, 75 per cent." My readers will probably think that I must have misquoted Dr. Hurter, in crediting him with the assertion that the large bulk of the HCl is not condensed in the lower part of a coke-tower, as the world had hitherto believed, but in the last 6 ft. of coke at the top; but I have quoted verbatim from the copy supplied to me, and I would rather not weaken the effect of that passage by any comment of mine.

In reply to Mr. Martyn, it is scarcely correct to say that four plate-towers are required to do the work of one coke-tower. There is only one small plate-tower for the pan and another for the muffle, and the cost of maintenance for these is no greater than for coke-towers. Nor is there any reason why the item for supervision should be greater in the one case than in the other, the small size of the plate-towers making them more easily accessible and manageable than coke-condensers.

In concluding the meeting the CHAIRMAN said that he wished to express his regret at the great loss the Section had sustained owing to the removal of Dr. Dunn to another part of the country. During 14 years he had rendered invaluable service as honorary treasurer and secretary to the Section, and at a special meeting of the Section shortly to be held, the members would have an opportunity of expressing in a material way their sense of the importance of these services.

SESSION 1894-95.

Dates of Meetings.

Glasgow.—Philosophical Society's Room, 207, Bath Street. January 8th; March 5th; May 7th.

Edinburgh.—Philosophical Institution, 4, Queen Street. December 4th; February 6th; April 2nd.

Meeting held in the Philosophical Society's Rooms, 207, Bath Street, Glasgow, on Tuesday, November 6th, 1894.

MR. R. IRVINE IN THE CHAIR.

### CHAIRMAN'S ADDRESS.

I HAVE to thank you for the honour you have conferred upon me in appointing me Chairman of the Scottish Section of the Society of Chemical Industry. It will be my earnest endeavour to uphold and increase its position and influence for good.

The able presidential address, delivered by Mr. E. C. C. Stanford at the Edinburgh meeting last July, must have impressed all who heard it, or have since read it in our Journal, with the vast and far reaching horizon of the work in which the Society of Chemical Industry is engaged; the beneficent influence it may have upon mankind in the present, and far more so in the unknown future of chemical science, as applied to its commercial developments.

Such an address deserves a distinguished place in the annals of our Society.

While entirely agreeing and sympathising with his views, it is somewhat trying to have to meet you in the emasculated condition the comprehensiveness of such an address leaves me. Therefore, instead of following the usual rule of confining my remarks entirely to the enumeration of new chemical creations during the past year, I may be excused if I occupy a part of your time in recalling some pleasant reminiscences in connection with our meeting in Edinburgh, where many old friendships were renewed, and from which many new and pleasant acquaintanceships originated.

Although Edinburgh and its immediate vicinity cannot claim to be a centre of chemical industry, her principal manufactures being alcoholic liquids, chloroform, and drugs, paper, printing-ink making, &c., still considering the interesting nature of the ancient town, with its beautiful surroundings, the hospitality of its magistrates and citizens (which was only bounded and controlled by the absurdly short time to which the meeting was confined), I am sure that visit must have come to many weary chemical souls as a pleasant change.

It was unfortunate that owing to the small-pox scare the attendance of members at this meeting was comparatively small, doubly so, considering the complete nature of the preparations made by the acting committee for the comfort

and convenience of a much larger number of guests; which arrangements, at the last hour in many cases, had to be entirely altered to suit the altered circumstances. Railway, coaching, and other arrangements were all dislocated, and general confusion must have resulted had it not been for the energy and administrative ability of the local secretary and treasurer.

The fact came home very forcibly to the committee that the three days set apart for the annual meeting were quite insufficient for the programme they had prepared.

Everything had to be so nicely timed that there was no room for expansion in the arrangements when any hitch arose. When next we welcome the Society to Edinburgh we must do our best to have the time extended so as to give members a reasonable opportunity of realising that the amenities of the town are not confined to refuse destructors, breweries, distilleries, &c.

As part of our programme, and in order that our guests might see something of the venerable "Old Edinburgh" the committee arranged to have "personally conducted tours" through that portion of the town lying between the Castle Rock and Holyrood House, representing as it does in its many relics much of the ghostly past in Scottish history. I had the curiosity to inquire how many took advantage of this opportunity, and found that only two members had been able to perform this interesting journey. The university, law courts, industrial museum, theatres, cathedrals, clubs, and citizens generally held open hands and doors to the harassed members in vain. Every moment of their time was otherwise occupied. Engagements, represented by numerous varicoloured tickets demanding their presence at so many places at one and the same time.

It is unnecessary to do more than thus casually refer to the holiday aspect of our meeting, and if some difficulties occurred, or mistakes arose, causing disappointment to individual members, these were the result of unfortunate circumstances over which the "hurricane committee" (as our local secretary quaintly designated it) had no control.

Before passing to review some of the chief industries visited in our excursions, it may not be invidious, however, to make an exception by recalling our very pleasant excursion to Perth, where the Messrs. Pullar and the magistrates of that town treated us as their guests with such princely hospitality.

#### Shale-Ore Industry.

In a former number of our Journal the general processes as carried out five years ago at Broxburn Oil Works are described in a paper by Mr. D. R. Stuart.<sup>†</sup>

Through the kindness of Messrs. Kennedy and Henderson, managing directors of that company, I am enabled to lay before you a concise account of the latest advances in the processes and manufactures by which means that great company has been able, "in a manner," to hold its own in face of the overwhelming competition of American and Russian natural oil supplies; with valuable statistics of the past and present condition of the mineral oil trade in Scotland, accompanied by a *history* of this industry, to which I will first refer.

TABLE I.

#### HISTORY OF THE MINERAL OIL INDUSTRY.

1830. Ireland, Peat Co. incepted by Mr. Moir Crane. First paraffin for candles.

1848-50. Alfreton Spring. Worked by Jas. Young. 300 gallons a day. Object—lubricating oil. Playfair, December 1847, letter to Jas. Young.

1851. Young's patent. Torbanchill coal, or Boghead.

1862. Boghead coal exhausted. 1862 Robert Bell worked shale at Broxburn.

1859. Petroleum. Colonel Drake.

Scottish trade.

1st period, 1850-64. Young's patent.

2nd period, 1864-72. Development of petroleum—(in 1871 there were 51 works).

3rd period, 1872-78. Great struggle for existence in 1873 (21 works gone). Smaller works disappear. Production concentrated.

4th period, 1878-87. Lucrative. 25 per cent. dividend at Broxburn. New oil fever. Over production—collapse increased production of ammonia becomes important.

5th period. Combination period. 13 works.

TABLE II.

The following table gives details of the progress of this manufacture from 1871 to 1894:—

	1871.	1878.	1887.	1894.
	End of 1st Period, 51 Works.	End of 2nd Period, 18 Works.	End of 3rd Period, 13 Works.	
Shale.....	Tons. 800,000	Tons. 850,000	Tons. 1,800,000	Tons. 1,947,812
	Galls. 25,000,000	Galls. 26,000,000	Galls. 52,500,000	Galls. 48,600,000
Crude oil.....	11,250,000	11,400,000	21,680,000	26,452,341
Naphtha and burning oil and gas.	2,500,000	5,000,000	9,000,000	8,745,253
Lubricating oil.....	Tons. 8,500	Tons. 9,200	Tons. 22,800	Tons. 19,150
Paraffin solid.....	2,250	4,750	18,483	28,000
Sulphate of ammonia		Capital, £1,300,000	Capital, £2,000,000	

TABLE III.

SHOWING OUTPUT OF SHALE IN SCOTLAND AND PRODUCTS FROM 1873 TO 1891 BY R. T. MOORE, C.E.

Output of Shale in Scotland from 1873 to 1891 (from paper by R. T. Moore, C.E., 1892—Federation Institute of Mg. Engs.)

Year.	Tons.	Year.	Tons.	Year.	Tons.
1873	524,005	1880	759,777	1887	1,300,320
1874	560,910	1881	912,171	1888	1,052,292
1875	424,023	1882	934,487	1889	1,086,500
1876	541,273	1883	1,133,720	1890	2,180,183
1877	684,118	1884	1,469,049	1891	2,337,302
1878	645,950	1885	1,741,750	1892	2,077,076
1879	712,428	1886	1,900,144	1893	1,917,842

Net prices realised at works (from paper by R. T. Moore, C.E.).

Year.	Naphtha and Burning Oil per Gall.	Lub. Oil per Gall.	Med. Oil per Gall.	Seal. per Lb.	Sulphate of Ammonia per Ton.
1877	Pence, 9.275	Pence, 11.004	Pence, 6.668	Pence, 4.31	£ s. d. 17 5 6
1882	4.313	7.347	4.005	2.49	18 2 5
1887	3.160	2.200	1.060	2.125	19 5 0
1891	4.176	3.715	2.806	2.262	19 7 1
1892	3.400	3.005	2.250	1.750	10 0 0
1893	2.730	2.950	2.100	1.750	11 12 6

Although the figures from 1889 show the production of shale to be larger, the quality has been deteriorating so far as oil yield is concerned. There is a great improvement in the quantity of sulphate of ammonia from the newer methods at work.

\* There seems to be a discrepancy between Tables II. and III., as to the output of shale. I think the figures of Table II. may be accepted as the more accurate, looking at the output of crude oil.

<sup>†</sup> Vol. VIII., p. 190. February 28th 1889, D. R. Stuart.

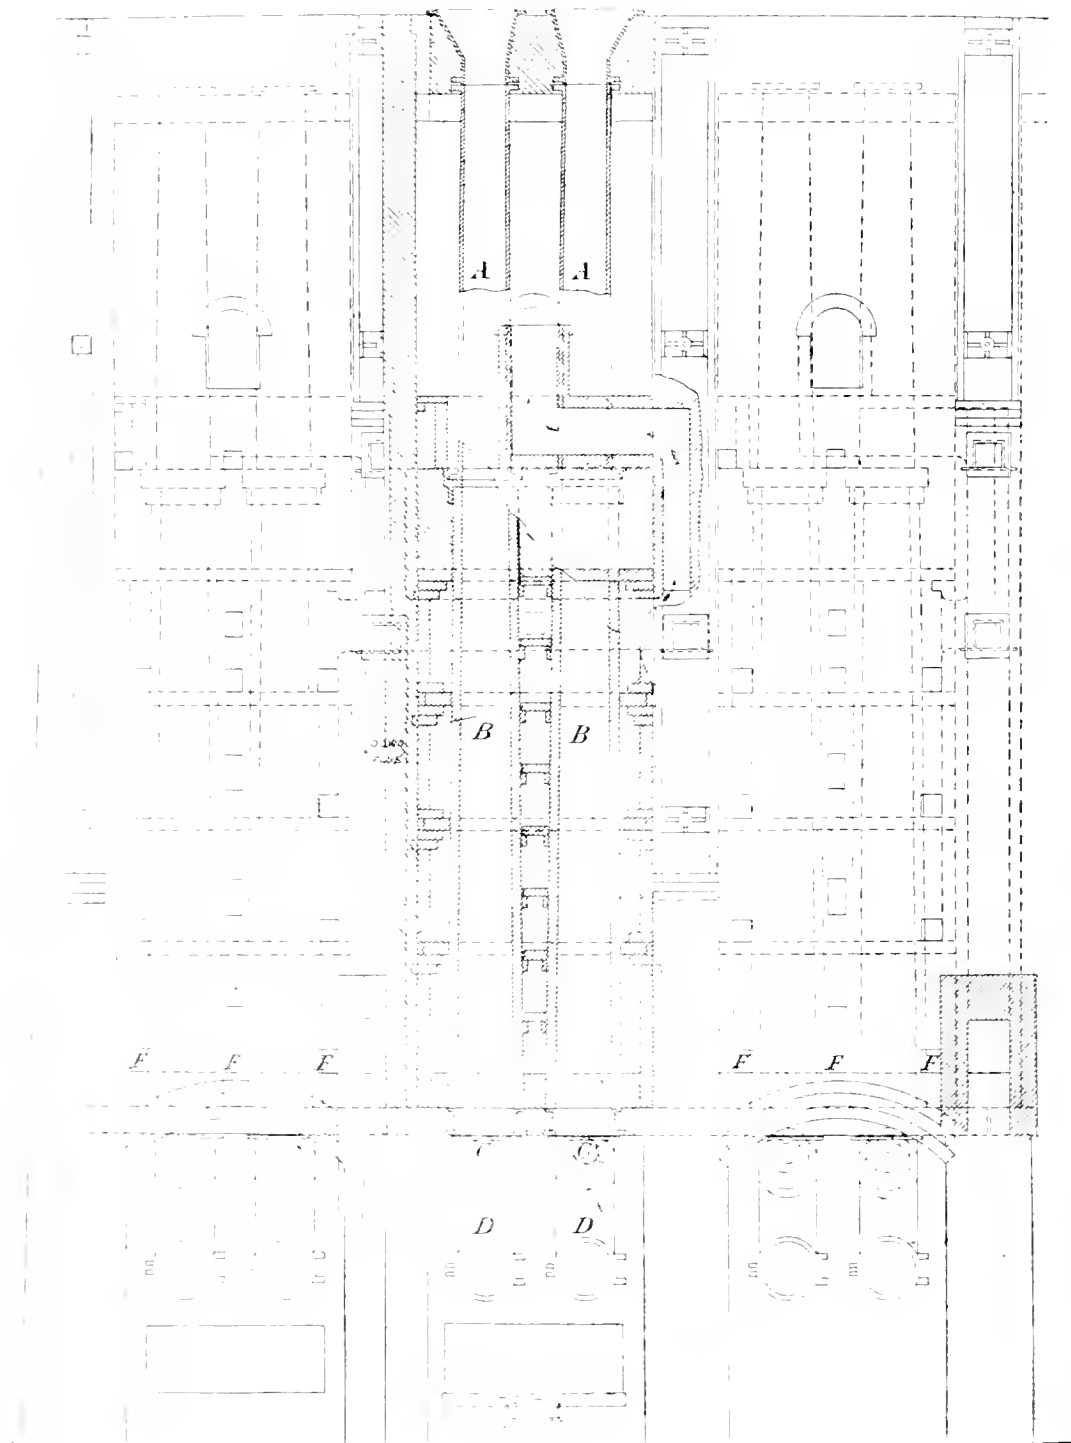

When first this great business was introduced the principal object was to obtain burning oil (then selling about 9d. per gallon), but competition, and more especially the flooding of the world's markets with burning oil from America and Russia, has now reduced the price of Scotch oil to less than one-third, namely, 2·730d. See Table III.

As has been the case with the coal gas and many other industries, so also in this, the residual products, which

at first had been considered of little importance, more and more came into prominence, and had to bear the burden of this reduction in prices, and consequently these have now practically taken the premier position as money earners for such Scotch oil companies as are now able to pay dividends.

In this respect the present position of matters at Broomburn is, that the sulphate of ammonia obtained from one

Fig. 1.

ton of shale (72 lbs. in weight) pays all expenses, including royalties, mining, and retorting, so that their crude oil costs them practically nothing, and consequently the shales, which in old days were considered too poor to work for oil alone, are now preferred, owing to the large amount of ammonia they produce.

Young and Bielby were the first to realise this important fact, and the success attending their investigations, and the practical results obtained by the use of their system of

shale distillation, must be patent to all conversant with the history of this manufacture, and I need not refer further to their process of retorting, as the following description of the new "Henderson retort" embodies their idea of a continuous distillation of shale, beginning at a low temperature, 200° F., and ending by exposing the shale char, from which the oil has already been extracted, to a very high heat, 1,500° F., in the presence of superheated steam.

Fig. 2.

HENDERSON'S IMPROVED PATENT RETORT.

At Broxburn Comp's Works we saw the new retort (patented by Mr. Henderson) in operation, and what must have struck all, with admiration, was the perfection of the apparatus, when appeared to do its work automatically, only requiring the guiding hand of man in trifling details.

TABLE IV.

DESCRIPTION OF DRAWINGS AND WORKING OF HENDERSON'S IMPROVED RETORT (Patent No. 6,726, A.D. 1889) FOR THE DESUBJECTIVE DISTILLATION OF SHALE, &c.

"The object of this improved retort is to get a larger yield of sulphate of ammonia without deteriorating the quantity and quality of the crude oil. The retorts are vertical, 28 ft. long. In the upper cast-iron portion of the retort A, the oil is first distilled off the shale at a temperature of about 900° F. The spent shale is then passed downwards into the brick portion of the retort B, which is kept at a constant temperature of about 1,300° F. The shale, in passing down through the retort, is kept in constant motion by a roller C at the bottom, which delivers it into a hopper D below, at the required rate. This continuous motion largely increases the yield of ammonia and permanent gases from the carbon of the shale; it also regulates the working of the quantity of shale to be put through, and prevents the exhausted material from fusing and sticking in the retort under the higher temperature. All the products of distillation are drawn off the top of the retorts through the branch pipe E.

"The retorts are heated with gas made from dross coal made in gas producers, and introduced at the ports F. The incondensable gases are also returned to the heating chambers, and mixed with the producer gas to assist in heating the retorts.

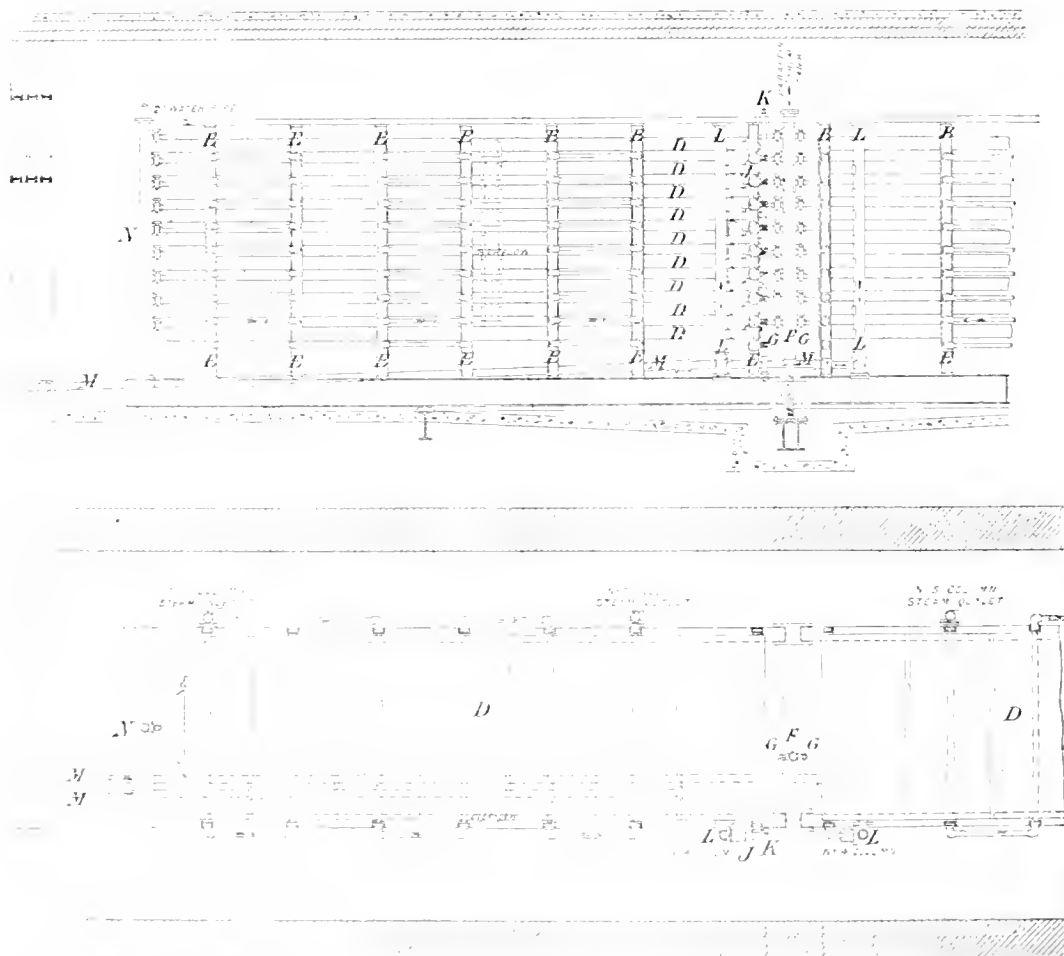

"On the tops of the retorts are fitted large malleable iron hoppers, capable of holding about 18 tons supply of the raw shale. These have been found to be of great advantage in the regular working, in dispensing with all night and Sunday labour.

"The above retorts are now adopted by the Broxburn Oil Company, Limited, and have proved most satisfactory, giving the maximum yield of products with the minimum of labour."

*Comparison of Past and Present Retorts, as worked at Broxburn.*

"The old Henderson patent retort of 1873, gave, with the Broxburn shale, about 31 gallons crude oil, 15 to 17 lbs. of sulphate of ammonia, 75 per cent. spent shale containing 12 or 13 per cent. of combustible matter, which was dropped hot into the furnace below for fuel; and about 2,000 cubic ft. of permanent gas. With the present retort, after extraction of the crude oil, 31 gallons to the ton, the spent shale passes into the brick retort below to be acted on by steam at a high temperature. This gives, for fuel, gas (like producer gas) of about 15,000 cubic ft. per ton of shale, and the sulphate of ammonia is increased to 44 lbs. per ton. With Drumshorland shale at the Broxburn Oil Company's

Fig. 3.

Roman Camp Works, the crude oil got is about 20 gallons per ton, and sulphate of ammonia about 72 lbs. Spent shale contains 26 per cent. of alumina, equal to about 14 per cent. of aluminium."

From the hurried nature of our visit to Broxburn, it was difficult to carry away a clear idea of the various processes now in use there, but all must have been especially impressed with the wonderful ingenuity displayed by Mr. Henderson in his new adaptation of the old sweating process for the purification of the dirty looking crude paraffin scale, into the pure translucent wax, entirely devoid of colour or smell, and directly fitted for the manufacture of candles. Subjoined are detailed explanations of the new system.

### Purification of Paraffin Wax.

#### DESCRIPTION OF WORKING.

"The crude solid paraffin from the filter presses, after being melted in a tank, is pumped direct through the vertical charging pipes and through the small cocks into the horizontal trays of the sweating apparatus."

"Before charging the trays, the diaphragms are covered with about half-an-inch of water from the small cocks on the charging pipes N which prevents the melted wax from running through the diaphragms, when the trays have been charged, the crude paraffin wax is allowed to congeal, then the water is run off from the bottom of the trays through the same swivel nozzles into its own receptacle. The chamber is now shut up and the suitable heat applied. Complete arrangements are made at the end of the horizontal pipes M for changing the various products into their own receptacles; beginning with the water, then with the various grades of paraffin, up to the refined wax. This can be regulated to any grade of paraffin required."

"This process has been largely adopted, and is now the only one used in the Broxburn Oil Works, being a great saving in labour over the old methods. In the old method of working, the crude paraffin wax was passed from the filter presses and further put through hydraulic plate presses, which entailed much more expense in machinery and labour than are necessary with the above improved process."

Fig. 4.

LONGITUDINAL ELEVATION AND CROSS SECTION OF APPARATUS FOR TREATING AND PURIFYING PARAFFIN WAX. (Patent No. 11,799, A.D. 1891.)

"The drawings accompanying this description show an apparatus capable of refining 14 tons crude paraffin wax at a time, and which can be charged from 2½ to 3 times a week according to circumstances."

"The sweating apparatus is arranged in a horizontal elongated chamber about 52 ft. by 13 ft. by 10 ft. high constructed of brickwork with a suitable roof, and fitted with pipes heated by steam. Besides the heating pipes A,

ranged along the sides of the chamber B, there are transverse heating pipes C, which also serve the purpose of carrying the trays D, being fitted in vertical standards E. The charging pipes F are fitted with cocks G. In the bottom of the horizontal trays D there is fitted a wire gauze diaphragm H. These diaphragms are fixed with bolts to the ends of the trays, and rest on cross bars I. The bottom of the trays communicate with short pipes with swivel nozzles J, constructed to work with worm wheels from worms on a vertical shaft K, this arrangement allowing all the swivel nozzles from the bottoms of the trays to be turned at once."

"The various liquids separated in the refining of the wax are drawn off through the swivelling nozzles into cups or hoppers on the standard pipes L, which lead them into horizontal pipes M, through which they pass to suitable receivers for collecting the various qualities of products."

The history of this oil industry is an object lesson. Not only so in respect to the civilizing influences it has had upon the mass of the people of the world, but of the unattainability of brightest hopes and prospects of those engaged in it.

As regards Scotland, we had her oil companies paying till within a few years from now, splendid dividends to their shareholders; then the clouds of misfortune descended, dividends ceased, and most men would have given up the unequal battle in despair, in place of which, however, skill and indomitable perseverance have overcome difficulties which seemed insurmountable, and with the improved processes now at work there seems a fair chance of a return of prosperity.

### Flash-point of Mineral Oils.

If I refer to the vexed question of the flash point of mineral oils used for burning in lamps, I do not seek to complicate a question which is at present "sub judice."

The subject is beset with a variety of complications which affect great commercial interests, but upon this part of the problem of course I have nothing to say.

Taking the question in its utilitarian aspect there can be no doubt that much of the oil sold in this country for household use is of an unsafe nature, and the *petroleum death rate* now ranks with other forces inimical to the human race.

Much has been, and is being written upon this important topic, but the supineness on the part of the public, coupled with the general want of interest in this vital question, makes it careless as to an evil and danger which happily only comes home to comparatively few.

Outside the Government commission, and apart from petroleum party confederations, the public should take up the matter and only buy and use such oil as is practically safe, and if insurance companies, who suffer so much from fire losses directly caused by the use of low flashpoint oil, were to bar the use of dangerous illuminants, this, to them, ever present danger would soon disappear.

Trifling causes generally sway the public taste, and the less unpleasant smell of Russian and American burning oils, which can be had at a cheap rate, keep them in favour, in defiance of any risk attending their use.

In this respect, with safe Scotch burning oil prepared from shale, the comparison is unfavourable. I venture to suggest that efforts should be made to overcome this sentimental (?) objection, and I have no doubt that sweet-smelling Scotch oil, with a flashpoint of 100° F., would then be preferred to the more dangerous varieties.

If the Scotch maker can accomplish this (and will do it), the Russian and American producers would in self-interest be bound to follow their excellent example by only selling safe oil. In America I understand the 100° F. flashpoint oil is in general use. Of course, there are many imported oils perfectly safe, but prices for such are high. The whole question relates to the oil supplied to the poor—not to the rich. Of course, opinions differ as to the cause of lamp explosions—Lamp *c.* Oil here—Oil *c.* Lamp there—one side believing that badly constructed lamps make it unsafe to use any mineral oil however high its flash point may be: the other side arguing, with some justice, that bad oil will be unsafe in lamps of the best construction.

Are we in Scotland not making too much of this low *v. g.* flash-point question? Regarding the above circumstances should we not rather try to meet the difficulty of dealing with low flash-point oils by a change in the construction of the lamp in which such oils are burned?

As presently constructed almost all of these lamps consist of a metallic burner and fittings, supporting the ink communicating directly with the oil reservoir, upon which the burner rests; only one or two inches of space intervening between a flaming heat of 1,000° F. and a considerable quantity of a very inflammable liquid.

Is it impossible to construct a lamp with the burner 6 or 8 inches above the oil reservoir (which could then form a convenient base for the lamp-stand), and thus remove the real source of danger, or let the oil reservoirs be the same distance horizontally from the burner?

#### Oil Gas.

At Perth Gas Works, the latest adaptation of the process for gas enrichment was seen in operation, by means of the addition of mineral oil gas to coal gas.

By this means the illuminating power of poor gas is raised to a degree beyond what would be expected taking the "*Light Values*" of both into consideration. This is a matter now becoming of great and essential importance, owing to the fact that most of our valuable and high-class qualities of *gas coal* are exhausted. The large supply of mineral oils now so low in price provide not only a cheap material for the enrichment of poor coal gas, but also (as practised in America) render non-illuminating water-gas (so called, obtained by passing steam through incandescent coke) of value as an illuminant.

There can be no doubt that this process which is a simple and economical one, will be universally adopted in the future and in many cases, this high-class gas will hold its own with its charming rival the electric light.

#### *Remedial Measures for purifying Water in connection with Paper Mills.*

At the mills of Messrs. A. Cowan and Sons and J. Brown and Co., Penicuik, the members had an opportunity of studying in detail the "Remedial Measures" now in common use in most paper mills in the vicinity of Edinburgh, especially those of the "Esk Waters" for the prevention of pollution.

These measures have been so successful, and the fouling of the water of these rivers has been reduced to such an extent that we may soon expect them to be teeming with trout (and even salmon), and a return to the condition of "fifty years ago" (before esparto boiling was dreamt of), when the disciple of Isaac Walton practised their gentle craft.

Dr. Stevenson Macadam, a prominent member of our society, may well be proud of his share in this great improvement.\*

The following details will be of interest not only to this Section but to the members of the Society generally. They apply to all the paper mills situated on the North Esk River, in the neighbourhood of Edinburgh, by whom they are strictly observed.

It is pleasant to reflect that such an agreement has been arrived at between the riparian proprietors and the paper-makers by which not only has the river water been rendered comparatively pure, but at the same time to the profit of the manufacturers, who have adopted the plans formulated by Dr. Macadam.

It is to be hoped that before long the conciliatory policy, which has in this case actuated the parties interested, may become of general adoption, not only for the prevention of this, but of all other forms of river pollution, which at the present day is a disgrace to our civilization.

The following are the rules observed by the paper-makers on the North Esk:—

"The general principles which regulate the mode of dealing with the impure discharges from the paper mills on the river are applicable to all the mills under the agreement,

but are sufficiently elastic to admit of considerable variation in the mode of working, so as not unduly to interfere with the individual methods of manufacture, or with the special arrangements of each mill. The separate schedule of regulations issued under the agreement to each mill is intended for the guidance of that mill alone, and may be regarded as the special method of carrying out the necessary preventive processes for dealing with the polluting materials.

The general remedial measures applicable to the whole mills on the river may be summarised as follows:—

1. All isparto boilings and second waters being first coolings go to the roasters, and none flow, directly or indirectly, through the ponds or otherwise to the mill lade or the river.
2. All other esparto cooling waters and stronger steeps, whether re-used or not, go ultimately to the roasters, and none pass, directly or indirectly, to the lade or the river.
3. All weaker esparto steep waters containing at the maximum not more than 200 grains of total residue in the imperial gallon, and on the average not more than 100 grains of total residue, and not more than five grains of alkalinity calculated as hydrated caustic soda in the imperial gallon, may be discharged through the pond system to the general outflow, provided no washing waters from the esparto breaking engines are passed away from the same mill.
4. Where no steep waters are discharged through the pond system to the general outflow, then washing waters from the esparto breaking engines may be sent through the ponds and general outflow instead thereof, provided these washing waters conform to the standard of quality given in paragraph 3.
5. When rags are used in esparto mills the boilings at least go direct to the roasters, and coolings, either directly or after re-use, go also to the roasters. Steeps from rags and washing waters from the rag-breaking engines may go through the pond system to the general outflow.
6. All spent bleach liquor to be re-used as much as possible, and the residual liquid may be sent through the pond system to the general outflow.
7. Presse-pâte waters and ordinary machinery waters to be re-used as far as possible, but when discharged to go through the pond-settling system and thence to the general outflow.
8. All discharge liquids flowing from the ordinary working operations of the mill to pass through the settling pond system and by a common outlet to the lade or river, and the *bona fide* combined effluent shall not be diluted with extra water at any stage, and shall not contain more than 100 grains of total residue in the imperial gallon. It should be neutral, but if alkaline, shall not exceed alkalinity equal to five grains of hydrated caustic soda in the imperial gallon of the discharge.
9. All drainings from the pond sludge ash filters to flow by a visible outlet to the lade or river, and shall conform in quality to the standard given in paragraph 8 for the general overflow.
10. Spent bleach sludge, settling pond sludge, causticising lime, ashes, founds of buildings, and other rubbish not to be deposited on the banks of the river or lade, or within reach of the water at any time.

The discharges from all the mills are repeatedly inspected during each week, in some cases every day, and occasionally several times in the day. Whenever the appearance of the outflow, or its alkalinity, or its effect in the lade or river indicate that the discharge is unduly polluting, then a sample is taken, and on subsequent examination a number of these samples are selected for analysis. The results prove that the discharges from the mills under the agreement practically fulfil the conditions of paragraph 8, alike as to total residue from the imperial gallon and as to alkalinity. The discharges which fail to come within the

limits of paragraph 8 are comparatively few, and are found to be unduly polluting from observed inattention to the practical remedial measures.

There can be no doubt, therefore, that with the employment of properly constructed remedial measures and with ordinary care and attention in the working of such, there need be no difficulty in keeping the quality of the discharge from any paper mill well within the given standards."

#### *Treatment of Town Refuse.*

To attempt to master even the literature (if I may use such an expression) of the sewage question would be almost as hopeless a task as the practical treatment of the subject has proved to be. Apparently only nature can regulate this vast volume of waste (?) material in her own economic ways. That great brooding mother—the ocean—into whose bosom the "waste matter" of the world is carried returns to us what we think we have lost. Thus, literally, we cast our bread into the waters, and it returns to us in the liberal food supplies she affords. With solid refuse of towns it is otherwise, farmers will not buy it, and we now burn it—sometimes not in a very skilful manner—in what we truthfully, and to our shame, call destructors. All the valuable nitrogenous matter, tar, &c., goes up the chimney, often to the annoyance of the public. Why is the refuse not retorted in the same manner as shale is, and the ammonia saved? Surely as much sulphate of ammonia would be obtained from town refuse as would make its treatment profitable instead of a burden upon the town rates.

#### *Gold Extraction.*

The importance of the increased production of gold during the last few years must have startled all who have watched the development of the gold getting industry, more especially in Australia and Africa.

Alluvial deposits have long since been practically worked out, and it is now exceptional to find gold in mass. The more troublesome and costly, although perhaps more certain, method of extracting the metal from its original matrix (of quartz or other rocks), or from the heaps of waste material—the residues of processes formerly in use and known as tailings—by chemical in place of mechanical means has given rise to a variety of new methods, some of which are now in successful and extensive operation, in gold bearing districts.

The well known "chlorination" process is suitable for certain classes of ores and for these is in common and profitable use, but in many cases, especially where the ore is of a basic nature, much chlorine is lost as it decomposes and combines with the basic matter before combining with the gold.

By far the most important and successful application of the many chemical processes for the extraction of gold, and especially suitable in the case of even the poorest tailings and most obdurate ores is the "cyanide of potassium" method, known after its introducers as the Macarthur-Forrest process. This may be termed a development rather than an invention, for it has long been known that gold was readily soluble in (or would combine with) solutions of alkaline cyanides. Be that as it may these gentlemen have succeeded where others have failed in developing what was merely a laboratory reaction into a profitable and important new industry.

They employ a very weak aqueous solution of cyanide, *about one tenth per cent.*, 2 lbs. of the salt being usually sufficient to dissolve the gold in one ton of ore or tailings, and this by simply filtering the cyanide solution through the powdered material. The lixivium so obtained is passed through filter boxes filled with the finest zinc shavings where the gold is deposited as a brown mud, the cyanogen which held it in solution passing away in combination with the zinc. Thereafter this mud is melted into bullion.

The following figures show what rapid progress this process has made in the comparatively short period of three years, and it seems to me if such a splendid advance continues to expand to its legitimate end we shall have in the future what will be equivalent to the discovery of such new sources of wealth as astonished the world in the

middle of this wonderful century—and what happened then as the result of great additions to our gold supplies will unquestionably hold good in the near future with the *additional supply of gold; land, and its animal, vegetable, and mineral products* will again rise in value, and the abnormal conditions, which to many in the past have suggested a bimetallic standard as the only way out of the scarcity of our real standard metal gold, will cease. Consequently wages will rise and commerce will be conducted on more sound and legitimate lines. This is not the language of romance. One company *alone* (to quote from actual figures, see below) if they continue their operations on the lines of the last three months will by means of the Cyanide Recovery process add nearly three million sterling per annum to the gold supply of the world.

The African Gold Recovery Company (Limited) announce that 55,000 ozs. of gold have been recovered at the Randt, and 7,100 ozs. in other districts, a total of 62,100 oz. during the month of September, by means of their Macarthur-Forrest cyanide process. The August total was 64,258 ozs., and that for July 57,500 ozs. For the past three months (the first three months of the company's financial year), the amount of gold obtained is 183,858 ozs., as against 102,390 ozs. for the same period of last year. The following are the details monthly to date since the company began operations:—

	1894.	1893.	1892.	1891.
	Ozs.	Ozs.	Ozs.	Ozs.
January.....	51,000	17,500	9,700	..
February.....	51,500	16,963	10,366	..
March.....	56,500	20,000	11,700	..
April.....	56,500	20,050	13,500	..
May.....	57,850	24,000	13,500	..
June.....	58,000	27,100	16,045	..
July.....	57,500	20,300	16,451	..
August.....	64,258	56,000	16,648	..
September.....	62,100	37,000	16,986	..
October.....	..	38,000	17,771	3,300
November.....	..	40,310	17,305	5,732
December.....	..	44,200	18,000	8,300

The enormous "placer" finds of gold during the period of 1850 to 1870 reached 30,000,000*l.* to 40,000,000*l.* sterling per annum, but these have now given place to a later yearly average output of 15,000,000*l.* to 20,000,000*l.* since that auriferous period gave out. Taking the later figures to represent the actual gold output of the world since then, we see the one Gold Company, quoted above, giving to the world from one-fifth to one-seventh of this whole amount; and that principally recovered from hitherto useless waste or refuse material.

By the application of the Macarthur-Forrest process to fresh ore (presumably richer in gold than these waste heaps of already partially exhausted material) we have reasonable grounds to infer that, apart from finding sporadically rich-bearing districts, the future gold extracting industry will yield to the world a very largely increased amount of bullion.

The successful adoption of the Macarthur-Forrest process has increased the demand for alkaline cyanides. This in turn has revived the old dreams of its preparation from atmospheric nitrogen—the El Dorado of many sanguine chemists,—but so far nothing has been done in finding a practical and profitable process. How soon success may attend these efforts, who can say?

A fresh source of the salt had, however, to be found for instant requirements as the output from the old "Prussiate"

\* We may be nearer a higher range of prices than many think.

process and from gas residual products was insufficient. To meet the new demand Mr. George Beilby, one of our distinguished members, with much patient work and great chemical ability has, I am informed, succeeded in preparing this substance on a practical scale in a condition almost chemically pure. For obvious and the best of reasons, my own ignorance, I cannot go into particular details: I can only thus briefly refer to his successful work by stating that he uses ammonia as the source of nitrogen in this new manufacture. Many others are working on the same lines, but as yet there seems to be little practical success outside his process. The field, however, is a wide one, and the workers are many, and we may any day hear of the discovery of even a simpler process than that invented by Mr. Beilby.

### *Coal Strike.*

This Section of the Society cannot fail to be interested in a result arising out of the late coal strike in Scotland.

Lamentable as its effects have been, still it has taught, or perhaps brought into greater and more pressing prominence, what most of us hitherto but dimly realised, viz., the superior value, as a fuel, of English as compared with the generality of Scotch coal. From a number of tests conducted on a large scale, my experience is that for steaming and heating purposes, quantity for quantity, four-fifths of English (Newcastle-on-Tyne) is equivalent to five-fifths of ordinary good Scotch steam coal. Prices being equal, therefore, Scotch coal is about 20 per cent. less in working value.

It must be a sorrowful reflection to the Scotch miners that English coal has now partly taken the place (in many instances with profit) of Scotch coal, and that such an anomalous condition of matters is not unlikely to continue. Also the coal fields of America, India, Australia, China and Japan, are gradually but surely cutting off the home markets.

There are many other matters it would be important to notice which I must pass over, but I cannot let slip this opportunity of addressing you, without advancing some personal opinions as to our procedure as a Society. Our Journal gives such full reports of the papers read at the several meetings of the Sections, and the discussions consequent thereon, that I need not make any special reference to our past work. But, looking forward to the session just begun, I would earnestly urge upon members the necessity of regular attendance at the Section meetings, and also in taking an active interest in the great object the founders of our Society had in view when it was established, namely, the communication of original papers, and thus diffusing useful information to our members.

But here a difficulty I have long recognised and to which I have before called attention comes into prominence. The interests of the Society corporate may often and naturally do clash with those of its individual members, in so far as inventors of new, or, of improvements in details of old processes, which it may be impossible properly to secure by patent rights, cannot be expected to lay the results of their hard earned work, by communications which our Journal thus lays open to the world over which it circulates. From such we cannot hope to have papers.

Young men fresh from the laboratory, a daily increasing host and for many of whom there is at present little or no scope, when engaged to act as work's chemist are generally bound down by agreement (legal or otherwise) not to disclose the processes they are engaged to watch or improve.

Work's managers are generally in the same position with the additional burden that they have to provide dividends for the companies they manage, so that the temptation here is all the other way. So it very much comes to this that the papers read before our Sections, with some bright exceptions, only relate to general matters, or are merely the description in bare outline of some chemical process with all the useful details necessary to success, carefully left unnoticed. Or they may be merely a rechauffé of old material in an encyclopaedic form. Or we may have sometimes wild schemes propounded in which chemical processes and known facts are alike disregarded. The wise member holds

his tongue as to what he knows or hopes to effect, for we can never forget that almost the entire membership of this Society are traders, united it is true to science by its noblest developments, but still traders, who have to make money, or to pay their chemists and managers to make it for them, and it is clearly against self interest to diffuse the means or processes by which we are, or would be, enriched. Thus one of the principal ends aimed at by our Society becomes in part its weakness and may be the cause of its failure in effecting the object for which it was established.

As time goes on, technical colleges and schools will more and more change this condition of matters. Already we have evidences of good work done in several important branches in the Arts, notably those of dyeing, calico printing and brewing industries, the results of which are published in journals dealing with these industries. Is it not our duty to affiliate such efforts more closely with our own?

Our late president referred to the admission of students or associates on easier monetary conditions than are now required, since the alteration of Rule 27 came into effect, which entails the payment of 2*l.* 5*s.* 0*d.* as admission fee, and the first year's subscription—a sum which although not high in itself may practically exclude a goodly number of young men to whom even such an expenditure would be a burden. I think it will be a great pity if this valuable suggestion be allowed to drop, as we must look to many of these young men not only ultimately to become members of our Society, but to fill and build up the ranks of the great army of Chemists and Managers of the Chemical Factories of our country.

The trying time for the student is when he leaves the scientific laboratory where he has been taught the theoretical rules and laws which govern chemical processes, but has had no opportunity of gaining experience of their practical developments, and I think it is the special duty of this Society to encourage, by every means in its power, any plan by which the young chemist may gain that experience which is required to fit him for his future work. In this the Chemical Society have an equal, if not a greater, responsibility than we have. I am delighted to see this is recognised by Dr. Armstrong in his address, delivered this year to that body, which forecasts the hope of a closer union and co-operation of chemical science, and its practical development represented by both Societies.

This may be met in part by Mr. Stanford's scheme which would provide for the sale of our excellent Journal along with the associateship of the Society at a small cost.

I would suggest a similar scheme should be adopted by the Chemical Society.

I confess that the great number of young chemists so situated who are eagerly clamouring for employment is a difficulty a way out of which in the present circumstances I cannot see the end, and which is becoming every year more accentuated. Either from fear of disclosure of secrets or the grudging of reasonable salaries, not only in chemical works, but also in many manufactories which, not being purely chemical in their nature, still have to deal with chemical processes, there is but one back analyst, if any, whereas, as is well known, in most chemical and cognate industries in Germany, Austria and France, every process is watched at every stage and carefully regulated by chemical skill. As an instance, in the "Badische Anilin und Soda Fabrik," employment is given to *eighty-one* manufacturing and research chemists at a very great annual cost, or for every fifty labouring men employed there is one chemical superintendent.

Would our neighbours continue such a system at what must be an enormous expenditure, if it did not pay? Did British chemical manufactures follow their example, firstly, adulteration of products would not be possible; secondly, partially manufactured material would not be sent out of the country to be returned fitted for the consumption of for example our dyeing and calico printing industries, as is the case with benzol, toluol, and other crude tar products; china clay, which we sell at 10*s.* or 20*s.* per ton, comes back to us as ultramarine, having a value 100 per cent. above that of the material from which it is made, and so on.

We are too fond of doing things in the "rough," content with selling coal and iron which require no particular skill in obtaining. Our alkali trade of such great importance (even in its present decadent condition) requires a chemical union to keep it alive, whereas the "Solvay" process invented and nurtured in France pays enormous profits.

Were our chemical works properly or correspondingly equipped with a staff of chemists equal to our foreign competitors we would not only manufacture our own material into its highest derivatives but provide means and even wealth for our other "raw" material in the multitude of well educated chemists which our universities every year pass into the workaday world.

It is by such means our foreign brother chemists obtain, and retain, their pre-eminence as chemical manufacturers, whilst we in Britain sustain a double loss in men and material. We have besides to contend with subsidies by their governments to foreign manufacturers, tariffs, taxes, cheap labour, all handicapping the British chemical manufacturer, who, in too many instances, will neither sow the seed for a future harvest, or even when niggardly sown refuses to stimulate it with sufficient nurture.

## New York Section.

Chairman: Alfred H. Mason.

Vice-Chairman: Arthur McGeorge.

Committee:

G. T. Bruckmann.	John McKesson.
T. Lynton Briggs.	W. H. Nichols.
H. Comer.	Francis J. Schleicher.

### PATENTS.

*An Improved Hoffman or Continuous Kiln for Drying and Burning Bricks and other Goods.* R. Cook, Kensal Rise, Middlesex. Eng. Pat. 19,848, October 21, 1893.

THE kilns are worked continuously with two rows of firing chambers, separated by a wide tunnel gangway which has three lines of rails running longitudinally and a smoke flue beneath, divided from the tunnel by air-tight iron plates. The firing chambers are so connected with flues and damper apertures, that each chamber may be placed in direct connection with either of those adjacent to it, and may discharge its products of combustion into the smoke flue; or when cooling may communicate its waste heat to any other chamber or to the tunnel between the two sets of chambers. A chimney shaft at one end provides draught. The roof of each chamber is formed of iron or steel joists 14 to 18 inches apart, with perforated bricks or lumps between, the bricks being grooved on opposite sides, to slide over the lower flanges of the joists; above them is a layer of cement concrete. The freshly-moulded bricks are placed on pallet boards, supported on a trolley, which is then run into the tunnel, where they are gradually dried at a gentle heat, and are afterwards stacked in a firing chamber; here they are first dried out by the aid of heat from a chamber which is cooling down, then fired, and finally, in cooling, serve to dry fresh batches of unbaked bricks. The trolley is specially constructed, having four corner uprights with stays; each upright has a rack with notches 7 inches apart, serving to carry longitudinal bars on which rest the pallet boards, kept in place by ledges fastened on their under sides.—W. G. M.

\* Any of these specifications may be obtained by post by remitting 8d.—the price now fixed for all specifications, postage included—to Sir Henry Reader Luck, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C.

*Imp. Means for Superheating Steam.* J. Musgrave and G. Dixon, both of Bolton. Eng. Pat. 20,359, October 28, 1893.

THE apparatus has reference to means for superheating a portion only of the steam produced in a boiler, and afterwards injecting it into the main body of the steam after it leaves the boiler. The superheater is constructed of a series of U-tubes secured to a steam chest provided with a division plate to separate the ends of the tubes; the apparatus is in Lancashire and similar boilers placed directly behind the boiler, so that the hot gases issuing from the flues may impinge on the superheater and heat the steam passing through it. The steam is taken from the main pipe by means of a branch, and the amount taken is controlled by a thermostat, which latter consists of a flat coil of piping filled with mercury, the outer end of which is connected by means of linkwork to a throttle valve placed in the branch pipe, and thereby controlling the amount of steam passing to the superheater. Modified arrangements are shown, applied to boilers of the marine and multitubular types, and in cases where it is desired to superheat the whole of the steam, some parts of the apparatus may be dispensed with and the superheater connected directly with the main steam pipe.—E. G. C.

*Improvements in Apparatus for Cooling Liquids or Gases.* J. Price, Liverpool. Eng. Pat. 20,944, November 4, 1893.

WITHIN a narrow vertical tank an endless travelling band is carried over a series of rollers arranged at the top and bottom of the tank so that the band exposes a large number of vertical folds with the lower ends passing over the rollers, dipping into the liquid to be cooled, whereby a large surface is exposed to a current of cold air blown through the tank. In this manner the temperature of the liquid becomes much reduced, and it is finally drawn off from the outlet in a cooled state. Gases are cooled by forcing them through the tank and exposing them to the action of a cold liquid such as water, which saturates the band as it passes under the lower guide rollers.—E. G. C.

*Improvements in the Manufacture of Finely-pulverised Substances for Use in the Production of Portland Cement, Pigments, and the like.* A. Patrick, Glasgow. Eng. Pat. 21,292, November 9, 1893.

THE raw materials are fed from a stone-breaker to an edge-runner, and thence by an elevator to a pair of stones, whence they pass by another elevator to a hopper provided with a rotating distributor, which carries the mixture into a current of air supplied by a Root's blower. The finely-divided portion is thus blown through a sieve, while the coarser particles fall to the bottom of the blowing chamber, and are returned to the stones. The material passing through the sieve falls into a large hopper, whence it is withdrawn by a rotating feeder. The dusty air is passed through a screen and fed into the intake of the blower, so that the same air circulates repeatedly. It is claimed that by this system the raw materials of cement-making are obtained in a finely-powdered state, free from gritty unground particles.—B. B.

*Improvements in Ovens for Baking or Firing Ceramic Ware and other Refractory Products.* J. B. Hanquiaux, Charleroi, Belgium. Eng. Pat. 22,637, November 25, 1893.

THE oven is of the continuous type, consisting of a series of compartments communicating by passages and arranged above generators, which can be fed through a space provided by the double wall separating the compartments of the kiln. The air before reaching the fuel is heated by passing through compartments the contents of which have already been burnt, and is at such a temperature that it ignites the fuel in the generators intermediate between the compartments. Each generator is provided with a movable bottom, which can be lowered at will, so that accumulation of ashes thereupon does not block the passage connecting

one compartment with the next. Thus the working of the kiln can be continued until the compartments have to be emptied in due order of the ware which has been burnt in them. Temporary connections can be made between adjacent chambers if required, and an auxiliary supply of producer gas may be fed in if necessary through the internal passages normally used for the introduction of solid fuel to the generators.—B. B.

*Improvements in and connected with Oil and other like Presses.* J. A. Johnson, London. From C. Gounelle, Marseilles. Eng. Pat. 23,595, December 7, 1893.

THE improvement claimed, facilitates the operation of clearing out the openings between the bars forming the sides of the cage of an oil-press, without taking the bars apart. The cage is made open in order to render the bars visible and accessible, and is preferably octagonal in shape, and constructed from a number of metal rings or hoops, provided internally and externally with projections and recesses. The rings are connected together at the required distance by vertical bars engaging with recesses on the exterior of the rings; this combination forms the skeleton of the cage, which is supported on legs resting upon hydraulic rams in the lower head. The materials are introduced into the cage and the charges are separated by metallic plates or filtering cloths (preferably woven wire cloths) until the cage is filled.—J. J. K.

*Improved Isolating or Non-conducting Material.* C. A. Peters, London. Eng. Pat. 11,560, June 14, 1894.

85-90 PARTS of kieselguhr are mixed with 15-10 parts of lime or cement, and the dry mixture thoroughly incorporated; moulds are filled with it, and placed in a vessel wherein they and their contents are subjected to the action of steam and water at high pressure. Pieces of wire netting, &c., may be inserted in the mixture as a core, for the purpose of stiffening it. The process is used for manufacturing steam-pipe coverings.—B. B.

*Improvements in the Process of and Apparatus for Heating and Concentrating Liquids.* F. Kleemann, Berlin. Eng. Pat. 14,184, July 24, 1894.

THE apparatus consists of a vertical cylindrical casing provided with jackets E and F, stirrers A driven from the

HEATING AND CONCENTRATING LIQUIDS.

pulley *p*, and a bell casing *D* fastened to the base *B*, in which the condensed water collects. Steam is allowed to enter the upper jacket *E* by the pipe *Q*, and, after circulating in this jacket, it escapes by the pipe *K* into the bell

D, where it is condensed, while at the same time the water of condensation from the jacket E passes into F by the pipe R. The water in D passes into the lower jacket F and away by the pipe T. The liquid enters by the pipe L, and, after being heated and concentrated in the casing, is discharged by the outlet M.—E. G. C.

*Improvements in Filtering Apparatus.* W. Oliphant, City of Paterson, U.S.A. Eng. Pat. 15,881, August 21, 1894.

WITHIN a closed casing are formed three separate filter beds, through which the liquid passes in succession, beginning with the one containing the coarse material and finally passing through the one containing the finest material. The liquid passes downwards through the first chamber, upwards through the second, and downwards through the third, after which it is led away by an outlet pipe. A sediment chamber connects the first and second filtering beds, having a discharge valve for the removal of sediment, while each bed is provided with a cleansing pipe in communication with the supply for cleaning out the chamber.—E. G. C.

## II.—FUEL, GAS, AND LIGHT.

*Observations on the Investigations of V. B. Lewes as to a Cause of Loss of Heat in Boilers.* M. Scheurer-Kestner. Bull. Soc. Chim. 1894, 11—12, 723—726

ACCORDING to Professor V. B. Lewes (*Engineering*, April 6, 1894), the essential factors representative of the waste as between the heat of combustion of a combustible and the heat practically utilised, are expressions of the radiation from surfaces, irregular admission of air, incrustations, and cooling of the flame on coming into contact with comparatively cold surfaces. He states the total loss as 40 per cent. of the heat of combustion. The author contends that this loss is over-stated, and refers to his experiments of 1885 with a triple-effect Alsatian boiler and a Green's reheater, the fuel being Altendorf coal, in which the steam produced involved the expenditure of 67.3 per cent. of the calories produced by the combustion of the coal; and later, in 1888, with English coal, the proportion reached 72.5 per cent. The loss is stated to be more nearly reckoned at 30 per cent. Several important factors are stated to be omitted in Professor Lewes's items of loss, namely: (1.) The calories carried away by the combustion gases as sensible heat (temperature of these gases), reckoned as between 5 and 10 per cent. as a maximum; (2.) The heat carried away by the same gases as latent heat (water vapour either produced in the combustion or arising from moisture in the fuel), reckoned as  $2\frac{1}{2}$  to  $3\frac{1}{2}$  per cent.; (3.) Calories represented by the smoke, produced even on the fire-grate; and (4.) The calories lost from incomplete combustion.

The author cites a memoir published by him in 1868, giving experiments showing that fire-gases deposit soot on a tube placed a little distance from the fire-bars of a steam boiler fireplace, through which cold water is run; and that the deposit disappears when the cooling is stopped, and explains that in such case the gases dissociated by the intense heat of the furnace on meeting a cold surface deposit carbon, which is afterwards transformed into carbonic acid by oxygen coming from the fire-grate as soon as the temperature admits of its combustion. The hydrogen remains free in the combustion products together with some hydrocarbons re-formed by what M. Sainte Claire Deville terms "partial recombination." The author discusses the bearing of these facts on the views of Professor Lewes.

—E. S.

*Difficulties in working Parallel Series of Gas Apparatus.* W. Leybold. J. fur Gasbeleuchtung, 1894, 301; Proc. Inst. Civil Eng. 1894, 118, 26—28.

THERE are certain limits to the dimensions of the various apparatus in gasworks; it is not advantageous for them to be too large, on account of the fluctuating demands of the different seasons of the year, and on account of the difficulty of erecting and handling. In large works it has been found advantageous to adopt small apparatus and to divide the works into separate sections, each dealing with a half or a third of the total production, or to have parallel series of apparatus dealing with portions of the make. The whole should be equal to one third or one-fourth more than the actual maximum daily production, as better results are obtained when the various appliances are not worked to their full capacity. Atmospheric condensers should have 4.6 to 7.6 sq. ft. of cooling surface per 1,000 cub. ft. of gas per 24 hours, and water condensers in the open air, 1.8 to 2.1 sq. ft. of surface for the same duty. In the open air, with the horizontal pipe condensers used in English works, or with the vertical condensers as used in Germany, the temperature of the gas in winter may fall below zero, while in summer it may rise instead of being reduced, with the result that naphthalene gets into the street mains. The dimensions of dry purifiers should be regulated so that the maximum velocity of the gas does not exceed 12 ins. per minute with the maximum make, assuming the purifiers to be empty. The actual flow of the gas is naturally greater than this when the purifiers are charged.

The gas generally passes from the condensers to the exhausters and then through the tar-separators, washers, purifiers, and station meters into the gas-holders. In order to work these in parallel sets, the pipe from the hydraulic main is divided into two before the condensers, and again united into one at the outlets of the same; from the exhauster, or exhausters, it passes into one main, which is again divided before the tar-separators, washers, and purifiers, and also for the meters and gas-holders. Condensers give very little back pressure, and equal quantities of gas will pass through two adjoining ones, except when one branch of the divided main is longer than the other, in which case the gas takes the nearest course; obstructions in the mains may also cause the gas to go principally in one direction; but such obstructions may be easily discovered by means of pressure-gauges, and also by the rise of temperature at the outlets. The gas is then driven through the two divided systems of tar-separators and washers. In the tar-separators a difference of pressures of  $2\frac{1}{4}$  to  $2\frac{3}{4}$  ins. should be maintained between the inlets and outlets.

The unequal division of the gas is less injurious in the tar-extractors than in the washers. The required quantity of water is regulated by taking tests at the tops and bottoms of the washers. With a single series this succeeds very well, but, with the parallel system, sometimes much, and sometimes little gas passes through one of the tar-extractors, and consequently through the washer attached to the same, with the result that the wash-water becomes too strong on the one side and too weak on the other. Pressure-gauges should be fixed on all the purifiers to indicate where increased back-pressure occurs. If each series contains four purifiers, one in each being kept in reserve, the difficulty of the unequal division of the gas does not occur when a box is being recharged, there being always three boxes in action on each side; but the purifying material may still become saturated with moisture. New material also causes less back-pressure than old, and a series with one or more purifiers containing new material allows more gas to pass than where there is only old material.

On reaching the gas-holders one of these is being filled while another sends out the supply; at times, when all the holders are full, gas has to be put into and sent out from one, at the same time, and this tends to produce stratification. When two or more holders are being used at the same time for the supply, attention must be paid to the varying pressures, or the heaviest one will drive gas into the lighter one.

The disadvantages that have been referred to, of working two parallel sets of apparatus, are only of importance as regards the washers, and these disadvantages may be avoided by a connecting pipe between the two systems. With four purifiers in each series the difficulty is not great, but only when series of three purifiers are used.

*On the use of the Auer Incandescent Mantle cause Partial Poisoning.* N. Gréhan. Comptes rend. 119, 1891, 342—350.

In a previous paper the author showed that the products of combustion from an Auer mantle contained a minute proportion of carbon monoxide—about  $\frac{1}{10000}$ th part. With a view to finding whether an animal breathing the air of a closed room, in which an Auer gas light was burning, could begin to be poisoned by the carbon monoxide—in other words, whether the quantity of this gas which is mixed with the other products of combustion, is in sufficient proportion in the air of a room, to be fixed by the blood—he repeated the classical experiment of Felix Leblanc. He operated with a dog, by first determining the volume of combustible gas contained in its normal blood, and afterwards, that contained in its blood after it had been placed a distance of one metre from a burning Auer light, in a room of 51 cubic metres capacity, where it remained seven hours. He found that only 0.15 cc. of carbon monoxide per 100 cc. of blood had been absorbed, corresponding to  $\frac{1}{66666}$ th part of carbon monoxide in the air of the room. He concludes therefore that the use of the Auer mantle is unattended with any danger of poisoning by carbonic oxide.—H. S. P.

#### PATENTS.

*An Apparatus for Notifying the Presence in the Air of Gases such as Fire Damp.* E. Hardy, Dreux, France. Eng. Pat. 15,329, August 11, 1893.

See under XXIII., page 1091.

*A New or Improved Apparatus for Burning Creosote and Similar Oil for Steam Generating and Heating Purposes.* W. Allen, Manchester. Eng. Pat. 18,656, October 5, 1893.

This liquid-fuel burner is one of those where the oil is atomised by steam alone and by a single supply of this substance, and where there is no admixture of the fuel with air by the burner.

Oil, controlled by F, flows through D into B, where its volume is again specially regulated by G. It then enters the tube A, and at the further end of this tube, is atomised by the high-pressure steam which is escaping through the surrounding tube A from the chamber B.

The chamber B, receives steam by an arrangement similar to that provided for the oil (but not shown in the figure).

The special features of the invention claim: (1) the valve body B, with its two chambers B<sup>1</sup> and B<sup>2</sup>; and (2) the provision G for accurate regulation of the oil supply; when once this regulation is effected it need be only very occasionally disturbed, as the oil supply may be shut off by the main valve.

The inventor inclines the burner, as shown, so that its jet may play upon the layer of fire brick or slag, with which he covers the fire bars, and upon the small coke fire, which he uses at starting. It will also be noticed that he leads the burner some distance into the fire-box.

—E. R. B.

*Improvements in Gas-making Apparatus.* J. W. Hartley, Kilmarnock. Eng. Pat. 19,161, October 12, 1893.

The improvements relate to gas generators, gas washers, and gas purifiers. The gas generator is of the ordinary vertical cylindrical type, lined with fire brick, in combination with which the inventor claims the use of one or more poker bars for removing clinkers, and an arrangement for indicating the level of the fuel in the generator. The pokers or bars, secured at the lower end to a cross bar, when operated are caused to rise vertically into the incandescent fuel, through slots in the circular frame surrounding the fire-grate, and cut away the clinker which forms upon the brick lining. The bars are next lowered to their normal position below the upper surface of the grate. The frame and fire-grate are now caused to rotate (as they are constructed to do) to a certain small extent, and the poker bars are again driven upwards to their full extent, and so on, until clinker is cleared away from the whole of the lower interior of the brick lining. For ascertaining the level of the fuel, a rod passes through the top of the generator, and to the inner end of which is fixed a cone-shaped weight, while the upper end is connected with a wire rope made to pass over suitable pulleys and ending in a counterpoise and indicator. The cone weight is lowered until it reaches the fuel, the counterpoise indicator showing the level. The improved gas washer or dust box consists of one or more concentric cylinders, the lower rims of which are slotted, suspended in a suitable cylinder to a short distance below the water level. The gas passes into the top of the inner cylinder, through the water, into the annular space between the cylinders, and so on to the outlet of the outer casing. A horizontal wheel in the floor of the apparatus and rotated by hand, is provided upon the upper side with scrapers to remove any deposit from the cylinders, which deposit, falling to the bottom of the apparatus, is guided by a scraper upon the under side of the revolving wheel, to an opening in the side of the washer, through which the deposit is removed and the wheel operated. The improved gas purifier consists of a suitable tank with horizontal partitions or shelves carrying the purifying material, and separated by another series of horizontal partitions constructed so that the spaces above the filtering material communicate with a common inlet, and the spaces below with a common outlet.—S. P. E.

*Improvements in Apparatus for Mixing Gas and Air for Gas Furnaces.* G. Axdorfer and C. F. H. Sass, both of Hamburg, Germany. Eng. Pat. 22,681, November 25, 1893.

The patentees provide a mixing chamber between the combustion chamber and the gas- and air-inlet nozzles of furnaces fired by gas. The lateral walls of the mixing chamber are provided with slots corresponding with the orifices of the said nozzles, which have also the form of slots. In the mixing chamber there is also fitted an adjustable grate slide, whose bars cover the slots in the two walls, more or less, according to the adjustment of the slide, the quantity of gas and air to be used in combustion being thus regulated.

Upon leaving the nozzles, the gas and air impinge against the bars of the slide and against the opposite wall of the mixing chamber; the "strong whirling movements" so produced, insuring a uniform mixing of the gas and air.

A considerable number of forms of apparatus, all embodying the above principles, are described: one of the simplest is shown in Fig. 1 where 1 is the central retort, with closed reservoir 1', and grate and ash-pit 2. Air enters at A and passes through the fuel in the central retort to arrive at 3, then to 4, finally leaving the apparatus as fuel gas at B. At 5, 6, 7, 8 any desired additional air or air and steam may be admitted.

The central retort may be vertical, horizontal, or inclined, and may be single or double.

The patentee has also applied his improved method of fuel-burning to the case of steam-raising. In this case his gas-making apparatus becomes an adjunct to the furnace of various types of boilers, and in most instances is combined with water-tube grates, all or part of the floor of which is fitted with mechanism capable of raking the fuel from the floor towards the back of the furnaces.

Most of the many modifications described are illustrated in considerable detail, one of the more elaborate arrangements being shown in Fig. 2. Here the fuel chamber 1 is formed by two series of curved tubular grate bars, 17 and 17', with air spaces between the tubes. Tubes 18 and 19 connect 17 and 17' with the water space of the boiler 20, so that there is efficient circulation in them. Between the front portions of 17' is the raking arrangement 21, consisting of segments 22, supported on rock shafts 23, which are operated by the lever 25 through the link 24. The fuel is progressively shifted on by the raker into the lower part of the grate. The partition wall 31 separates the chamber 32 from chambers 26 and 39, while the "water-wall or curtain" 34 and the wall 35 encloses the upper and lower parts of chamber 33.

The course of the air is as follows. From chamber 26, through the grate and fuel, into chamber 1; thence, through the more strongly incandescent fuel lying between the bent parts of 17 and 17', into chamber 32. In passing from 32 to chamber 33 the fuel gases again pass through incandescent fuel, and combustion is finally completed in the boiler tubes 37, which open from chamber 33. The toothed or grated cylinder 38 allows of the disintegration and removal into the ash-pit 39 of clinker and cinder. Any fuel which may chance to fall through the grate 21 is caught by the grate 29 and is burnt by the air entering by doors 27 or 28.

—E. R. B.

*Improved Incandescent Vapour Lamp with Vapour Generator.* C. Schinz, St. Petersburg. Eng. Pat. 13,419, July 11, 1894.

This incandescent vapour lamp is provided with a retort or generator, in which the hydrocarbon is converted into vapour, this vapour then passing out as a fine jet into the lower opening of the chimney, drawing air with it, the mixture burning at the upper end with an intense blue flame. The lamp has the usual form of reservoir for the hydrocarbon, vertically fixed in the centre of which is a tube containing the wick. Surrounding this tube, and fitting closely around it at the bottom end, is a second one, open to the air above, thus forming an air space around the inner tube and keeping it cool. The tube containing the wick has at the top a lateral enlargement which constitutes the retort in which the hydrocarbon that is carried up by the wick, is vaporised by the heat from a second smaller wick burning beneath it. This second wick and the retort are enclosed by a suitably-shaped chimney or cover made to slide outwards horizontally for uncovering and igniting the wick. A small nozzle leads from the top of the retort, through which the vapour issues, into the bottom of the chimney, carrying the air necessary for combustion with it. The vaporisation is regulated and the lamp extinguished by raising or lowering the smaller wick, suitable means for which are provided —S. P. E.

*An Improved Method of and Apparatus for Detecting and Measuring the Presence and Amount of Inflammable Gases or Vapours Mixed with Air.* B. C. Tilghman, jr., Philadelphia, U.S.A. Eng. Pat. 15,153, August 14, 1894.

If a metal wire be raised to a suitable temperature—for example, by the passage through it of an electric current—and if the surrounding atmosphere contain inflammable gases, these latter will burn on the surface of the metal, with the consequence that the temperature of the wire will rise. The greater the amount of gas so burned, the higher will be the temperature of the wire.

Now certain metallic conductors—for example platinum—have their electrical resistance increased by increase of temperature, according to a definite ratio; it is therefore obvious that by measuring the increased resistance of the platinum wire part of the circuit of suitably constructed instrument, the amount of inflammable gas present in a given atmosphere can be ascertained.

In his patent, the inventor describes the structures and uses of such instruments, including a special form of Galvanometer.

In Fig. 1 is represented a vertical section of the detecting instrument. The metal casing A carries a block of asbestos or fire-clay  $d^2$ , in the axial passage  $d^3$ , of which is disposed

Fig. 1.

the platinum spiral S; this, in the absence of inflammable gas, is kept at a just visible heat when the current passes through  $a a'$ . The heated spiral causes a current of air to pass through the instrument, traversing  $d^1$ ,  $d^3$ , and  $d^5$ , successively. The sloping roof  $d^1$  and the gauze baffles FF and F' F' minimise draughts, the gauzes also preventing the ignition of inflammable atmospheres.

For the quantitative estimation of the inflammable gas indicated by the foregoing instrument, "any proper means for measuring resistance may, of course, be used"; but the patentee, while not limiting himself to any particular means, specifically claims, in combination with his instrument, the Wheatstone bridge, the rheostat, and the fixed resistance methods. Where quickness of manipulation is desired, it is preferable to use a balancing resistance, and for this purpose he employs a second platinum coil, like to the testing-coil, and under like conditions, except that it is surrounded by an atmosphere free from inflammable gas.

It is this arrangement also which he uses in his portable instrument, represented in Fig. 2, where S is the testing-

Fig. 2.

spiral, carried at the end of the pole T, S<sup>1</sup> the balancing spiral, G the patentee's special galvanometer (for further description of which, reference must be made to the specification of this patent), B a small battery, and H a window through which the indications of the galvanometer may be noted. From the battery, the first circuit (indicated by the dot and dash lines) is via c, c<sup>1</sup>, G, c, a, S, a<sup>1</sup>, and (when the key K is depressed) through h<sup>1</sup> to c<sup>1</sup>; the second circuit (indicated by full lines) being via c, c<sup>1</sup>, G, c<sup>2</sup>, S<sup>1</sup>, and, when K is depressed, through h<sup>1</sup> to c<sup>1</sup>.

There are thirteen claims covering the various combinations of the pieces of apparatus proposed (including the modified galvanometer) among themselves, and the electrical currents manipulated, while two further claims cover the methods employed. These are respectively, that, where the varying resistance of the testing spiral is measured, and that, where the resistance of the testing-spiral under the influence of inflammable gas is compared with that of another not so influenced.

Special advantages of the method are, according to the inventor, that "the indications given are positive, and do not in any way depend upon the judgment of the person making the test," and that there is no necessity for the collection of samples, nor for the observer to go to the, perhaps, dangerous place where the gas itself is being tested; indeed, in the case of mines, there may be permanently fixed in the levels any number of testing apparatus, which all record at the office at the surface.

It is evident that with an instrument of this kind, as, indeed, is pointed out by the inventor, *any change* in the temperature of the gas circulating about the testing-spiral, and also with a given air temperature, the rate of flow of the current of air, would affect the indications and that thus, with, for example, a colder current, an amount of hydrocarbonous less than really existed at the time might be indicated. So far as such a state of things as this might be brought about by draughts, the inventor considers the ganze baffles, &c. of the instrument a sufficient preventive.

With regard to the temperature at which the spiral is maintained during testing, though the patentee prefers to keep it "barely luminous in diffused daylight," yet he states that if the spiral be caused to "glow brightly, the increase in resistance under the same proportions of gas or vapour in the air will be practically the same as when less strength of current is used."—E. R. B.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*The Crude Petroleum occurring in the Trenton-Limestone.*  
O. Mühlhäuser. Dingl. Polyt. Jour. 292, 1894, 116—119.

THE name "Trenton-limestone oil" (from its occurrence in the Lower Silurian Trenton limestone) is proposed for the crude petroleum, hitherto known under the name "Ohio oil" or "Linna oil," and distinguished by the large proportion of sulphur it contains. Owing to the sulphur compounds present, the oil was practically useless for illuminating purposes and was only employed for heating. The quantities raised, up to 1884, from the Berea sand (compare table) had been comparatively so small that processes for the elimination of the sulphur were not seriously considered until the large quantities, tapped from the Trenton-limestone, drew the attention of technologists to this important problem, viz., to so refine the oil as to render it useful for illuminating purposes. A successful process has been invented and carried out in practice by Frasch, consisting in the treatment of the oil with metallic oxides, whereby the sulphur compounds (termed "skuunks," on account of their nauseous smell) are destroyed, and almost the total quantity of sulphur (from 0.4 to 1.0 per cent. of the oil) recovered in the form of metallic sulphides.

#### TRENTON (OHIO, LINNA), OIL PRODUCTION.

Year.	Barrels.	Year.	Barrels.
1876	3,754	1883	47,632
1877	29,888	1884	30,984
1878	38,479	1885	60,000
1879	29,442	1886	478,370
1880	38,940	1887	701,844
1881	34,867	1888	1,001,658
1882	50,760	1889	1,247,136

According to Lange, at present 23,725,000 barrels are refined per annum by Frasch's process, yielding 28,105 tons of sulphur. This enormous quantity of sulphur might yield about 90,000 tons of sulphuric acid of 66° B, but hitherto the sulphur has been allowed to escape into the air as sulphurous acid.

The author, referring to Mahary and Smith's paper (this Journal, 1891, 628), discusses the several series of sulphides—adipathic sulphides and thiophen compounds—that may be assumed to exist in the Trenton oil; and from the fact that the sulphides can be extracted by means of concentrated sulphuric acid, he draws the conclusion that the sulphur cannot occur in the form of sulphides of the series  $(C_nH_{2n+1})_2S$ . For his speculations as to the manner in which the sulphur may be linked with the carbon atoms, the reader must be referred to the original paper, as no experiments are given to substantiate them.—J. L.

*Products of the Distillation of Petroleum Tar.* W. Tistchenko. Jour. Soc. Ph. Ch. russe de St. Pétersbourg, 1893, No. 2.

THE distillation of this tar was carried out with superheated steam. The gaseous products of the distillation are incompletely absorbed by bromine. The brominated hydrocarbons which were obtained belong to the ethylene series. Two series of hydrocarbons were obtained, boiling from 90° C. upwards, which differ clearly from each other in the range of their specific gravities:—

LOWER.	
94—96	0.7100
120—122	0.7275
116—118	0.7468
170—172	0.7995
190—192	0.7823
HIGHER.	
106—108	0.7726
131—136	0.7759
160—162	0.7786
183—184	0.7943

The elementary analysis of these fractions showed that most of them contain oxygenated compounds, and, further, that the fractions of that series distinguished by the higher specific gravity, contain more hydrogen and carbon than the other fractions. Besides these hydrocarbons, the crude distillate contains some products which are formed during distillation. These are (1) sulphides (mercaptans) capable of combining with mercuric oxide; (2) nitrogenous compounds, which can be extracted from the crude distillate either by hydrochloric acid or mercuric chloride, and which in the free state form an oily liquid possessing a very penetrating smell, and boiling at from 170° to 265° C.; (3) crude phenols were obtained by extracting the distillate with a solution of caustic potash, and treating the latter with carbonic acid. Treating this solution after the removal of the phenols with sulphuric acid, some liquid acids, possessing a strong, rancid smell, were liberated.

#### PATENTS.

*An Improved Process for Recovering Alkali from a Waste Product.* J. B. Murray and M. B. Baird, both of Glasgow. Eng. Pat. 18,786, October 7, 1893.

THE waste product of shale oil works, known as soda-coke, is crushed and heated in a crucible, with stirring, as long as flames are produced. The residue, reduced to about three-fourths its original weight, is boiled with water in a suitable pan, and, after settling, the clear liquid is transferred to a copper pan to be concentrated until fit for running off to crystallise, soda crystals being obtained. The coke is again boiled with more water, and the process repeated as long as alkali is extracted. The coke that remains is about 37½ per cent. of the original soda-coke, and after thorough drying may be ground up with oil for making black paint or blacking.

The soda solution, instead of being crystallised, may be causticised by lime in wrought-iron tanks, the contents being boiled up by steam. The lye and the stronger washings obtained are concentrated in cast-iron pans, steam-jacketed or heated direct. Foreign salts fall at a certain point of concentration.—E. S.

*Improvements in or connected with Retorts for Distilling Shale or Oil-yielding Minerals.* J. Gray, Loanhead, North Britain. Eng. Pat. 21,485, November 11, 1893.

THE improvements are in connection with the present vertical type of coal retorts, in which gases and vapours are formed for heating the retorts employed for distilling shale or other oil-yielding minerals. One or more communications are made between the top of the retort and the bottom near the outlet for the gases, formed either of pipes outside the brickwork or flues constructed within, and provided with suitable regulating valves and doors for removing any deposit that may accumulate. The main object of this arrangement is to allow any gases formed at the upper part of the retort, to escape into the flue at the bottom without having to force its way through the column of fuel.—S. P. E.

*An Improved Process for Purifying Petroleum.* J. Schrader, Stuttgart, Germany. Eng. Pat. 15,323, August 11, 1894.

THE process consists in distilling petroleum with phosphoric or boric acid, or with the salts of these acids, together with sulphuric acid, for the purpose of destroying any resin or other impurities that the hydrocarbon may contain.

—S. P. E.

#### IV.—COLOURING MATTERS AND DYES.

*Colouring and other Principles contained in Mang-Kouda.*

A. G. Perkin and J. J. Hummel. (Trans. 1894, 851.) *Proc. Chem. Soc.* 1894 [142], 175.

MANG-KOUDOU is the root bark of *Morinda umbellata*, largely used in Java for producing fast reds in the native calico prints. The authors correct their previous statement (this Journal, 1894, 940) that its colouring matter was alizarin, and now show it to be morindone. The have isolated 11 distinct substances from the root, which also contains free acid, the nature of which has not yet been determined. No cane sugar was found, a distinction from chay root (*loc. cit.*) and from madder. Full details of the methods employed in extraction and separation are given, and the behaviour of the substance as a dyestuff is described.

#### PATENTS.

*The Manufacture or Production of a Trihydroxynaphthalene Monosulphonic Acid.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 19,624, October 18, 1893.

THE compound described is obtained from naphthalene tetrasulphonic acid (Senhofer, Ber. **8**, 1486) by fusing it with alkalis above 240° C. The naphthalene tetrasulphonic acid is produced either by sulphonating naphthalene or 2,3'-naphthalene disulphonic acid. The new trihydroxynaphthalene monosulphonic acid may also be obtained from the naphthol trisulphonic acids or the dihydroxynaphthalene disulphonic acids which are formed as intermediate products in the fusion of naphthalene tetrasulphonic acid with alkalis at temperatures below 200° and 250° respectively, since Senhofer's acid is a mixture of two tetrasulphonic acids. The fusion may be conducted in open or closed vessels, the proportion of potash or soda to acid being 2:1. When complete, the melt is dissolved in water and the solution made acid with hydrochloric acid, when, if potash has been used, the potassium salt of the trihydroxynaphthalene sulphonic acid separates out. The neutral salts of the new acid dissolve in water to red-coloured solutions with a slight bluish fluorescence. Bleaching powder gives a wine-yellow coloration, which is destroyed by an excess. In solutions of the acid salts, ferric chloride gives a brown colour.

—T. A. L.

*Process for Producing Insoluble Azo Colours on Fibre.* O. Luray, London. From "The Farbwerke vormals Meister, Lucius, and Brüning," Hoechst-on-the-Maine, Germany. Eng. Pat. 21,087, November 6, 1893.

THE specification relates to the production of an insoluble blue azo dyestuff on the fibre by padding the latter with β-naphthol and passing the prepared fibre through a bath containing diazotised dianisidine together with cupric chloride. The following quantities are given. The padding solution made up to 10 litres, contains 150 grms. of β-naphthol in 250 grms. of soda lye of 22° B., together with 400 to 500 grms. of Turkey-red oil. The goods, having been padded, are dried and printed with or passed through the diazo solution prepared from 61 grms. of dianisidine, 106 grms. of hydrochloric acid of 22° B., 600 cc. of water, 300 grms. of ice, and 265 grms. of sodium nitrite. For the printing solution 15 grms. of the diazo solution, 6 grms. of cupric chloride of 40° B., 50 grms. of gum water, and 35 cc. of water are mixed together. Other phenols may be used in place of β-naphthol, and the effect of adding cupric chloride to the diazo compounds of other bases than dianisidine, is to confer greater fastness on the azo colours produced by this process on the fibre.—T. A. L.

*Improvements in the Manufacture and Production of New Azo Dyes.* J. Y. Johnson, London. From "The Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 21,753, November 14, 1893.

IN Eng. Pat. 14,678 of 1893 (this Journal, 1894, 724) the preparation of a *m*-phenylene diamine disulphonic acid is

described. According to the present patent, one molecular proportion of this compound is capable of combining with two molecular proportions of a diazo compound, either of the same or of different ones. Valuable products result from combining one molecular proportion of *m*-phenylene diamine disulphonic acid with one molecular proportion of diazotised primuline and subsequently with one molecular proportion of a diazotised amine or its sulphonic acid, such as aniline, *o*- or *p*-toluidine, *m*-xylydine, *a*- or *β*-naphthylamine, *m*- or *p*-sulphanilic acid, naphthionic acid, and the *β*-naphthylamine sulphonic acids 2.1', 2.3', and 2.4', &c. About 13 kilos. of aniline hydrochloride are diazotised with 7 kilos. of sodium nitrite and 15 kilos. of 30 per cent. hydrochloric acid and diluted to 500 litres. This solution is stirred into 27 kilos. of *m*-phenylene diamine disulphonic acid and 45 kilos. of crystallised sodium acetate in 500 kilos. of water. After stirring for from 5 to 8 days, diazotised primuline from about 56 kilos. of primuline (corresponding in any case to 7 kilos. of sodium nitrite), 7 kilos. of sodium nitrite, 500 litres of water, and 49 kilos. of hydrochloric acid, is added and the whole is stirred for a few days. Hydrochloric acid is then added to precipitate the dyestuff, which is filtered off and mixed and ground with sufficient soda to form the soluble sodium salt. The colouring matter so obtained is a brown powder soluble in water giving reddish-orange shades on unmoordanted cotton. A bright orange for cotton is obtained by diazotising the amount of primuline corresponding to 7 kilos. of sodium nitrite as described above, and adding this to an ice-cold solution of 27 kilos. of *m*-phenylene diamine disulphonic acid and 28 kilos. of calcined soda in 400 litres of water. After stirring 24 hours, 30 kilos. of crystallised sodium acetate are added, and the diazo compound from 19.5 kilos. of sodium sulphanilate, 7 kilos. of sodium nitrite, and 39 kilos. of hydrochloric acid is run in. The whole is then stirred for from 5 to 8 days, when the liquid is heated, acidified with hydrochloric acid, and the dyestuff precipitated with salt.

—T. A. L.

*Manufacture of Blue Acid Colouring Matters of the Triphenylmethane Series.* O. Imray, London. From "The Society of Chemical Industry in Basle," Basle, Switzerland. Eng. Pat. 22,741, November 27, 1893.

By heating together equimolecular proportions of dimethyl- or diethyl-aniline, methyl- or ethyl-*o*-toluidine and *m*-oxybenzaldehyde in presence of a condensing agent there result trialkylated derivatives of diamido-phenyl-tolyl-*m*-oxyphenylmethane which after sulphonation and oxidation give useful blue acid colouring matters. These dyestuffs differ from the analogous ones from tetra-alkyl-diamido-*m*-oxytriphenylmethane in giving bright blue shades on wool and silk which are not changed by artificial light. The following details are given as an example:—12.2 kilos. of *m*-oxybenzaldehyde, 12 kilos. of dimethylaniline, 12 kilos. of methyl-*o*-toluidine, 50 kilos. of hydrochloric acid, and 16 kilos. of sulphuric acid of 66° B., are heated in an enamelled vessel on the water-bath for 24 hours. After careful neutralisation with an alkali, the product is steamed and the leuco base remaining behind is washed two or three times with warm water and dried at 100°. 10 kilos. of this leuco base are dissolved in 40 kilos. of sulphuric acid of 66° B. at a temperature of 60° C. and sulphonated by adding 10 kilos. of fuming sulphuric acid containing 24 per cent. of anhydride. The sulphonation is complete when a test dissolves completely in sodium acetate. The melt is then poured into 200 litres of water and the solution of the lime salt is mixed with 6 kilos. of sulphuric acid and oxidised with 2.8 kilos. of sodium bichromate. The chromium oxide is precipitated with ammonia, filtered off, and the solution of the colouring matter is evaporated, giving a dyestuff in the form of a powder with a metallic lustre easily soluble in water with a blue colour. It dyes wool or silk blue from an acid bath. The order of the sulphonation and oxidation may be reversed, proceeding in the usual manner for the formation of colouring matters of the malachite green series and sulphonating the basic colouring matters obtained with 4–8 kilos. of fuming sulphuric acid at a temperature below 30° C.—T. A. L.

*Manufacture of New Bases and their Sulpho Acids.* C. D. Abel, London. From "The Actien-Gesellschaft für Anilin-Fabrikation," Berlin, Germany. Eng. Pat. 23,310, December 1, 1893.

By reacting with aldehydes on the chrysoidines, there result so-called amido-triazines, which are very stable bodies, not even decomposed by heating with mineral acids under pressure to 170–180° C. Since they contain an amido group they may be diazotised and combined with amines and phenols and their sulphonic and carboxylic acids. The following formula represents the constitution of the simplest of the bodies derived from benzaldehyde and the chrysoidine from aniline and *m*-phenylene diamine—

On sulphonation, these products may be converted into mono- or disulphonic acids according to the quantity of fuming sulphuric acid used and the temperature. Certain of these sulphonic acids have a sweet taste. A solution of 25 kilos. of chrysoidine and 11 kilos. of benzaldehyde in 11 kilos. of concentrated hydrochloric acid and 50 kilos. of ordinary acetic acid is heated for 6 hours on the water-bath until the colouring matter has disappeared. The melt is then poured into 1,000 litres of water, filtered, and the base precipitated by adding sodium carbonate. The sulphate crystallises from water in white needles. The base obtained therefrom is colourless and insoluble in water, but easily soluble in hot alcohol and benzene. It forms a stable diazo compound which is sparingly soluble in water. In order to convert the base into a monosulphonic acid, one kilo. is dissolved in 3.6 kilos. of fuming sulphuric acid containing 20 per cent. of anhydride, and the temperature of the melt is slowly raised. On pouring it into water, the monosulphonic acid separates in white crystalline flakes, and gives a tolerably easily soluble diazo compound. By continuing the action of the sulphuric acid at the temperature of the water-bath, a disulphonic acid is obtained which may be separated in the form of the calcium or sodium salt.

—T. A. L.

*Manufacture of New Condensation Products and Colouring Matters for Dyeing and Printing.* J. C. L. Durand, G. E. Huguenin, and A. J. J. d'Andiran, St. Fons, Rhone, France. Eng. Pat. 15,064, August 7, 1894.

This is an extension of Eng. Pat. 24,802 of 1893 (this Journal, 1894 247), and relates to the condensations of phenols and their sulphonated derivatives, and more especially the *β*-naphthol sulphonic acid of Schaeffer with the gallocyanines which are obtained by condensing the salts of nitroso-diethylaniline or of dialkylamidoazobenzene with gallic acid and its derivatives, such as gallamic acid, gallanilide, the gallonaphthylamides, and methyl gallic ether. The patentees further claim the condensation of pyrogallol or dimethyl-*m*-amidophenol with the gallocyanine from nitrosodimethylaniline hydrochloride and gallic acid, and also the condensation of resorcinol with the gallocyanines from nitrosodimethylaniline hydrochloride and gallamic acid or methyl gallic ether. All the leuco products thus obtained are subsequently converted into colouring matters on oxidation, and if necessary are sulphonated as described in Eng. Pat. 24,802 of 1894. About 33 kilos. of the colouring matter obtained by the action of gallamic acid on diethyl-amidoazobenzene or nitrosodiethylaniline hydrochloride, is added to a solution of 40 kilos. of 2.3'-naphthol sulphonic acid in 160 kilos. of sulphuric acid of 66° B., and the melt is heated on the water-bath until the reaction is complete. The melt is then poured into water, when the leuco product precipitates and may be used directly for printing if it be oxidised on the fibre. This oxidation, which takes place preferably in an alkaline solution, produces an acid blue colouring matter which dyes wool and silk blue from an acid bath and will also dye on mordants. The shades obtained on chrome mordants are fast to light and washing. Two tables are given in the specification, giving the reactions

of the dye compounds and of the colouring matters with various reagents.—T. A. L.

## 7.—TEXTILES: COTTON, WOOL, SILK, Etc.

*Souple Silk.* H. Silbermann. *Färb. Zeit.* 5, 352—355 and 365—366.

*Souple silk* is raw silk treated in such a manner that a portion only of the silk-gum is removed, while at the same time it acquires the feel and lustre of boiled-off silk. It is used only for weft. During the soupling process the fibre increases in thickness, owing probably to swelling of the silk-gum. It has these advantages over boiled-off silk, that there is less loss of weight, an important consideration with an expensive fibre, and that it possesses a greater capacity for taking up vegetable and mineral weighting materials. The latter property it possesses even in a greater degree than raw silk, probably owing to the swelling up of the silk-gum. Soupling may be regarded as a morphological alteration of the raw silk fibre, whereby the sericin, without being removed, becomes soft, pliant, and lustrous.

For coloured silks the soupling is carried out in boiling baths containing an acid salt, such as cream of tartar or sodium bisulphate, the completion of the process being indicated by the requisite softness of feel, &c. having been attained.

For black silk, soupling is combined with the weighting and dyeing processes, and the method here described is for the production of a moderately weighted black on souple silk, noting especially the influence of each operation on the tenacity and elasticity of the fibre.

The raw silk, after scouring, is mordanted with basic ferric sulphate. The bath is much weaker and the basicity less than in the dyeing of boiled-off silk, for, owing to the non removal of the sericin, the fibre has a greater power of dissociating iron mordants. In consequence of this rapid dissociation, frequent additions of soda are made to keep up the original basicity. Sodium sulphate accumulates in the bath, and from time to time a fresh bath must be brought into use. To obtain a black weighted to about 190 per cent., four passages through the iron bath are given, the silk being passed after each dip through a lukewarm sodium carbonate solution to complete the fixation of the iron. Serimetric measurements show that these operations decrease the tenacity by 4.5 and the elasticity by 2.5 per cent.

The silk is now dyed Prussian blue by working in a bath of potassium ferrocyanide. The temperature of the bath is lower, and the amount of acid used less, than for boiled-off silk. The Prussian blue is much more superficially fixed than on boiled-off silk, and its injurious action on the fibre is much greater. The tenacity is decreased by 11.7 and the elasticity by 1.9 per cent.

The next operation, the soupling proper, is effected by means of a tannin material, usually catechu. The silk is worked for  $1\frac{1}{2}$ —2 hours in a boiling catechu decoction at 7° B., the bath cooled to 70° C., and 10 per cent. of stannous chloride added; the silk is then worked some time longer, or even allowed to steep overnight; the weight is greatly increased in this operation, after which the tenacity is less by 0.2 and the elasticity by 12.4 per cent. Very great care must be exercised to prevent exposure to air during the treatment with stannous chloride, the neglect of this precaution having sometimes resulted in the total destruction of the fibre.

A passage through weak soap solution follows, and then another ferric sulphate bath, not followed by treatment with soda. Like all metallic salts, this mordant very injuriously affects the tenacity (decrease of 15.1 per cent.) and elasticity (37.3 per cent.). These tests, however, were not made until a few months after the operation, in order to ascertain the practical effect of the compounds fixed on the fibre. The silk has now a reddish-black tone. After a thorough washing it is worked in a sumach decoction at 12—14° B., entered at 50°—60° C., the temperature raised to 90—95° C. in three-quarters of an hour, and worked half an hour longer. The effect is favourable; the tenacity increases by 5.8, the elasticity by 16.7 per cent. The silk has now a deep bluish-black colour.

The next bath contains pyrolignite of iron at 20° B., and has an injurious effect on the fibre (—13.4 tenacity, —12.3 elasticity); the black is now redder in tone and contains much uncombined iron. It is changed to a greenish-black by working in a bath of potassium ferro- and ferriyanides (10 per cent. of each) with 15 per cent. HCl. Enter cold, raise to 60° C. in half an hour, continue for some time. The effect is to increase the tenacity by 10.2 and the elasticity by 23.3 per cent. A second passage through pyrolignite of iron decreases these properties by 3.1 and 3.8 per cent. respectively.

The treatment which follows, aims at increasing the weight and preventing direct contact of the iron with the logwood, as this leads to undesirable lustrous precipitates on the fibre. It consists in a passage through a weak sumach bath, and the silk is then dyed in a bath containing 50—60 per cent. of logwood and 40 per cent. of soap at a temperature not exceeding 50° C. for some hours, or it is steeped overnight. The sumach and logwood baths increase the tenacity by 11.8, the elasticity by 9.8 per cent.

Brightening completes the process. An emulsion consisting of 8 per cent. of olive oil and 8 per cent. potassium carbonate (on the weight of silk) is poured into a bath containing 12 per cent. of crude acetic acid. The silk is worked a quarter of an hour in this bath. The tenacity is thus decreased by 8.1, the elasticity by 3.6 per cent.

During the whole process the silk loses 28.2 per cent. of its tenacity and 32.5 per cent. of its elasticity.—R. B. B.

*The Crystallisation of Cellulose and the Chemical Composition of the Vegetable Cellular Membrane.* E. Gilson. *Bull. Soc. Chim.* 11—12, 1894, 590.

## PATENTS.

*Improvements in Machinery for Cleaning Cotton Seed.* J. Bibby, Liverpool. Eng. Pat. 21,372, November 10, 1893.

See under XII., page 1070.

*An Improved Process for the Retting, Cleansing, and like Treatment of Textile Fibres.* A. Gruschwitz, Neusalz-on-Oder, Germany. Eng. Pat. 15,140, August 8, 1894.

This relates to an improvement upon the invention described in Eng. Pat. 3506 of 1893, in which the boiling operation, in the retting, cleansing, and deoxidising of textile fibres, is described as being performed at a temperature not exceeding or under 100° C. The present improvement consists in working at a temperature as high as 115° C., which is found necessary for treating certain materials.—S. P. E.

## VI.—DYEING, CALICO PRINTING, PAPER-STAINING, AND BLEACHING.

*The Chlorinating of Wool.* A. Balard. *Monit. Scient.* 42, 1891, 333—336.

Most previous writers on this subject have insisted on the fact that a prolonged action of chlorine on wool is to be avoided, as it imparts to the fibre a yellowish colour and a harsh, unpleasant feel. These authors generally state also that a once-used chlorine bath can be strengthened for further use by the addition of an amount of hypochlorite less than the original quantity. These two statements the present author denies. The chlorinating of cotton is a gradual and progressive action; not so, however, with wool, where the action is very rapid, the whole of the chlorine being absorbed by the wool in at most two minutes, and strengthening of old liquors is quite useless. The experiments on which these conclusions are based were made with a piece of woollen fabric weighing 20 grms., which had previously undergone the operations of soaping, stoving, washing, &c. A solution was prepared containing 5 grms. of sulphuric acid and 12 cc. of hypochlorite of soda (corresponding to 0.6 gm. of dry bleaching powder of good quality) in one litre of water. One volume of such a solution immediately decolorises one volume of a solution of indigo in sulphuric acid, so diluted that its colour is just visible. The wool is steeped in the chlorine bath for one minute, and, after removing it, the bath no longer decolorises indigo solution, showing that all chlorine has been removed by the wool. Sometimes, indeed, half a minute suffices for the removal of the chlorine. Another 12 cc. of hypochlorite are added to the bath and the wool re-entered for a minute; all chlorine has again disappeared from the bath, and this may be several times repeated, always with care that an excess of acid be present. After three or four operations the wool acquires a yellowish tint and a harsh feel. Even when the hypochlorite bath is four times as strong as the above (eq. to 12 per cent. of bleaching powder on the weight of wool), in two minutes every trace of chlorine will have been removed by the wool. The essential point for consideration is evidently the relative proportions of chlorine and wool, rather than the time of action. The best proportion is 2–5 per cent. of bleaching powder, or its equivalent. If calcium hypochlorite be used the acid must be hydrochloric, with sodium hypochlorite either hydrochloric or sulphuric; an excess of acid must always be present. As hydrochloric acid tends to render the wool yellow when used for this purpose, the employment of sodium hypochlorite with sulphuric acid is to be preferred. Chlorates are not here available as the source of chlorine. The acid bath may precede, or follow, the chlorine bath; preferably the former.

A mechanical difficulty to be overcome is that of rendering as even as possible the absorption of chlorine by the wool. If dyed in chain form, those portions reaching the liquor first absorb too much chlorine, while the latter portions receive little or none. It is better therefore to dye in the open width, making use of a frame similar to that employed in vat-indigo dyeing; the parts of the frame must be constructed of some material capable of resisting the prolonged action of chlorine.

The rapid removal of chlorine from the bath might have been attributed to the action of the sulphurous acid present in the stoved wool, but for the striking result of an experiment carried out with a piece which had been stoved but not subsequently washed. This piece was steeped in the acid bath, then in sodium hypochlorite, and finally in a second bath containing sulphuric acid. In the last bath a considerable evolution of sulphur dioxide occurred. On washing, the wool was found to be satisfactorily chlorinated. Evidently the sulphuric acid and hypochlorite reacted to produce chlorine, and a certain amount of the liberated soda combined with the sulphurous acid to form sodium sulphite, this being decomposed in the second acid bath with liberation of sulphur dioxide. The satisfactory result of the chlorination indicates that, in the presence of wool and sulphurous acid, chlorine is more readily absorbed by the former than rendered inactive by the latter.—R. B. B.

*The Cleaning and Dyeing of Cattle- and Horse-Hair, and of Pigs' Bristles.* M. Ganghofer. *Farb. Zeit.* 5, 366—368.

Before making use of cattle- and horse-hair, they must be thoroughly washed. Cattle-hair should be steeped in cold water for 1–2 days, the treatment repeated with fresh water, and the hair then washed with hot water. Horse-hair, if from the tail, is generally less dirty, and washing in hot water suffices; but if from the mane, the steeping is also necessary. In many places a police order is in force, according to which horse-hair must be disinfected by warm hydrochloric acid, as the grease upon the hair, in a state of decomposition, has caused blood poisoning among the workmen. Pigs' bristles are steeped in cold water, and then washed in cold running water. The hair from the sides of pigs (pigs' wool) can be put directly into the dye-bath without washing. For stuffing purposes these various kinds of hair are generally dyed black by the process to be described. After washing, they should be at once dyed, or ammonia may be formed, which acts injuriously on the colour and on the other properties of the hair. Pigs' wool and bristles are the most easily dyed and require the least dyestuff; cattle-hair and that of the horse's tail require more dye and longer boiling; hair from the mane must be boiled long and carefully, since it is easily matted. Goats' hair, camels' hair, and other similar products may also be dyed according to the following method:—

*The Black-dyeing of Hair.*—The hair is packed very closely in the dye-bath. For every 100 lb. of hair, 3 lb. of solid logwood extract and  $\frac{3}{4}$  lb. solid fustic extract are dissolved in water and the solution poured into the bath. 3 lb. ferrous sulphate are dissolved and this solution also poured in. The bath is then filled up with water, and the hair pressed tightly down by means of boards weighted with stones, so that it cannot rise during boiling. The bath is raised to the boil; pigs' wool and bristles are boiled for 2–2½ hours, cattle- and horse-hair (tail) 3 hours, and horse-hair from the mane, at least 4 hours. At the end of this time allow the goods to remain 1–2 hours in the cooling dye-bath. The liquor is then run out, and, except for pigs' wool and bristles, the shade is made darker by working in a weak solution of potassium bichromate at about 80° C. for  $\frac{3}{4}$  hour. Allow to cool, and wash. It is most economical to use as large dye-vessels as possible, holding, for instance, 1,000–1,200 lb. If not more than 300 lb. are dyed in one lot, 2½ hours boiling is sufficient for any variety of hair. In every case the material should be allowed to remain some time in the dye-bath after boiling.—R. B. B.

## VII.—ACIDS, ALKALIS, AND SALTS.

*Improvements in the Sulphuric Acid Industry.* P. de Boissieu. *Bull. Soc. Chim.* 1894, 11—12, 726—729.

THE large capital involved in providing sulphuric acid plant, with extensive lead chambers, is commented on, and it is stated that the smallest chambers in use, producing 1,500 kilos. of acid daily, cost 70,000 francs; while plants turning out 5,000 to 10,000 kilos. cost from 100,000 to 200,000 francs. The problem of manufacturing sulphuric acid with a much greater economy of space and capital, appears, it is said, to have been solved by E. J. Barbier, while the produce is not lessened, nor the cost of production increased.

The three reaction towers shown (Fig. 1) in the smallest apparatus (for production of 800 to 1,000 kilos. of acid per day) are respectively 5, 6, and 7 metres high, and  $1\frac{1}{2}$  m.

Fig. 1.

THE BARBIER APPARATUS.

square in the base. They are lined externally with sheet lead 3 mm. thick, to prevent leakage of gases. The interiors are filled with special cells (Fig. 2), made, like the towers,

Fig. 2.

of acid-resisting material, which give a surface of about 70 superficial metres for each cubic metre occupied. The oven at the base of the towers carries the concentrating basins, arranged *en cascade*, in which the sulphuric acid is concentrated as it forms, and flows continuously from the lowest basin at  $58^{\circ}$ — $60^{\circ}$  B. The sulphurous acid gas from the pyrites burner, after having heated the space below the basins, enters the upper part of a special tower, where it is washed by strong sulphuric acid, free from nitrous products, and is thereby freed from dust. The gas then circulates through the three towers, and lastly enters the Gay-Lussac column terminating the apparatus. The first tower is washed with water and dilute nitric acid; the other towers by concentrated acid. Thus, in each part of the system sulphuric acid is continuously produced and flows to the base of each tower, whence it overflows into the concentrating basins, in which denitration simultaneously goes on, so that water vapour and nitrous products return to each

tower to aid the reactions. The acid produced does not come into contact with lead, and is not soiled, like chamber acid.

It is a feature of the Barbier apparatus that the temperature of the tail part is always over  $50^{\circ}$  C., and that of the first tower over  $90^{\circ}$ , thus having a wider and higher range than the ordinary chambers, the temperature in which varies between  $40^{\circ}$  and  $60^{\circ}$ . It follows that the new apparatus may be established in warm countries without any loss of advantage. As dilute nitric acid does not react on sulphurous acid at ordinary temperatures, but only at between  $60^{\circ}$  and  $80^{\circ}$ , which latter temperature is never attained in the ordinary chambers, it is considered probable that the reactions which produce sulphuric acid in the Barbier apparatus, differ in certain respects from those occurring in the chambers.—E. S.

*Vinegar: its Manufacture and Analysis.* R. T. Thomson.  
A Paper read before the Glasgow City Analysts' Society.  
Abstracts. No. 1, 1893-94, 3.

THE author's special object is to indicate how and to what extent chemical analysis can show from which of the various sources a sample of vinegar has been derived. For this purpose, the percentages of acetic acid, organic matter non-volatile at  $100^{\circ}$  C., ash, potash, and phosphoric acid are determined. The "original solids" are then calculated by Hehner's method, viz., multiplying the acetic acid by 1.5 and adding the result to the total solids.

The first column in Table II. shows the composition of undistilled vinegar of average strength prepared from pure malt, the figures being based upon analyses of malt extracts prepared by the author, as well as of genuine commercial extracts. To produce a vinegar of this composition, a malt infusion of sp. gr. 1.035.5, containing 9.2 per cent. of total solids, would have to be fermented to a specific gravity of about 1.000, which is the usual practice. During acetification, the specific gravity would gradually rise to about 1.014, if no loss took place, and the total solids would decrease to about 1.7 per cent. The relations of the ash, potash, and phosphoric acid to the original solids, and especially the relative proportions of potash and phosphoric acid, would be practically unaltered by the fermentation; these are therefore the most reliable data, as they do not vary with the strength of the vinegar. Table I. gives these data for vinegars prepared from various materials, and it will be observed that in the sugar and molasses vinegars the phosphoric acid forms a very small proportion of the ash. As the percentage of ash in sugar and molasses varies largely, the comparison with malt must be made on the composition of the ash. To distinguish wine vinegar, the presence or absence of tartaric acid is a valuable criterion; and the percentage of nitrogen is useful in discriminating between starch-glucose vinegar and other vinegars.

The value of the phosphoric acid estimation has been impugned on the ground that if a hard water were to be used in washing the malt, the phosphoric acid would be precipitated as phosphate of lime. The author has, however, calculated that in mashing, conducted on the

strength of wort mentioned above, a water having at least 120 of hardness would be theoretically required to remove all the phosphoric acid. It is unlikely that water with more than 30 of hardness would be used, involving the possible removal of one fourth of the phosphoric acid; but even against this must be set the appreciable acidity of the wort, which would probably be sufficient to more than neutralise the alkalinity of the water. But rather than set up too strict a standard, the figures given for mixed grain might reasonably be adopted for undistilled malt vinegar.

Referring to the typical analyses in Table II., although No. 1, from the percentages of potash and phosphoric acid in the ash, is of doubtful source, there is no warrant for saying it is not a pure malt vinegar, as there is not a wide enough range of facts to establish an essential difference between it and genuine malt vinegar. No. 2, however, cannot possibly be undistilled malt vinegar, nor can it be fully fermented undistilled sugar vinegar, as in that case it would yield at least 0.3 per cent. of "total solids" consisting of succinic acid and glycerin. The conclusion is inevitable that it is a distilled vinegar, but from what source it has been distilled is not known. Some chemists have regarded the absence of any trace of alcohol in a distilled vinegar as a proof that the sample cannot have been made by fermentation, but must consist of wood vinegar; this is, however, founded on the mere assumption that alcohol cannot be perfectly fermented. According to a decision of the Glasgow Sheriff, distilled malt vinegar is as truly "malt vinegar" as the original article.—L. A.

*The Estimation for Industrial Purposes of Boric Acid in Boronatrocalcites.* G. A. Le Roy. *Monit. Scient.* 42, 1894, 522.

See under XXIII., page 1094.

#### PATENTS.

*Improvements in Apparatus for Concentrating Sulphuric and other Acids.* E. Dyson, Manchester. Eng. Pat. 17,699, September 20, 1893.

THE concentrating vessels are constructed of cast-iron lined internally with an acid-resisting enamel, and are set in an inclined chamber and arranged generally in the fashion now well known in connection with "cascade apparatus." The fire-gases pass from the ascending chamber containing the stills or concentrating vessels, into the upper flue in communication with the chimney, thereby heating the

supply tanks for maintaining the supply of acid to the stills below. To connect the concentrating vessels one with the other, the use of siphons constructed "with a double curve or double U form to deliver acid from the bottom of one vessel to the top of the next," is claimed, as also a suitable float valve with hollow stem extending up the inlet-pipe, the bottom end of which corresponds with the shape of the valve described in the specification.

There is also claimed the combination of the cooler and cooling-vessels described, with the furnace and concentrating vessels.—E. S.

*Improvements relating to the Manufacture of Alkaline Carbonates and Silicates.* J. Reich, Vienna. Eng. Pat. 18,139, September 27, 1893.

SODIUM or potassium chloride solution (or other soluble alkali salt) is treated with fluosilicic acid, and the dried precipitate is heated with silica in a clay retort, to obtain the alkali metal as a silicate, and silicon fluoride gas, which is absorbed by water, to form fluosilicic acid and silica for re-use. If the alkaline silicate is not intended to be used as such, it is dissolved in water and dosed with carbonic acid, to form a carbonate; the silica which precipitates is collected for use in the described process.

The process may be modified by using "boron hydrofluoric acid or hydrofluoric acid for effecting the double decomposition into an alkaline boron fluoride or an alkaline fluoride," the fixed product being, as before, an alkaline silicate, and the volatile products boron fluoride and silicon fluoride, or the latter only, as the case may be. Details are given. In this process, after forming an alkali fluoride, this may be retorted with alumina, instead of with silica, the reaction being thus represented, " $AX$ " standing for the alkali metal:— $12AX + 2Al_2O_3 = Al_2F_6 + Al_2(OH)_6$ , the products being an artificial cryolite and an aluminat. By lixiviation, an alkaline aluminat is dissolved, and the solution, treated with carbonic acid, yields an alkaline carbonate in solution, and a precipitate of aluminium hydroxide.—E. S.

*Improvements in Lime Kilns.* B. Dawson, Malvern Link. From Quarez Frères, Villeneuve-sur-Verberie, France. Eng. Pat. 20,791, November 2, 1893.

See under IX., page 1062.

*Improvements connected with Apparatus for the Manufacture of Bleaching Powder (Chloride of Lime) or similar Commodities.* J. M. Milnes, St. Helens, and A. Milnes, London. Eng. Pat. 21,356, November 9, 1893.

THE inventors employ spear heads or conical tips to the rakes used for stirring the material to be impregnated with chlorine gas, in order to prevent adherence of the pasty substance, and that every particle of lime may have similar exposure. These improved rakes are to be used in combination with other appliances described in Eng. Pat. 15,833, 1891 (this Journal, 1892, 967), and in Eng. Pat. 19,180, 1892 (this Journal, 1893, 263).—E. S.

*Improvements in the Utilisation of the B. An Bricks used in the Deacon Chlorine Process, and the Recovery of Copper therefrom.* J. R. Wyde, Pres., and D. Williams, St. Helens. Eng. Pat. 21,412, November 10, 1893.

THESE bricks become useless after a time, owing to formation in them of cupric sulphate, which is inactive for the decomposition of hydrochloric acid. According to the present invention, the spent bricks are lixiviated, preferably by water containing about 5 per cent. of hydrochloric acid. The copper solution thus obtained is precipitated with iron in the usual way, and the washed bricks are dried, and are then again available for use.—E. S.

*Paper on the Preparation and Manufacture of Hydrosulphurous Acid and Hydrosulphites.* J. Grossmann, Manchester. Eng. Pat. 16,967, August 23, 1894.

SOLUTION of sodium mono-, bi-, or metasulphite, or a mixture of these, of such strength as to contain from 15 to 25 per cent. of total sulphurous acid, is placed in a closed vessel fitted with an agitator, and having a pipe reaching nearly to the bottom. About a tenth of the bulk of the liquid, of 10 per cent. sulphuric acid, is introduced by the pipe, and, after agitation, an excess of zinc dust or other suitable reducing agent is quickly added, followed by agitation, with the usual precautions as regards temperature and exclusion of air. When the reagents are exhausted, fresh portions are added in like manner successively, until about half the bulk of the original liquid in dilute sulphuric acid has been introduced. The reagents are then added in smaller portions, until suitable tests show that the maximum of hydrosulphurous acid has been formed. The proportions thus once determined may be adhered to afterwards. To ascertain the point when the maximum quantity of hydrosulphurous acid has been formed, Berthsen's test as modified by Rawson is recommended. The process may be applied in the case of other than sodium sulphites, and even with difficultly soluble sulphites, as of calcium or zinc, which are held in suspension in water, instead of in solution. Also, dilute sulphuric acid may be replaced in the process by solution of an acid salt, as of sodium bisulphate.—E. S.

## VIII.—GLASS, POTTERY, AND ENAMELS.

*The Weathering of Glass and its Decomposition by Water.* F. Foerster. Zeits. anal. Chem. **33**, 1894, 322—335.

From a long series of experiments of his own on these subjects, and from the work of others, the author draws the following conclusions:—

1. The weathering of glass is caused by the decomposing action of the atmospheric moisture. The carbonic anhydride of the air does not act directly on the glass, but only on the alkaline products of the aqueous decomposition.

2. Dry carbonic anhydride is without action on dry glass.

3. There is no proof that water can be retained by glass, except when it enters into chemical combination therewith.

4. The weathering of glass and the decomposition of glass by water are similar processes, and are both preceded by the taking up of water into the glass molecule.

5. The surface changes caused by weathering are comparatively slight with good glass.

6. The action of water on weathered glass is only temporarily more rapid than it is on new glass.

7. Glasses (lime glasses) are more hygroscopic and weather more easily, the more easily they are attacked by water.

8. Even after long action of water, glass is still capable of becoming weathered.

The following table gives the results obtained. The glass used had the composition  $\text{SiO}_2 = 69.4$ ,  $\text{CaO} = 7.0$ ,  $\text{Al}_2\text{O}_3 = 3.0$ ,  $\text{MnO} = 0.4$ ,  $\text{K}_2\text{O} = 7.1$ ,  $\text{Na}_2\text{O} = 13.1$ . The glass was in each case treated with water at  $20^\circ$  for one minute, and the amount of alkali removed estimated. The glass was then put in fresh water and left therein for 24 hours, when the water was again renewed, and this was repeated each day:—

Alkali removed by Water at  $20^\circ \text{C}$ .  
In Thousandths of a Milligram per 100 sq. cm. exposed.

—L. T. T.

*The Action of Acids on Glass.* F. Foerster. Zeits. anal. Chem. **33**, 1894, 299—322.

In order to complete his own and Mylius' work on the action of water, of alkalis, and of saline solutions on glass, and to control the work of others on similar lines, the author has carried out a long series of investigations on the action at different temperatures of acids of different strengths on glasses of different composition. From his own results and those of others, he draws the following conclusions:—

1. With alkali-lime glass as generally employed for chemical apparatus, and with lead glasses not richer in

lead than is crystal glass, the action of aqueous acids is less than that of pure water, is independent of the nature and (within certain limits) the concentration of the aqueous acid, and is due to the water contained therein; and the action of the acid consists almost solely in neutralising the alkali dissolved out by the water.

2. With glass rich in lime and with flint glass very rich in lead, aqueous acids exert a strong action, which is dependent on the nature and the concentration of the acid.

3. On ordinary lime glass boiling strong sulphuric acid has less action than boiling water.

4. At high temperatures sulphuric acid vapour attacks glass strongly, forming a coating of alkali sulphates which produce a deep-seated change in the surface of the glass.

The following tables give the principal numerical results with the various kinds of glass experimented on.

Experiments with Wollastonite, Labradorite, and other silicates (and even some varieties of glass) showed that when the proportion of base to silica is much larger than in the usual varieties of glass the action of acids is much greater than that of water.—L. T. T.

## PATENTS.

*Improved Apparatus for Manufacturing Pottery.* J. Slack, Nottingham. Eng. Pat. 18,023, September 26, 1893.

A THROWING-WHEEL with a hollow vertical shaft is provided with a disc, to which are attached jointed vertical arms controlling the movement of the plates used in moulding the ware. A second disc is attached to a second vertical shaft working within the main shaft, and carries the joints on which the plates are hinged. Similar internal plates serve to mould the inner side of the ware. A lifting-rod is provided for removing the article from the mould, after its ornamentation by means of the plates, has been effected.—B. B.

*Improvements in Ovens for Baking or Firing Ceramic Ware and other Refractory Products.* J. B. Hanquiaux, Charleroi, Belgium. Eng. Pat. 22,637, November 25, 1893.

See under I., page 1048.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

## PATENTS.

*Improvements in Cement Kilns.* E. de Pass, London. From L. E. A. Lavocat and E. L. Candlot, Paris, France. Eng. Pat. 19,259, October 13, 1893.

THE patent relates to the utilisation of the waste heat from cement kilns, particularly those of the continuous type, for drying the raw materials, whether in the form of slurry or bricks. Two drying chambers are connected with the exit flue of the kiln in such a manner that the waste gases can be sent through either at will. The tops of the drying chambers may also be used for drying a further portion of slurry. The arrangement, although primarily intended for continuous kilns, may be utilised for intermittent kilns of the ordinary English pattern.—B. B.

*An Improved Hoffman or Continuous Kiln for Drying and Burning Bricks and other Goods.* R. Cook, Kensal Rise, Middlesex. Eng. Pat. 19,848, October 21, 1893.

See under I., page 1047.

*Improvements in Lime Kilns.* B. Dawson, Malvern Link. From Quarez Frères, Villeneuve-sur-Verberie, France. Eng. Pat. 20,791, November 2, 1893.

GAS from a separate producer, preferably with water bottom, is introduced under pressure through suitable channels into peripheral openings in the lining of a kiln of circular section, and through other ports in a smaller central chamber, below, and concentric and continuous with, the first. Air is supplied below every gas port by natural draught, and both gas and air flues are provided with dampers, so that the supply of each to any point is under control. Thus combustion is complete, and heat distribution uniform. The discharging doors for the burnt lime are hermetically sealed when not in use.—W. G. M.

*Improvements in the Manufacture of Finely-pulverised Substances for Use in the Production of Portland Cement, Pigments, and the like.* A. Patrick, Glasgow. Eng. Pat. 21,292, November 9, 1893.

See under I., page 1048.

*Improvements in the Manufacture of Cement Mortar.* M. Williams, Liverpool. Eng. Pat. 22,227, November 21, 1893.

ABOUT eight parts of furnace ashes, slag, or coke, four parts of slaked lime, and one of clay, are taken and mixed dry so as to form a cement, which, on mixing with water, sets in the ordinary way. The proportions of the materials may be varied so as to produce either an aerial or hydraulic cement.—B. B.

*Improved Process for Manufacturing Hydraulic Cement.* G. W. A. Stein, Wetzlar, Germany. Eng. Pat. 5971, March 10, 1894.

BRICKS or blocks of raw materials for cement-making are usually mechanically weak, and have to be protected from weather and be artificially dried before being burnt to clinker. The present patent prescribes the addition of 5–10 per cent. of a slag cement of the usual composition (e.g., 75 per cent. of granulated slag and 25 of slaked lime) to the raw materials, in order that the bricks may be strong enough for convenient handling, prior to burning.—B. B.

**Improvements in Kilns.** H. J. Haddan, London. From The Columbian Pottery and Brick Kiln Company, Chicago, U.S.A. Eng. Pat. 2516, May 15, 1894.

THE improved kiln is annular in shape and surrounds a central smoke-stack. The floor is divided into five (or more) equal radial sections, and being mounted on rollers is capable of being rotated bodily, but independently of the walls and roof. On one side of the kiln three movable partitions serve to separate two of the sections from the remainder of the kiln and from one another, and each of the two sections thus separated has a door for charging or discharging; the outer partitions are formed of two iron sheets with asbestos between them; the other is of wood. On the opposite side of the kiln a vaulted fire-brick combustion chamber is built over the roof of the central section, and apertures conduct the heated products of combustion downwards into the kiln; over the sections on either side of this, similar chambers of ordinary brick are erected, one with a perforated roof the other plain, but only the central section is fired. Below the floor level are two apertures connected with the smoke-stack, one corresponding with the firing section, and one with the adjoining section, which has the plain roof. The whole of the annular floor is perforated, the perforations communicating with interlaced flues beneath, which flues are arranged in five equal sections independent of one another, and corresponding to the sections of the kiln. The flues independently converge at five apertures symmetrically arranged on the inner side of the ring, and two only of the systems are therefore in communication with the smoke-stack by means of the apertures above alluded to. In use, while one section is being charged, the next to it is being discharged through the two openings provided, and air-holes in the roof at this side of the kiln allow free ventilation. The partitions are then raised and the floor is turned through one-fifth of a revolution, so that each section is moved on, and the partitions are again lowered, charging of the section emptied the previous day, and discharging of the newly-exposed section taking place as before. The chamber, previously being heated by radiation, has now passed into the firing section, and that which was fired is now cooling ready to be discharged at the next shift. The air used for combustion is preheated by radiation from the cooling section of the kiln. The floor of the kiln is shifted once in 24 hours.—W. G. M.

**Improved Method of Vulcanising and Drying Wood.** C. Howard, New York City, U.S.A. Eng. Pat. 15,231, August 9, 1894.

THE wood is enclosed in an air-tight cylindrical chamber, from which the air is then exhausted; a gentle heat is employed, which, aided by the reduced pressure, causes vapourisation of the moisture in the wood and expansion of the air within its pores. Air pressure is next applied and the heating continued; and finally the wood is cooled, air being meanwhile circulated through the cylinders and through a condenser, for the removal of moisture.

—W. G. M.

**Improvements in Plastering for Ceilings and Partitions.** E. H. Jung, Daggens Road Station. Eng. Pat. 15,589, August 16, 1894.

THE patent relates to the production of sheets of plastering material, about two square yards in size, from various mixtures of water, slaked lime, tar, shavings, sawdust, "sifted kiln refuse," cow-hair, heather, cocoa-nut fibre, and plaster of Paris, made into a paste with water and cast into slabs in suitable moulds. An india-rubber sheet is placed on the table used for casting, so that the mixture is spread thereupon and can be subsequently removed. The mixture sets in about 20 minutes, and is ready for use in two or three weeks. It can be nailed to the joists of ceilings and be coated with ordinary plaster to make good the joints between the slabs.—B. B.

**Improvements in and relating to Damp-resisting Materials.** R. J. Goddard, London. Eng. Pat. 15,756, August 18, 1894.

A MIXTURE of asphaltic or bituminous materials is prepared and cut into strips or sheets on a slab or table, so as to be in a form suitable for use as a damp-proof course, in building construction. A lining or backing of canvas or other fabric may be applied to the strip of composition so as to form a portable material which may be laid in place to form a damp-proof course.—B. B.

## X.—METALLURGY.

**Desulphurisation. The Action of Iron Sulphide on Manganese, Aluminium, Nickel, Chromium, &c.** Bull. Soc. Chim. 11 12, 1894, 583—587.

THE Soc. Chim. de Paris, through its *Bulletin*, has previously promoted a discussion relative to the desulphurisation of the products formed during the Saniter process, with the object of determining whether the reaction—

is possible in the absence of a reducer such as carbon. The facts collected do not justify any absolute conclusion. Ledebur in *Stahl und Eisen* gives the arguments on both sides and suggests that a purification by means of a basic calcareous slag is not indispensable to the verification of the said reaction. Another explanation is possible, namely, that the iron sulphide dissolves in the basic slag. There appears no reason why this substance should not dissolve without decomposition. Further, the dross of puddlings, even if poor in manganese and without lime, gives off sulphur in the free state. Lime slags can remove sulphur from iron under certain conditions; but, on the other hand, slags containing sulphur, even if basic, give it up to the metal. Thus, an iron rich in sulphur can be purified at high temperatures by a fluid basic slag containing little sulphur, but, on the contrary, an iron poor in sulphur would absorb that element in contact with a slag containing much sulphur and but slightly fluid. The Saniter process has, then, a certain theoretical value if one regards the addition of calcium chloride (its special feature) as merely a means of making the slag more fluid.

The desulphurising influence of manganese can be explained by the fact that manganese sulphide, which is less soluble in metal than iron sulphide, will rise to the surface and is more easily absorbed by basic slags.

The employment of lime slags with manganese is advantageous because the slag becomes more fluid and a more powerful solvent. Up to the present we depend almost entirely on manganese to desulphurise iron. In the Thomas converter the higher the initial percentage of sulphur the greater the proportion eliminated. Experiments made in Pennsylvania show that in remelting in the cupola for the Thomas process the sulphur increases in proportion as the manganese is low, and with less than 0.7 per cent. of manganese one gets a metal containing more sulphur than in the original metal.

Hüfenstock has tried to find out the reciprocal action of sulphur on iron and certain metals, and also the action of sulphurous gases on iron, manganese, and certain metallic oxides. He found that on mixing and heating together iron sulphide and a rich ferromanganese (sufficient to make manganese sulphide) a mottled mass was obtained infusible at a white heat. If, however, the two were melted apart and then mixed, the manganese sulphide separated in the solid form, leaving the metal liquid. By analysis the iron was found practically desulphurised.

By melting separately and then mixing iron sulphide and aluminium, an energetic reaction took place, with partial combustion of the iron and aluminium. A dross rose to the surface, quickly separating from the refined metal. The iron was of fine grain. The dross, at first black and liquid, became a grey powder and gave off sulphuretted hydrogen.

Treated in the same way iron sulphide and nickel, the mass did not separate, a complex sulphide of iron and nickel being formed. Copper acted in a similar way. For chromium a chrome iron containing 38 per cent. of chromium and 3 per cent. of manganese was used. A refined metal containing 10.56 per cent. of chromium and 0.037 per cent. of sulphur, and a heterogeneous dross, chiefly iron sulphide, was obtained. Probably chromium acts less energetically than manganese.

A ferro-silicon containing 15 per cent. of silicon was poured, when melted, into the molten iron sulphide. The mixture separated completely into metal and dross. The ferro-silicon changed but little, and absorbed very little sulphur, which confirms Turner's observation that silicon hinders the absorption of sulphur.

A current of carbon dioxide containing in turn small quantities of (1) hydrogen sulphide, (2) sulphur dioxide, (3) carbon disulphide, was passed over ferromanganese containing 80 per cent. of manganese, and over finely-powdered metal containing 1.5 per cent. of manganese, and 0.06 per cent. of sulphur, heated to a red heat. Coal-gas *per se* was also employed. The following figures show the percentage of sulphur absorbed in each case:—

	H <sub>2</sub> S.	SO <sub>2</sub>	CS <sub>2</sub>	Coal-Gas.
	S per Cent.	S per Cent.	S per Cent.	S per Cent.
Ferromanganese.....	16.04	1.18	2.69	0.96
Metal.....	12.62	1.95	1.09	0.18

Using sulphur dioxide with steel, the absorption was 1.36 per cent. of sulphur, and with nickel 2.08 per cent.

Finally, the gases previously dried by calcium chloride and equally diluted with carbon dioxide, were passed through metallic oxides placed in glass tubes; the percentages of sulphur taken up were:—

	H <sub>2</sub> S.		SO <sub>2</sub>		CS <sub>2</sub>	
	Low Red.	Bright Red.	Low Red.	Bright Red.	Low Red.	Bright Red.
Fe <sub>2</sub> O <sub>3</sub> .....	0.292	0.377	0.566	0.100	11.020	26.350
MnO.....	1.762	5.043	1.270	4.880	7.065	23.370
CaO.....	3.528	0.990	5.050	5.080	0.650	3.960
MgO.....	1.394	0.960	2.244	0.660	0.718	0.530

All the oxides take up sulphur according to the temperature and the gas employed. What the influence of the carbon dioxide is, and in what state the sulphur is retained, afford field for useful research.—A. W.

*The Dressing of Spathic Iron Ore at Allevard.*  
G. Gromier. Bull. de la Soc. de l'Ind. Min. 1893, 465.  
Proc. Inst. Civil Eng. 1894, 118, 62—64.

In the neighbourhood of Allevard in the Dauphiny Alps numerous workings have been opened by Messrs. Schneider and Co. upon veins containing spathic iron ore in sandstones and crystalline schists, the former being of Permian or triassic and the latter of pre-Cambrian age.

The mineral, a magnaniferous spathic ore very much mixed with waste, including particles of the enclosing sandstones and schists, and quartz often very closely aggregated.

The calcination of the coarse material is effected in tall kilns heated by gas, from producers worked with closed ash-pits and water injection. The point of combustion is at about one-third of the height of the stack, the space below forming a hopper for cooling the burnt ore, which gives off its heat to the air employed for combustion. Four kilns, each of the capacity of 25 tons in 24 hours, are used; the consumption of coal is 3 per cent. of the weight of the ore treated. The loss of weight is 28 per cent., the

burnt ore retaining about 2 per cent. of carbon dioxide, care being taken to prevent clinkering by the formation of silicate when the heat is raised too high.

The calcined ore discharged from the kilns is raised by a direct-acting hydraulic lift, worked by a head of 1,309 ft. of water, to a second picking-house, where it is divided by a 130-mm. sieve, and passed over balanced picking-tables. The object of this second hand-picking is to remove the closely intermixed quartz, which can be readily done in the larger pieces, as the ore is rendered friable by the calcination. The smaller-sized stuff is cleaned by crushing and sizing through a 9 mm. wire sieve, and passing the fine powder over a series of wooden rollers, each carrying 72 horse-shoe magnets, which take out the magnetic dust from the ore as it falls, the deposit being continuously removed by a rotating brush behind each row of magnets.

The smaller stuff separated by the first picking-house contains from 25 to 30 per cent. of waste material which can only be removed by washing, but on account of the small difference in density between spathic ore and quartz, 3.76 and 2.60, tolerably close sizing is necessary as a preliminary to jigging. With a consumption of about 120 gallons of water per minute about 120 tons of material can be passed through the dressing machinery in 10 hours, with a loss of weight of 10 to 23 per cent., the proportion of waste being reduced from 25 to 30 per cent. in the rough ore, to 12 per cent. in the clean ore. The washed ore is received in hutches, where the adherent water drains off, and is afterwards loaded into waggons for removal to the calcining furnaces. These are of two different patters, one being vertical and the other inclined, but both are heated by gas made from coal in a separate producer, with forced draught and steam injection. The vertical furnaces are arranged in groups of four in a tower 46 ft. high and 18 ft. in diameter, the fine ore fed in at the top falling in an interrupted stream down a narrow zig-zag passage between inclined walls, in a similar manner to that adopted in the Hasenclever Heibig furnace, where it is subjected to the flame of gas burnt with hot air, together with a free supply of air for oxidation. The slope of the inclined walls varies from 45° above to 30° below, as the ore is found to run down more easily as it becomes drier and hotter. The inclined furnaces resemble those used in Styria for treating small spathic ore, and in Sardinia for calamine. They are in narrow reverberatory furnaces with beds about 65 ft. long and 5 ft. broad, with a strong upward inclination, so that the feeding hopper is about 45 ft. above the fireplace. The output of both classes of furnace is about the same, namely, 25 tons in 24 hours, but the consumption of coal is 6 per cent. of the weight of the calcined ore, or double that required in the kilns. The inclined furnace is considered to be the best, being simpler in construction and more easily managed than the vertical form.

The calcined ore, when drawn from the furnace, is quenched with a jet of water, in order to slake the caustic lime and magnesia formed by the calcination of the dolomitic constituent of the vein stuff. It is then carried by a travelling band to an elevator, which supplies the agglomerating machine. Finely-ground hydraulic lime is then added to the quenched ore, which contains about 12 per cent. of water, in the proportion of five parts of the former and 95 of the latter. The mixture is then moulded in a double compression Couffignal briquette machine, into blocks 140 mm. square and 120 mm. long, weighing 15½ lb. each, under a pressure of about 4 tons per square inch. The briquettes, after drying for a week on a platform over the ash-pits of the gas-producer, are sufficiently coherent to bear a pressure of 200 lb. per sq. in., and are removed by railway.

The motive power required for the different operations is as follows:—

	H.P.
1. First-sizing and hand-separator.....	12
2. Magnetic separator.....	8
3. Sizing and washing small ore.....	45
4. Briquette machines.....	40
5. Hoists for kilns and washed ore.....	5

*The Manufacture of Open-Hearth Steel in Sweden.*  
Erik G. Östeltjärna. Trans. of the Amer. Inst. of Mining  
Eng. 1894; Proc. Inst. Civil Eng. 1894, **118**, 64-67.

Only three kinds of open-hearth steel are made in Sweden:—

1. The softest steel, containing 0.15 per cent. or less of carbon;
2. Tool steel, containing 0.45 per cent. or more of carbon; and
3. Steel castings.

Steel containing between 0.20 and 0.40 per cent. of carbon is seldom made, except at works which manufacture heavy plates. Of these, however, a considerable quantity is exported to England and other European countries.

*Soft Steel.*—In making the softest steel, pig iron as free as possible from sulphur is selected, this impurity being under no circumstances allowed to exceed 0.015 per cent. if the best quality of steel be required. The scrap used is as free as possible from rust, which in most cases contains a considerable amount of sulphur taken up from the coal smoke of factory chimneys. The finer scrap is often cleaned in a rotating apparatus. The author describes the process of manufacture as such that, in the case of the toughest Swedish soft open-hearth steel, the percentage of sulphur and oxygen in the metal at the end of the melt shall be so small that no ferro-manganese, or at most only a few tenths of 1 per cent., need be mixed with it. One fourth of 1 per cent. of manganese decreases the toughness of the steel more than an increase of phosphorus from 0.020 up to 0.045 per cent., which latter is the highest phosphorus percentage in first-class soft Swedish open-hearth steel.

*Tool Steel.*—For the manufacture of hard, first-class tool-steel, pig-iron made from Swedish ores as free as possible from phosphorus is used, with charcoal also nearly free from phosphorus. In hard steel the amount of phosphorus is kept under 0.03 per cent., and no steel is called first-class that contains 0.035 per cent. or more. The best sorts contain 0.022 per cent. and less. The pig-iron and steel are not allowed to contain more than 0.02 per cent. of sulphur; and, with the careful roasting of the ores always performed at the blast furnaces and the use of fluxes free from sulphur, it very seldom happens that the percentage of this impurity in the pig-iron is higher than that figure. If the steel is coming from the furnace too hot, so that piping is to be feared, it is either kept long enough in the ladle to sink to the proper temperature, or the De Laval heat-rings—iron rings lined with fire-proof material heated to a very high temperature—are used. These rings are placed on top of the moulds, and, in casting, are filled with steel, which remains melted in them, and sinks until the ingot below the ring is entirely solidified.

*Steel Castings.*—To make steel castings of perfect quality, a temperature has to be maintained in the furnace during the melting so high that the metal never becomes free from silicon, whereby the absorption of gas is resisted. For this reason the furnaces are much more severely strained in this manufacture than in making steel to be rolled, and do not last half so long as in the latter case.

The main point in the production of steel castings is that the moulds shall be made of proper materials. In Sweden a coarse-grained red sandstone and the purest quartzite (preferably amorphous), containing 99 per cent. or more of silica, are used for this purpose, both being ground to a suitable degree of fineness. The material is bound together with molasses, a solution of carpenter's glue, beer, wheat, flour, or Dutch clay. The facing material is either the finest quartz dust, or, more generally and preferably, a pure siliceous earth (*Kieselguhr*) obtained from Germany and stirred into a solution of carpenter's glue.

At a number of basic furnaces, magnesite imported from Germany is used as a lining and is considered the best material; but in many places dolomite is preferred because of its abundance in Sweden and its consequent cheapness. The operation of the basic process is the same as in America, except that, owing to the low percentage of phosphorus in the material used, no tapping of phosphoric slag towards

the end of the process is necessary. But, since as much pig iron and as little scrap as possible is used, about as much lime is added to counteract the silicon of the pig-iron. The greatest difficulty to be overcome in the basic method as practised in Sweden, has been to make solid hard steel and steel castings without adding aluminium; but this has been met by the addition of ferro-silicon and ferro-manganese, previously melted in a crucible, to the steel in the ladle.

A peculiarity in both the acid and the basic open-hearth process of Sweden is that it is preferred not to recatharise.

According to the reports of the Royal Department of Commerce, the production of open-hearth steel in Sweden was, in 1886, at 3 works, 22,460 tons, and in 1892, at 22 works, 76,556 tons.

*Contribution to the Study of the Structure of Steel.* F. Osmond. Comptes rend. **119**, 1894, 329-331.

By employing the method of polishing sections of steel in bas-relief described by the author in a previous communication (séance of the Académie of 9th April), he has obtained further insight into the structure of steel.

Working with a steel of medium hardness containing C = 0.45 per cent.; Si = 0.07 per cent.; S = 0.016 per cent.; P = 0.036 per cent.; Mn = 0.35 per cent., he heated it to a constant temperature of 825° C., a temperature sufficiently high to ensure all the transformations of the carbon and iron during heating, and then quenched it at decreasing points of temperature in water at 15° C., and examined its structure microscopically. He describes the microscopical appearance when quenched at 720° (before the beginning of the transformations of the iron); at 690° (during the transformations of the iron); at 670° (after the maximum disengagement of heat which accompanies the transformations of the iron); at 650° (during the transformation of the carbon); at 640° (after the transformation of the carbon). Analogous results were also obtained by varying the rapidity of cooling, starting from the steel at a temperature of 720° and quenching it in water at 15°, in boiling water, and in melted lead.

In the case of a hard steel containing C = 1.24 per cent.; Si = 0.35 per cent.; S = 0.012 per cent.; P = 0.017 per cent.; Mn, strong traces; all the points of transformation unite in one change at a temperature of 675° whilst cooling, and at 705° whilst heating, and the diffusion of the tempering carbon takes place more uniformly than in steels of medium hardness, and within a more restricted range of temperature. For the same reasons the structure of the tempered metal is more homogeneous and the variations on tempering at different temperatures are less sharp. We pass more suddenly from the point of no temper to the point of maximum temper. By tempering the steel heated to 735° in water at 15°, fissures were even produced in a disc of 12 mm. At this temperature also, the heating having been effected at about 1° per second, the decomposition of the carbide of iron was not yet complete; it would seem as if the dissolved carbon hindered the dissociation of the carbide by what might be called a certain osmotic pressure.

*Manganese steel containing 12 per cent. of manganese.*—As is known, without decreasing in hardness, this steel becomes much more malleable after tempering at a bright red or white heat. By polishing in bas-relief it was seen that the particles of the alloy were surrounded, after cooling slowly, by a hard envelope, and after cooling suddenly, by a soft envelope or by none. Hence the above-mentioned difference in mechanical properties: the tempering in this case acts by preventing the liquation of a hard and brittle carbide.

The author admits that all the facts he enumerates have not yet been explained, and points out that the impossibility of isolating all the different constituents of steel prevents us from defining them sufficiently by analysis, but he nevertheless concludes that the study of the structure of steel, especially of the medium hard steels, which are the most important, often furnishes very precise information upon—

1. The maximum temperature of heating.

2. The temperature at which the steel has been tempered.

3. The speed at which it has been cooled.

The observer notes that it is always useful to record the observations by photography, and that an enlargement of 800 times is sufficient, necessary and is generally sufficient.

—H. S. P.

*Temperature of Fusion of Tin.* P. Bogodanoff, Journal Soc. Phys. Chim. Russe de St. Petersbourg, 1893, No. 1.

The tin which has been used in these recherches was purified by a double transformation into metastannic acid, and regenerated by reducing with charcoal. In a series of experiments the author plunged the thermometer into the tin, and marked the mark which corresponded to the point of fusion. The surfaces of the tin and of the alloy which was employed as a bath, were maintained at the same level.

The mean of a number of experiments gave the melting point as  $231.14^{\circ}\text{C}$ . In another series of experiments the monometal method has given a mean result of  $231.17^{\circ}\text{C}$ . With English tin, as ordinarily purified, containing traces of antimony, arsenic, and phosphorus, by the method of immediate immersion, the point of fusion was found to be  $230.93^{\circ}\text{C}$ , and the point of solidification  $230.97^{\circ}\text{C}$ .—A. W.

*Methods of Estimating Carbon in Iron.* Götting, Verhandl. Ver. zur Beförd. des Gewerbell., October 1893.

See under XXIII., page 1096.

*Quantitative Estimation of the Impurities most commonly found in Commercially Pure or Rolled Nickel.* T. Fleitmann. Zeits. anal. Chem. 33, 1894, 335.

See under X., page 1096.

*The Part played by the Transformations of Iron and of Carbon in Tempering.* G. Charpy. Comptes rend. 1894, 113, 1258—1260.

From his experiments already described (see this Journal, 1894, 40 and 737), the author has concluded that an allotropic change is produced in iron by hardening, and that it is indicated by the disappearance of the characteristic halt in the stress-strain curve. It has long been known that the intensity of the Eggertz carbon coloration is also reduced by hardening; and in this paper the author seeks to define the conditions under which the two changes occur. Bars of good open-hearth steel, containing 0.71 per cent. of carbon, were cut from the same ingot for the purposes of the test: they were heated, for periods ranging from five minutes to an hour, to different temperatures between  $700^{\circ}$  and  $1,050^{\circ}\text{C}$ , and were then quenched in boiling water or in cold oil, and in one case in cold water. No change in the carbon colour is indicated in samples quenched at temperatures below  $740^{\circ}$ , although in some of the samples there are signs of iron alteration. Above  $740^{\circ}\text{C}$  the iron is completely changed, while the carbon change proceeds more gradually, and is accompanied by an increase in tenacity and decrease in extensibility. It is noteworthy that the allotropic iron change exerts but slight influence upon the tenacity of the metal, whilst the carbon transformation appears to be correlative with the increase in hardness.

The following table gives the details of the experiments upon 24 bars:—

#### IRON AND CARBON TRANSFORMATION IN TEMPERING.

Table of Results of Experiments.

*Improvements in Metallurgical Furnaces for the Reduction and Refining of Ores and Metals.* J. B. Torres, London. Eng. Pat. 13,696, July 11, 1893.

A COAL or crucible of refractory material is fixed within a heating chamber, and this is heated by means of gas from a two-step grate gas-producer. The grate-bars are hollow, and water is made to flow through them, so producing steam, which, passing through the burning fuel, yields water-gas by dissociation.—J. H. C.

*Improvements in the Treatment of Zinc Produced by Electrolysis.* W. Wright, Bettws-y-Coed, and J. B. Hamoud, Bromley. Eng. Pat. 17,166, September 16, 1893.

THE spongy metal at first produced is pressed into thin sheets between rolls, which is found to be better than pressing it into blocks.—J. H. C.

*Improvements in the Extraction of Gold and Silver from Ores or Matte.* B. Mierisch, Niagara. Eng. Pat. 22,397, November 22, 1893.

THIS is a modification of the chlorination process, in which hypochlorites and chlorates of alkalis and alkaline earths are employed to render innocuous the sulphur, arsenic, and low oxides existing in roasted pyrites or arsenious ores. The ores are mixed with sodium hydrate and then treated with chlorine, the admixture of sodium sulphate with the concentrated salt solution serving for lixiviation being prevented, if necessary, by replacing a portion of the sodium hydrate with a corresponding quantity of calcium hydrate. The precious metals, and also lead and zinc, are separated from the iron and copper contained in the solution by saturating it with sodium hydrate. The solution so obtained is passed through granulated zinc to separate the gold, silver, platinum, mercury, and lead, and the zinc solution is afterwards electrolysed in order to recover the zinc in a metallic condition, chlorine and soda solution being re-produced and again used in the process.—J. H. C.

*Improved Method of and Apparatus for Hardening or Tempering Steel Plates and other Articles.* H. W. C. Fairfax, London, and W. Beardmore, Glasgow. Eng. Pat. 4199, February 27, 1894.

THE tempering medium is a liquid which has been artificially cooled below the temperature of melting ice. The chilling process is in some cases applied to the metals while in a molten or semi-molten state, in a mould, and under pressure. Devices are described by which special parts may be cooled, such as the apices of conical projectiles.—J. H. C.

## XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

## PATENTS.

*Improvements in Carbons for Electrodes and other Purposes.* H. Y. Castner, London. Eng. Pat. 19,809, October 20, 1893.

THE present invention relates to the preparation of electrodes for use in electrolytic processes, such as that set out in the inventor's prior Eng. Pat. 16,046, 1892 (this Journal, 1893, 768), to prevent their rapid disintegration under the combined action of oxygen and chlorine. This he proposes to effect by heating gas-retort carbon to a high temperature by an electric current, while the carbon is surrounded by charcoal powder or otherwise protected

from any oxidising action. A current of 350 to 500 amperes passed through a carbon rod one inch square raises it in a few minutes to dazzling whiteness. Ordinary gas-retort carbon under similar treatment gives off an inflammable gas, decreases in weight by from 3 to 7 per cent., swells slightly, and increases in electric conductivity.—J. C. R.

*Improvements relating to the Deposition of Metals and Compounds.* S. O. Cowper-Coles and Captain Sir B. W. Walker, London. Eng. Pat. 21,760, November 14, 1893.

THE authors claim the addition to the liquid, in electrically depositing metals or compounds, of the finely-divided metal or compound, which is kept in suspension during the passage of the current by mechanical or other means.—J. T. D.

*Improvements relating to the Coating of Plates and other Metal Articles to Protect the same from Corrosion, and Apparatus therefor.* S. O. Cowper-Coles and Captain Sir B. W. Walker, London. Eng. Pat. 22,203, November 20, 1893.

THE authors claim the electro-deposition, on iron and other articles, of a thin coating of zinc, enough to protect them from oxidation till they can be painted, then the application of a coat of oil or oily compound over the zinc, by dipping in an appropriate bath, and finally the coating of the whole with paint. They also claim the mode of arranging the depositing tanks and connections for altering the disposition of the current, the mode of supporting the anodes and their connections with the source of current, and an apparatus for rotating the anodes when necessary to face articles of irregular shape.—J. T. D.

*Improvements in or connected with the Electro-Deposition of Zinc or Zinc Compounds, and the Treatment of the Deposited Metal or Compounds.* S. O. Cowper-Coles and Captain Sir B. W. Walker, London. Eng. Pat. 7145, April 10, 1894.

HERE is claimed the use of an alkaline electrolyte in which zinc or a zinc compound, finely divided, is suspended; also the alternation of brief currents of high density with longer currents of lower density to brighten the deposited metal. The use, too, of a sort of sand blast to brighten the metal after deposition is included, and the plan of coating iron with a film of magnetic oxide on which to deposit the zinc.—J. T. D.

*Improvements in Portable Primary Batteries.* W. Morison, Montclair, New Jersey, U.S.A. Eng. Pat. 9862, May 21, 1894.

THESE improvements relate to a portable battery produced by moulding some insulating material to form a liquid and gas-tight box or case to contain the electrolyte, at the same time embedding connections to join up the electrodes. The case shown is divided into three vertical compartments, each containing a pair of electrodes, zinc and carbon, communicating with each other by an open chamber at the bottom. A safety valve is provided. The electrodes not extending to more than half the depth of the box, and the electrolyte not half-filling the box, the battery is brought into or thrown out of action by being inverted or tilted, the mechanism for which, suitable for application to bicycle and miners' lamps, is provided.—J. C. R.

*Improvements in Process and Apparatus for Electrolytically Treating Salts in Solution or in Molten State.* H. C. F. Störmer, Christiania. Eng. Pat. 13,377, July 10, 1894.

A DOUBLE perforated partition is used in the electrolytic cell, into which is led from above a slow stream of conducting liquid, usually the electrolyte itself. In this way

the wandering of the ions and consequent recombination is prevented. Any excess of liquid, should the rate of entry exceed the rate of decomposition, is led off by overflow pipes and collected again.—J. T. D.

*Gravity Battery.* C. E. Baell, North Plainfield, New Jersey, U.S.A. Eng. Pat. 14,634, July 31, 1894.

The inventor claims "a gravity battery cell," having "the combination of an iron upper electrode, a copper lower electrode, and an electrolyte consisting of solid or crystalline copper sulphate with water."—J. C. R.

*Electrical Battery.* A. I. Feeny, London. From F. Dubers and P. Mohrdieck, San Francisco, U.S.A. Eng. Pat. 14,612, July 31, 1894.

This is a battery having sea water for the electrolyte. For the negative electrode, blocks of carbon are employed surrounded by "manganese or other suitable or desired material" in coarse particles, which are contained in a cylinder having perforated sides. This cylinder, or cylinders, is caused by any suitable means to rotate on a shaft journaled at a tank through which the sea-water circulates, and "being rotated at a very slow rate, a portion of it will always be submerged in the liquid and another portion will be constantly exposed to the air, where it, and the contents will be partially dried and will absorb a certain amount of oxygen from the atmosphere, which remains therein when it is again plunged beneath the surface of the exciting liquid."—J. C. R.

*Improvements in or connected with Diaphragms for Electrolytic Purposes.* M. Kiliani, W. Rathenau, and C. Suter, Neuhausen, Switzerland, and the Corporation. "Elektrochemische Werke," Berlin, Germany. Eng. Pat. 15,276, August 10, 1894.

THESE improvements relate to the construction of "an acid proof and alkali proof diaphragm" in the form of a vessel built up of a permeable membrane ("parliament, glass-wool, asbestos, card, or like") held between frames of lattice-work. This lattice is composed of parallel laths, bars, or rods of acid proof material, such as glass, porcelain, or like, secured to end frames which are indented or notched to receive them. The frames thus determine the shape of the diaphragm or receptacle, as rectangular frames for rectangular vessels, oval, or round frames for corresponding shaped diaphragms. The permeable or porous material is tightly stretched around this edge, and surrounded by another outer casing of similar lattice work, retained in position by india-rubber rings, or by wire wound round them.—J. C. R.

*Improvements in Apparatus for Refining Metal by Electrolysis.* H. A. House, sen. and jun., East Cowes, and R. R. Symon, London. Eng. Pat. 16,002, August 22, 1894.

A TANK containing the solution is fitted above the level of the liquid, with a horizontal rotating shaft, on which are wheels of insulating material provided with metal poles near the rim, connected with a segmental commutator near the axle. These wheels are alternately anodes (the crude metal being attached to the pole) and cathodes. Contact pieces make and break with each segment as it comes into and out of the solution. Above the solution are arranged brushes to clean the anodes, and blades or scrapers to remove the deposited metal from the cathodes, at each revolution. The new metal falls into appropriate chutes or receptacles, while any which falls into the trough, or any material falling from the anodes, is caught in a series of canvas bags arranged under the wheels.—J. T. D.

## XII.—FATS, OILS, AND SOAP MANUFACTURE.

*The Bleaching and Purifying of Refuse Greases from Slaughter-houses.* L. Virolleaud. Bull. Soc. Chim. 11—12, 1894, 526—528.

THE animal refuse coming from slaughter-houses is placed in tanks of 100 galls. capacity. 50 galls. of water and about 2 per cent. of sulphuric acid (53° B.) are added, and the whole is then boiled by means of a perforated steam coil, laid in the tank. As soon as the mass begins to boil, the admission of steam is so regulated that the temperature remains at between 80° and 90° C. After two hours' treatment the steam is shut off, the tank covered and left standing until the following morning. The grease which has collected on the surface of the water is removed. The insoluble residue which has settled to the bottom of the tank, when dried, forms good nitrogenous material for fertilisers. The grease thus obtained, is freed from the disagreeable odour and the objectionable green colour which are peculiar to it after treatment with potassium permanganate. This operation is carried out by melting the grease with direct steam, then adding for each 100 kilos. of grease under treatment a previously-prepared mixture of 1 kilo. potassium permanganate with 300 grms. of sulphuric acid, and energetically agitating the whole mass. After this treatment, the whole is again left over night, and on the following morning the now odourless and colourless grease is separated from the acid solution upon which it is floating.—C. O. W.

*The Examination of Wool-fat.* W. Herbig. Dingl. Polyt. J. 292, 1894, 42—47 and 66—69.

PREVIOUS investigators of the chemistry of wool-fat (with the exception of some of the earliest workers) have taken as a starting point the material obtained by adding the fatty acids precipitated by acidifying the potash soaps, which can be extracted from raw wool by simple washing with water, to the true wool-fat consisting of cholesterol and the esters derived from it. The author has adopted the preferable plan of extracting raw wool with ether, and thus obtaining the wool-fat free from any educt, such as a fatty acid arising from the decomposition of the potash soap naturally present in the fleece. Complete separation of the wool-fat and the potash soap is not practicable in one operation, as the former, when extracted from the wool by dry ether, carries with it a certain quantity of the latter, and the latter, if removed by washing with water, emulsifies a portion of the former. The present investigation was confined to the examination of the behaviour of wool-fat on saponification, particularly in respect to the action upon the fat of sodium ethylate,—and to the separation of the fat into constituents differentiated by the greater or less ease of the saponification. Four samples of wool were used, their places of origin being New Zealand, Australia, South America, and Russia. Large differences in quality were observed.

The samples of wool-fat examined by the author were obtained by extracting portions of 200 grms. of very finely shredded wool for about 16 hours with dry ether, filtering the resulting solution, distilling off the ether, and spreading out the fat in large shallow dishes, which were heated on the water-bath until all ether had been driven off, special care being necessary on account of the persistence with which wool-fat retains the last portion of a solvent. Prolonged exposure to 100° C. is inadvisable, although the author dissents from the supposition of Lewkowitsch (Chem. Centr. 1892, 1, 652; this Journal, 1892, 136 and 137), that the formation of anhydrides or lactones is likely to occur when fatty acids are treated in this manner. The character of each sample obtained from the wool extracted in the manner described above, is appended.

(1.) *Wool-fat from New Zealand Wool.*—The raw wool felt very greasy, contained many clots of fatty matter, some red-yellow and others black in colour. The fat obtained was fairly soft when fresh, but became harder on keeping.

(2.) That the saponification proceeds farther with  $\frac{n}{2}$  potash in a copper tube under pressure than in a flask with a condenser, and that the point thus reached varies with the character of the fat.

(3.) That the limit of saponification of all wool-fats is reached by one hour's heating, under pressure, with  $2n$  potash. (This Journal, 1892, 137.)

On account of the value claimed for the use of sodium ethylate as a saponifying agent, the author made a series of experiments with this reagent (10 grms. of sodium in 150 cc. of alcohol), adding it in regulated amount (15 cc.) to the wool-fat either suspended in alcohol or dissolved in ether. The results are recorded in tables, and may be verbally summarised as follows:—Saponification of wool-fat with sodium ethylate in alcoholic solution (or suspension) never reaches the limit arrived at by the method of heating under pressure (see this Journal, 1892, 137). In ethereal solution it proceeds to the same point as that arrived at by saponification with  $\frac{n}{2}$  alcoholic potash under pressure, but fails to saponify that portion of the fat which requires the use of  $2n$  alcoholic potash under pressure for its complete attack. The author concludes that the use of sodium ethylate presents no tangible advantage in the treatment of fats difficult of saponification.—B. B.

*Studies in Oil Analysis.* H. Ballantyne. A paper read before the Glasgow City Analysts' Soc. Abstracts No. 4, 1893-94, 6.

See under XXIII., page 1100.

*Evaluation of Wool Fat.* E. v. Cochenhausen. Dingl. Polyt. J. 292, 1894, 91-96; 112-116.

See under XXIII., page 1100.

## PATENTS.

*Improvements in Recovering Grease from Waste Suds which have been used in Washing Wool, Hair, or other Fibre.* A. J. Inston, Kidderminster. Eng. Pat. 17,309, September 14, 1893.

THIS patent is for a method of recovering the grease contained in waste suds from the washing of wool, hair, or other fibre. The ordinary method consists in treating the suds with sulphuric acid, and collecting the "recovered grease" which rises to the surface. The patentee seeks to avoid the use of any acid. He first strains or filters the suds to remove suspended impurities, then adds "an alkali such as caustic soda, caustic potash, or the like," and boils for about two hours. "On the liquor cooling, the grease will be found in a solid or viscous state at the top," and can be separated and dried or pressed in the ordinary way, the liquor beneath being run to waste. This is the first method claimed. The second consists in using, instead of the alkali, oil, tallow, or other oleaginous material, the process otherwise being the same. The third method consists in using a mixture of alkali and oil.—L. A.

*Improvements in Machinery for Cleaning Cotton Seed.* J. Bibby, Liverpool. Eng. Pat. 21,372, November 10, 1893.

THIS relates to a machine for removing the adhering fibre or lint of cotton-seed after the bulk of the cotton has been removed, and for cleaning the seed thoroughly without damaging it. It is composed of an outer cylinder and an inner revolving barrel, the axes of which are horizontally disposed. The inner surface of the cylinder and the outer surface of the barrel are lined with emery, which holds the seeds against the rotary action of the barrel. By this means the cotton is removed, and the surface of the seed polished. In some cases wire netting (through the meshes of which the emery in a moist or plastic condition is squeezed) is

attached to the surfaces of the cylinder and barrel. The barrel surface is preferably ribbed or fluted. At the feeding end of the machine a number of saws are placed, which facilitate the introduction of the seeds into the space between the barrel and the cylinder. The same arrangement of saws, together with a brush to remove from the saws the fibre adhering to them, is placed at the exit end of the machine.—J. J. K.

*Improvements in and Connected with Oil and other like Presses.* J. Y. Johnson, London. From C. Gounelle, Morilles. Eng. Pat. 23,595, December 7, 1893.

See under I., page 1048.

*Improvements in the Manufacture of Cleansing, or Soap Powder for Washing Fibrous and other Materials.* Andrew Ross Scott, Glasgow. Eng. Pat. 1963, January 20, 1894.

COCA-NUT or palm-nut oil is saponified with caustic soda in slight excess, the excess being afterwards allowed to remain, or neutralised with any suitable acid or acid salt, preferably boric acid. Water and soda-ash are then added in such proportions that the mixture will contain from 20 to 60 per cent. of crystallised sodium carbonate. The mixture is cooled, pulverised in a disintegrator, and then intimately mixed with ammonium sulphate in proportion equivalent to the sodium carbonate. The ammonium carbonate formed by double decomposition imparts the desired properties to the compound.—L. A.

*Process and Apparatus for Obtaining Glycerin and other Products from Soap-Makers' Spent Lyes.* J. V. Ruyembeke and W. F. Jobbins, New York, U.S.A. Eng. Pat. 12,367, June 26, 1894.

THERE are 49 claims, the gist of which consists, *firstly*, in an improved process for recovering products from the spent lyes by removing the heavy impurities as a sediment, allowing the lye to cool, whereby suspended soap is brought to the surface, and dissolved soap is separated and suspended, and, as such, is brought to the surface and the separated soap skimmed off, the operation being carried on previous to the addition of any chemicals to the lye.

*Secondly*, in an improved dash-plate for use in vacuum evaporators or similar chambers in which liquids or fusible solids are heated, comprising the annular dash-plate within the chamber, and an imperforate dash-plate supported above or below the annular one, and in line with the opening therein.—J. J. K.

*A New or Improved Apparatus for Treating Substances containing Fats and Oils.* W. O. Robbins, New York. Eng. Pat. 14,821, August 2, 1894.

THIS is a complete self-contained apparatus for extracting oil from seeds, wool, and other substances by means of a solvent, and for recovering the solvent for use again. It consists of a cylinder for receiving the material to be treated, a pipe for conveying gasoline from a tank and spraying it through the material within the cylinder, steam-pipes for heating the gasoline after admission to the cylinder, an air-compressor for expelling the solution of the oil in gasoline from the cylinder into a still, where the oil and solvent are separated, a vessel connected to the still to receive the extracted oil, a worm for condensing the gasoline vapour, and a pump for forcing the condensed gasoline back into the vessel from which it started. The whole series of vessels, pumps, and condensing worm are connected by pipes and valves, so that after the material has been placed inside the cylinder, and the latter closed, the complete extraction of the oil, the separation of the oil and solvent, and the drying of the material, can be effected without opening any part of the apparatus. The material to be treated is contained in a cylindrical ear of wire netting, fixed on wheels, which runs on rails within the cylinder. The single claim is for the complete apparatus as described and illustrated in the specification.—L. A.

*Solutions of Sweet Carbamides in Oils, Fats, Waxes, Resins, and Process of Making the same.* A. Sommer, Cambridge, U.S.A. Eng. Pat. 15,168, August 14, 1894.

THE inventor has found that an agreeable sweet taste can be communicated to the saponifiable oils, fats, waxes, and resins by dissolving in them certain sweet carbamides, such as paraphenetol carbamide ("Dulcine"), which he uses almost exclusively. He finds that the solubility of this substance in the neutral oils, fats, &c. is almost nil in the cold, and greatest between 140 and 160 °C., but that when once solution has been effected in the hot oil, and any excess of the carbamide which may have crystallised out on cooling has been filtered off, enough is still retained in solution to impart a sweet flavour to the cold oil, &c., the proportion so retained varying from less than 0.1 per cent. to over 5.0 per cent. of the oil, &c. taken. He has further found that the free acids of the above products dissolve the sweetening agent much more freely than the neutral products themselves, and by taking advantage of this fact he has devised another method of effecting solution. Thus, if the oil, &c. to be sweetened does not already contain sufficient free acid, he adds some, or produces some in the oil itself by partial saponification, followed by decomposition of the soap with acid and washing with water. He then dissolves the carbamide, either in the free acid before adding it to the oil, or in the naturally acid or artificially acidified oil itself, solution being hastened by heating the mixture in the water-bath. Another method of effecting solution is to dissolve the carbamide in a volatile solvent, which is then mixed with the liquid or liquefied oil and afterwards evaporated off.—L. A.

acid, yielding the acetic acid required for the preparation of the lead acetate. This salt may also be obtained electrolytically, a specially designed apparatus being described and figured in the specification. T. H. L.

*Improved Decorative Paper for Walls, Ceilings, Door Panels, and the like.* J. F. H. Vander Hoop, London. Eng. Pat. 20,353, October 27, 1893.

ANY suitable paper is coated with oil paint on one or both sides, and, when dry, any ornamented figure is printed with oil paint upon its surface. To obtain the impression in relief in gold, silver, or bronze, the metal powder is applied while the paint is still in the sticky condition.—S. P. E.

*Improvements in and relating to a Process of Making Green Oxide of Chromium.* F. L. Stoeum, Pittsburgh, and C. Y. Wheeler, Allegheny, U.S.A. Eng. Pat. 15,473, August 14, 1894.

TEN parts of powdered potassium or sodium bichromate are moistened with strong hydrochloric acid, and one part of finely-divided wood-charcoal added, and the whole made into a paste with three parts more of hydrochloric acid. The mixture is then placed in a suitable furnace, and allowed to burn without admission of air, and the oxide finally washed and dried.—F. H. L.

### (B).—RESINS, VARNISHES.

*The Latex of the Lacquer Tree.* G. Bertrand. Comptes rend. 118, 1215—1218.

By making an incision in the bark of several species of *Rhus* (*Anacardium*) which occur in the south-east of Asia, a latex is obtained which the Chinese and Japanese use as a varnish for their furniture under the name of lacquer. This latex, which is known under the name of "So'n-mat-Dai," is a thick cream of a bright yellow, almost white colour; it has a feeble odour recalling butyric acid, and reddens blue litmus paper. It may be kept for a long time without undergoing alteration, in flasks, if the latter are quite filled and well stoppered; but in contact with air, it rapidly oxidises, becomes brown, and in a few minutes there is formed a black pellicle, insoluble in the ordinary solvents. It is on account of this remarkable property that the latex is employed, and it is only necessary to observe some precautions in applying it, in order to obtain a brilliant and permanent coating of black.

When the latex is treated with alcohol this alteration does not take place, and a precipitate is formed of a body which is chemically identical with the gums, and contains an enzyme designated by the author, laccase; whilst the portion dissolved in the alcohol is an oil insoluble in water named laccol, which oxidises very readily when exposed to the air, becoming red—the more readily, however, in presence of dilute alkaline hydroxides. Towards the last-named compounds it behaves like pyrogallol; thus, the liquid becomes warm with the production of first a green coloration and then a deep black, a large absorption of oxygen taking place simultaneously. Ferric chloride in alcoholic solution is immediately reduced, the mixture becomes green, and a black amorphous metallic derivative separates; lead acetate produces a white precipitate, becoming bluish-green and finally black by slow oxidation. In the natural product, the gum and laccase are dissolved by a little water, the laccol being simply emulsified. The characteristic property of furnishing a lacquer is due to the successive actions of oxygen and laccase on the laccol.

*Analysis of Sealing Waxes.* C. Mangold. Zeits. anal. Chem. 1894, 33, 477—478.  
See under XXIII., page 1100.

## XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, Etc.

### (A).—PIGMENTS, PAINTS.

#### PATENTS.

*The Manufacture or Production of Paints.* W. A. and R. H. C. Wilson and W. B. Priest, London. Eng. Pat. 17,159, September 12, 1893.

By the addition of about one part of amorphous lead hydrate to two parts of such substances as barium or calcium carbonate or sulphate, iron oxide, ochre, umber, sienna, &c., it is claimed that these latter become far more valuable pigments for grinding in oil, the lead hydrate increasing their otherwise small body and covering power.

—F. H. L.

*Improvements in the Manufacture of White Lead.* J. H. Noad and S. Z. de Ferranti, London. Eng. Pat. 20,239, October 26, 1893.

A FAINTLY alkaline solution of ammonium acetate, prepared as described in Eng. Pat. 6009, 1892 (this Journal, 1893, 363), is added to litharge and heated by steam in a closed still. So long as the latter is kept in excess, only the lead monoxide is dissolved, all impurities and higher oxides being unattacked. The ammonia liberated is condensed and carbonated by being passed through coke towers through which a stream of carbonic anhydride obtained from lime kilns or washed furnace gases is ascending. The filtered lead acetate solution, still at the boiling point, is run into another vessel provided with an efficient agitator, and the ammonium carbonate sprayed in; the white lead is filter-pressed, and the filtrate is ready to dissolve a fresh amount of litharge. To economise the amount of heat required for this process, the still may be worked under diminished pressure.

As an alternative process, a solution of basic lead acetate is prepared in the usual manner, and mixed with the calculated proportion of ammonium carbonate, prepared as above described, the white lead filter-pressed, and the ammonium acetate distilled with chalk or lime to form fresh carbonate or hydrate (to be afterwards carbonated), the calcium acetate being finally decomposed with sulphuric

## PATENTS.

1 *Process of Manufacture of Films Imitating Mother-of-Pearl.* S. Hahn, Berlin. Eng. Pat. 13,139, July 6, 1894.

WHEN nitrocellulose, dissolved in alcohol and ether, or in soda- or potash-soluble glass, is spread over a surface of wood, paper, glass, porcelain, or metal, and the solvent allowed to evaporate, the film remaining is said to have the appearance of mother-of-pearl. The proportions recommended are:—

1 part of nitrocellulose.

78 parts of alcohol (90 to 100 per cent.).

21 parts of ether.

With soluble glass as solvent 10 parts of this to 90 parts of water are employed.

The nitrocellulose may be pure or crude, or in different stages of nitric acid, as gun-cotton, &c. Ethyl or methyl alcohol and sulphuric or acetic ether are recommended. The degree of concentration of the nitrocellulose may be varied within certain limits, which variations produce different results. The addition of bisulphide of carbon in the proportion of 25 parts to 100 of the above solution, or the addition of benzene, produces a difference in the brilliancy and arrangement of the colours of the iris developed on the mother-of-pearl-like surface.—S. P. E.

*Method of Varnishing Metal in Light-resisting Colours by Means of Alizarine Colours.* J. Perl and P. Herrmann, Berlin. Eng. Pat. 15,327, August 11, 1894.

THE objects are dipped in a colourless pyroxylin varnish and then heated in a current of air at 80° C. until the varnish is thoroughly dry, when they are immersed for a few seconds in a two per mille alcoholic solution of alizarin, followed by a wash in water, to change the colour from the original light yellow to a golden red.—F. H. L.

## (C.)—INDIA-RUBBER, &amp;c.

## PATENTS.

*Improvements in Artificial India-Rubber.* P. A. Newton, London. From A. Nobel, Paris. Eng. Pat. 20,234, October 26, 1893.

By dissolving nitro-cellulose or nitrated hydro- or oxy-cellulose in a suitable non-volatile or slightly volatile "solvent," such as nitronaphthalene, dinitrobenzene, nitro-toluene or its homologues, products may be obtained varying from a gelatinous consistency to the hardness of ebonite. The proportions will vary from about 20 per cent. of nitro-cellulose in the finished product, forming a soft rubber, to 50 per cent., imitating celluloid, and the "solvent" chosen will depend on the use to which the rubber substitute is to be put, the liquids giving a more elastic substance, while mixtures of solids and liquids may be employed when the product is to be used at high temperatures. By means of rollers—steam-heated, if desired—the incorporation may be accomplished without the aid of a volatile liquid, or the nitrocellulose may be employed wet, the water being re-

moved after "solution." It is advisable to use the cellulose nitrated only just enough to render it soluble, in order to reduce the inflammability of the finished product.—F. H. L.

*An Improved Preparation for Cleansing Vulcanite.* L. and S. Levy, London. Eng. Pat. 3,180, February 14, 1894.

THE improved preparation consists of a "chemical compound" of washed and levigated calcium carbonate, coleothar, rectified spirit, methyl alcohol, and water, the addition of a little ammonia solution being an improvement. It is rubbed on with a rag, the vulcanite being afterwards washed with water and polished with chamois leather.

—L. A.

## XIV.—TANNING, LEATHER, GLUE, AND SIZE.

*The Water-Content of the Common Tanning Materials.* Von Schroeder. Dingl. Polyt. J. 1894, 292, 284—287.

FOR the scientific comparison of tanning materials a knowledge of the percentage of tannin in the anhydrous material is all that can be desired, but for the purposes of the tanner, who deals with the moist bark, it is obviously of little value. The question thus arises—What is the water-content of the sample submitted for analysis? Is the moisture in the sample when it reaches the analyst identical with that contained in the sample when it was drawn from the store? Disputes between buyer and seller may possibly be due to a variation in the water-content of the material.

The author has examined 11 different tanning materials, some ground and some unground, whilst some were partially ground or pulverised. The object of the examination was to ascertain the degrees of variation which occur in their water-content at different seasons. After the samples had been kept in a room—which was chosen so that the conditions might resemble those of the tanner's store as nearly as possible—for three weeks, in order that they might attain an equilibrium of moisture proper to the situation, the percentage of moisture in each was determined, and thereafter the samples were merely weighed from time to time, the variation in weight being calculated into variation of content of water. The samples varied in weight from 1,400 to 4,500 grms., and were contained in linen bags of known tare; the hygrometric variation of these was sufficiently slight to be neglected. In a second series of experiments about 100 grms. of the sample were contained in metal cylinders open at the top except during the weighing process. The percentage of water calculated from the monthly weighings are tabulated in the original paper, and a very close agreement is observable between the results obtained in the two sets of experiments. The state of division of the material has hardly any effect on the water content; the variation which occurs in the different materials will be appreciated from the following table, comprising the mean values for all the experiments:—

Material.	Jan.	Feb.	Mar.	April.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.	Mean.

It is right to add that in 1885, the year of this investigation, the weather suddenly became very warm in April, that the temperature rose during May, and became very high in June.

It will be found by examining this table that the variation in content of water of the common tanning materials amounts to from 3 to 5 per cent.; if the results of analyses are calculated on the mean value for the whole year, there is an error owing to this amount of moisture being about 2 per cent. too low in winter and about 2 per cent. too high in summer. In the author's opinion, however, it is best to adopt the mean value in returning the percentage of tannin in the sample, although it is quite reasonable to make the correction indicated for the time of year when the sample is received.—A. G. B.

*The Amount of Water contained in Air-dried Bark-tanned Leather.* Von Schroeder. *Dingl. Polyt. J.* 1891. **293**, 139—143, 164—167, 187—192.

In the first part of this paper the authors describe the character and tannage of the samples used in the investigation, and the method of exposing them to the air so that they might take up or lose moisture under conditions such as prevail in the trade. Full analyses of samples are given, these differing chiefly, of course, in the content of fat; 12 out of the 24 samples were dressed leather.

The most salient points elucidated by the investigation are the following:—

In the first series of experiments, in which the samples were exposed in a shed resembling in its conditions a normal leather store, it was found that the water-content of air-dried leather is highest in the three winter months (December—February), and generally attains a maximum in February, whilst the minimum occurs in June. The following lines of figures, selected from the author's table, will illustrate the monthly variations for undressed and dressed leather:—

	Sole Leather (lined).	Kip Upper Leather (black).
	Per Cent.	Per Cent.
January .....	20.15	15.00
February .....	19.69	14.96
March .....	17.34	12.60
April .....	16.08	11.41
May .....	16.04	10.90
June .....	15.59	10.76
July .....	16.80	11.61
August .....	16.78	12.03
September .....	17.50	12.65
October .....	17.74	12.86
November .....	20.30	13.57
December .....	19.55	14.28
Mean .....	17.80	12.67

It is generally the case that dressed leather contains less water than undressed leather. The mean water-content of undressed leather for the whole year may be taken as 18 per cent. Untanned hide is much more hygroscopic, and the water in it may vary from 28.20 to 19.14 per cent., the mean for the whole year being 23.13 per cent.

As might be expected, the higher the content of fat in a dressed leather, the lower will be the percentage of water. It is possible to calculate the water ( $w$ ) in a dressed leather when the percentage of fat ( $F$ ) is known and the percentage

of water ( $a$ ) in the corresponding fat free leather is known, by means of the following formula:—

$$w = \frac{100 \times (100 - F)}{100 - 100 \times a + a(100 - F)}$$

The mean value for  $w$  for all classes of dressed leather is 10.35. The value  $a$  may be taken as 18.

Bark-tanned leather which is exposed at a low temperature to an atmosphere saturated with water, will take up about 24 per cent. of water.

The deviation of the percentage of water with the time of year from the adopted mean of 18 per cent. for an undressed leather, may be said to be  $\pm 2.50$ . A leather which suffers loss of water through any period from August to February must be reported as improperly dried. A decrease of 2 per cent. of water in the warmer months of the year does not necessarily indicate that the leather has been badly dried; but a loss amounting to 4 per cent. must certainly be reported as such. It must be remembered, however, that these remarks apply only to the normal conditions of the atmosphere, and due attention must be paid to the hygrometer readings in the room in which the exposure of the leather is effected.

In the second series of experiments the samples were exposed in a room where the temperature throughout the year was far more equable than in the shed. This difference of condition made but little difference in the mean water-content of the leather for the whole year, but, as might be expected, the monthly variation was far smaller. This is illustrated in a table giving the figures.—A. G. B.

*The Practical Extraction of Tannin from Myrabolans.* Von Schroeder. *Dingl. Polyt. J.* **292**, 213—214.

THE use of myrabolans, the fruit of *Terminalia Chebula* (Willd.), is yearly extending in Germany. In 1891 there were imported 62,870 centners (1 centner = 50 kilos, or 100 lb.); and in 1893, 101,394 centners. Myrabolans contain on the average 30 per cent. of tannin, and tannin can be bought at present in this form cheaper than in almost any other. The price of myrabolans of good medium quality is 7 marks per centner (7s. per 100 lb.), which corresponds to 0.24 mark per centner for 1 per cent. of tannin, compared with 0.59 mark for oak-bark tannin and 0.26 mark for fir-bark tannin. Somewhat inferior qualities of myrabolans, containing, however, very little less tannin, can be had for 5.5 marks, or a cost of 0.18 mark for 1 per cent. of tannin. The only material approaching this in cheapness is quebracho wood, 4.25 marks per centner, containing 23 per cent. of tannin, or 0.19 mark for 1 per cent.

Myrabolans alone do not give satisfactory results in tanning, imparting an unpleasant, greenish-yellow colour to the leather. They are largely used in mixtures with more expensive materials, e.g. oak-bark, in order to lower the cost, and in some cases can replace knoppreri and valonia. If the colour is not important, myrabolans and quebracho wood form a very cheap mixture, the addition to which of fir-bark considerably improves the colour.

The fruit is more or less pointed at both ends, and on the average 3 cm. long. The more expensive kinds have a light yellowish-brown colour, the lower qualities being darker in appearance and containing nearly as much tannin. The fruit consists of an outer fleshy rind, of loose, parenchymatous tissue, in which most of the tannin is contained, and within this a hard stone enclosing the seed and bearing very little tannin. While the rind is easily reduced to powder, the stone is extremely difficult to grind. The rind on the average forms 65 and the stone 35 per cent. of the whole fruit. The following analyses show the proportion of tannin in different qualities of myrabolans and in different parts of the same fruit. They are calculated on the average percentage of water = 13 per cent.

## I.

Selected dark myrabolans, inferior in appearance, consisting of 63.5 per cent. rind and 36.5 per cent. stone.

	Rind.	Stone.	Whole Fruit.
	Per Cent.	Per Cent.	Per Cent.
Water .....	13.00	13.00	13.00
Tannin substances .....	35.46	3.52	23.80
Organic substances (not tannin) .....	23.65	3.22	16.19
Ash of extract .....	2.74	0.71	2.00
Insoluble in water .....	25.15	79.55	45.01
	100.00	100.00	100.00
Total extract .....	61.85	7.45	41.20
Sugar (calculated as grape sugar) .....	4.74	0.39	3.15

## II.

Selected light-coloured myrabolans, of good appearance, with 67.58 per cent. rind, and 32.42 per cent. stone.

	Rind.	Stone.	Whole Fruit.
	Per Cent.	Per Cent.	Per Cent.
Water .....	13.00	13.00	13.00
Tannin substances .....	42.34	2.60	29.46
Organic substances (not tannin) .....	20.98	2.58	15.02
Ash of extract .....	3.35	0.58	2.44
Insoluble in water .....	20.33	81.24	40.08
	100.00	100.00	100.00
Total extract .....	66.67	5.76	46.92
Sugar (calculated as grape sugar) .....	7.40	0.50	5.16

Myrabolans are used either in the ground condition or as extract. In the former case, since the stones contain little tannin, and are difficult to grind, the rind and stone are sometimes separated mechanically, and the rind only ground to powder. Such a separation is necessarily very imperfect, while the stones form a by-product difficult to make use of, and, if this product is considered as waste, the expenses of grinding are considerably increased. To illustrate the incompleteness of a mechanical separation, two samples were obtained from a tannery, ground on the spot for their own use, of which one should consist chiefly of ground rind, the other of the residual stones. On analysis the percentages of tannin in the two are found to be very near together. Water is assumed at 13 per cent.

	Tannin Substances.
	Per Cent.
Nominally consisting chiefly of rind .....	35.89
" " " " " stones .....	31.91

It may be concluded, then, that it is better either to grind the whole fruit or to extract it. Extraction of myrabolans is a very rational method, because the greater part of the tannin-containing rind is soluble in water. On boiling with water, the rind takes up water and the swollen fruits give up almost all their tannin if the liquor be changed sufficiently often. The extraction of whole myrabolans

succeeds well in practice. Some time ago, in the Freiberg tanning school, a sample lot of myrabolans was extracted in a closed extraction boiler. The fruits were analysed before extraction and after three- and fourfold boiling, with these results (water reckoned at 13 per cent.) :—

	Before Extraction.	Three Times Extracted.	Four Times Extracted.
	Per Cent.	Per Cent.	Per Cent.
Water .....	13.00	13.00	13.00
Tannin substances .....	32.14	4.65	3.18
Organic substances (not tannin) .....	11.05	3.30	1.48
Ash of extract .....	2.27	0.49	0.29
Insoluble in water .....	41.54	78.65	82.05
	100.00	100.00	100.00

The weight of the myrabolans dried in air after three extractions is 52.8, and after four extractions 50.6 per cent. of their original weight. Hence, of the 32.14 per cent. of tannin in the fruit, after three extractions, 2.46 per cent. remains, and after four, only 1.61 per cent. is still in the residue. Thus, in the last case, of 32.14 parts tannin, 30.53 parts are brought into solution—a highly satisfactory result, and one that points to the extraction of unground myrabolans as a safe and commendable process.—R. B. B.

*The Estimation of Sugar, and on the Sugar-Content of Tanning Materials, Tanning Extracts, Tanning Liquors, and Weighted Leather.* V. Schroeder, A. Bartel, and W. Schmitz-Dumont. Dingl. Polyt. J. 1894, **293**, 229—237, 252—260, 281—287, 297—304.

See under XXIII., page 1101.

## PATENTS.

*Improvements in or connected with Tanning Hides and Skins.* J. Durio, Turin, Italy. Eng. Pat. 16,783, September 6, 1893.

The hides are limed, unhaired, fleshed, and treated to remove the lime, as usual. They are then immersed in a solution of "granular hydrate of soda," containing 3—12 kilos. of hydrate per 100 kilos. of hides and 400 kilos. of water. They are then placed in a centrifugal machine to remove the absorbed hydrate, washed, and pressed. Degreasing by means of a suitable solvent in a centrifugal machine concludes the preparation.

The prepared hides are suspended in a drum into which liquid tannic extract (in the condition in which it is sold in the trade and without dilution) is introduced at intervals in gradually increasing quantity until the tanning process gets slow, whereupon the quantity introduced is gradually decreased. The drum should receive a continuous motion so that the hides may be agitated in the tannic extract; the rapidity of agitation is regulated according to the quality and thickness of the hides, the minimum time of tannage being about two hours and the maximum about 24 hours.

The advantages claimed for the process are that it can be used in any district, and the tanner thus rendered independent of the quality of the water supply, and that the product is better than that obtained by the old methods.

—A. G. B.

*Improvements relating to the Manufacture of Artificial Whalebone and to Apparatus therefor.* M. Levy, A. Rustin, and L. Boyer, Paris. Eng. Pat. 20,144, October 25, 1893.

To unite two pieces of buffalo horn in order to make a long piece of artificial whalebone, the ends of the pieces are immersed for from 5 to 10 minutes in a hot solution of

bicarbonate of soda (10 grms. per litre), the pieces are allowed "to sweat," and then bevelled. The horn is softened by the hot alkaline liquid, so that by wrapping paper round the joint and applying pressure whilst it is hot the union may be made perfect. To prevent fracture at this joint it is again dipped in the solution of bicarbonate of soda.

The above method is the only point of chemical interest in the specification, the remainder of which relates to the machinery necessary for effecting the union and cutting of the horn. Figures of this machinery are given.—A. G. B.

*An Improvement in Softening and Cleansing Hides.*  
W. L. Jackson, London. Eng. Pat. 22,819, November 28, 1893.

Raw hides and skins, before they are unhaired, are softened and cleansed by thoroughly soaking them and then beating them by fulling stocks or equivalent apparatus. The improvement consists in adding a soluble antiseptic during this process; common salt, chloride of magnesium, calcium carbonate, or sodium sulphate is recommended. For a full sized hide 1—1½ lb. of the salt should be added.

—A. G. B.

*Improvements in the Manufacture of Animal Charcoal.*  
C. W. Kriens, London. Eng. Pat. 8112, April 24, 1894.

Waste leather or scrap, or the trimmings, or curriers' cuttings of hides or skins, are steeped in water at 100°—110° F. for 48 hours, and then pressed to expel the absorbed liquid. The steeping process is repeated for another 48 hours and the materials are again pressed; they are now tightly packed into an iron cylinder, provided with the usual condensing apparatus for the recovery of by-products, and the whole is introduced into a retort to effect the carbonisation.

—A. G. B.

*Improvements in Processes and Apparatus for Cooling Glue and Forming it into Sheets.* P. C. Hewitt, New York, U.S.A. Eng. Pat. 11,426, June 12, 1894.

The liquid glue is allowed to flow on to a series of cylinders A—A<sup>5</sup> (see figure), cooled internally by a flow of water, and all revolving in the same direction. The solidified sheet of glue is thus caused to travel forward on to an endless band composed of the wire network usually employed for drying glue. When it is desired to make a

sheet of twofold thickness, the endless band is inclined so that the sheet may be deposited upon a second sheet, itself borne on an endless band and formed in the same way; such an arrangement is shown in the figure. A steam-pipe *k* serves to heat the two sheets and to cause their adherence to each other. By flowing liquid glue on to the lower sheet, through the tap *C*, a threefold thickness may be obtained. Various modifications for combining the sheets are depicted. The method serves for the combination of glues of different grades of quality.—A. G. B.

*Improvements in Clarifying or Removing Impurities and other Substances from Glue.* P. C. Hewitt, New York, U.S.A. Eng. Pat. 43,369, July 10, 1894.

CASEIN, separated from skimmed milk by rennet, is dissolved in lime water, and the solution is added to the glue solution. In the case of some glue solutions it is advisable to add albumin (preferably blood albumin) to the casein solution. For some uses it is desirable that the casein should not be alkaline, in which case it may be neutralised, preferably by phosphoric acid.

By the present process of glue manufacture the other constituents of the stock, dissolved by the gelatin during the rendering by heat, are removed by large filters and by the use of clarifying agents, such as albumin and alum; these clarifying agents are expensive, leave the glue foamy, and cause a precipitate which is filtered with difficulty. By this new process about 1 lb. of the dry clarifying agent, mixed with an appropriate quantity of water, is mixed with 1,000 lb. of the hot glue solution (containing 10 per cent. of dry glue); the coagulation is aided by heat, or by addition of acid or of rennet. The precipitate is sufficiently hard to cause but little impediment during filtration. The clarified glue is bleached by sulphurous acid or "hydrosulphurous" acid (zinc and sulphurous acid) in the usual manner.

—A. G. B.

*A New or Improved Process for the Production from Skins or Hides of a Substitute for Whalebone, Horn, or the like.* F. Hartmann, Berlin, Germany. Eng. Pat. 14,697, July 31, 1894.

This new product, to be called "whalebone leather," is made from the unhaired, fleshed, scoured, and cleansed skin or hide, by first submitting it for a short time to the action of wet steam, and then steeping it in a turpentine-bath until it has become perfectly saturated with that material; it is finally dried in the open air, and varnished and glossed to render it weather-proof.—A. G. B.

## XV.—MANURES, Etc.

### PATENTS.

*Improvements in the Manufacture of Mineral Manure.*  
G. F. Redfern, London. From J. Hensel and F. Spiethoff, Soermsdorf, Kynast. Eng. Pat. 17,235, September 13, 1893.

PRIMITIVE rocks, such as porphyry, granite, gneiss, syenite, or basalt, are heated to a cherry-red heat, quickly cooled in water, and then crushed as fine as possible. This artificial stone meal is then intimately mixed with finely-powdered coal, in about the proportions of 10 parts of coal to 100 parts of stone. The manure is then ready.

The rocks supply potash, soda, and phosphoric acid to the crop, whilst the coal co-operates as a result of the presence of "nitrogenous hydrocarbons" in it. To make the manure act more quickly sulphuric acid may be added to it, or it may be mixed with other mineral manures.

—A. G. B.

*An Improved Method of Utilising and Means for Treating Yeast.* E. W. Greening, Thames Ditton, Surrey, and E. O. Greening, Lee, Kent. Eng. Pat. 20,060, October 24, 1893.

See under XVII., page 1082.

## XVI.—SUGAR, STARCH, GUM, Etc.

*The Properties of Caramel.* A. Sabanejeff and A. Antouchévitch. Soc. Ph. Ch. de Saint-Petersbourg, No. 1, 1893.

For authors arrived at the following conclusions:—

1. Caramel, precipitated from a solution of the crude product by alcohol and then dialysed, is not a carbohydrate. The formation of caramel from sugar is accompanied by evolution of carbon dioxide. The formula of that compound is very approximately expressed by  $C_{12}H_{13}O_4$ . The formation of caramel is illustrated by the formula—

2. Dialysed solutions of caramel undergo modification under the influence of temperature and light, their coloration diminishing at the same time. By a process of hydrolysis, substances of a lower molecular weight are formed.

3. Dialysed solutions of caramel are capable of a special (mucilaginous) fermentation. The coloration diminishes thereby, and by a process of dehydration, substances of considerably higher molecular weight are formed.

4. Gélis' caramel is merely dialysed caramel modified by the elevated temperature of the solutions.

5. Graham's caramel, the dialysability of which is only one quarter that of albumin, is a product of the mucilaginous fermentation of dialysed caramel.—C. O. W.

*Composition of Honey-Dew: Influence of a Summer in which Honey-Dew is abundant, on the Character of the Honey.* E. von Raumer. Zeits. anal. Chem. 33, 397—408.

HONEY-DEW forms a thin glutinous sweet-tasting coating on the upper surface of leaves of various trees and shrubs; in some summers, especially if hot, dry weather prevail, it is very abundant, in others it is scarcely to be found. By some chemists honey-dew is looked upon as an exudation from the leaves themselves, but the major portion now regard it as a secretion of the "vine freter."

The author quotes the historical portion of the subject from Büsgen's biological study (Jenaer. Zeits. f. Naturwissenschaft., 1891, 25, 339). It appears that the first analyses of honey-dew were published in Gothe's treatise "Zur Morphologie" (Band I. S. 299, Cotta, 1817). The next to examine honey-dew was Unger in 1837 (Ber. k. Acad. Wissensch. Wien. Math.-nat. Cl., 25, 449), and further analytical values were published by Boussingault in 1872 (Comptes rend. 74, 87). The author then mentions that the most recent analyses of honey-dew were carried out

simultaneously with his own, viz., in the summer of 1893 (Jour. Amer. Chem. Soc., 1893, 350). He has not been able, however, to refer to the original paper.

The honey-dew examined in the present paper was prepared as follows from maple leaves:—The leaves were treated with cold water, and allowed to remain therewith for only a few minutes, after which the liquid was decanted off and evaporated to a syrup, which was finally decolorised by repeated evaporation over animal charcoal.

The author's results may be briefly summarised thus:

1. Almost all kinds of honey contain more or less dextrin of slight fermentability; its presence is ascertained by a comparison of the amount of sugar as found by the Soxhlet-Allihn method with that calculated from the alcohol obtained on fermentation with pressed yeast.

2. Hable's dialysis method (Zeits. anal. Chem. 33, 99), should be modified, in that the honey is not subjected directly to dialysis, but only after fermentation; the reason being that by direct dialysis the sugar, even after a protracted period, cannot be completely removed.

3. The dextrans of honey-dew probably undergo an alteration in the organism of the bee, which enhances the dialysing power of the sample.—A. R. L.

*Estimation of Saccharose.* Zeits. anal. Chem. 1894, 33, 474.

See under XXIII., page 1101.

### PATENTS.

*Improvements in the Manufacture of Sugar and in Apparatus Employed therein.* J. Y. Johnson, London. From J. E. Pellegrini, Barcelona, Spain. Eng. Pat. 14,686, July 20, 1893.

THE patentee claims to have discovered a process whereby sugar (saccharose) may be synthesised from carbonic anhydride, ethylene (or other hydrocarbon of the  $C_2H_4$  series), and water; these reagents are said to interact when brought together under the conditions to be described in accordance with the equation—

The apparatus employed for carrying out the process consists of a rectangular box or case (Fig. 1) constructed of cast iron or other suitable material; the interior of this box is nickel plated and planed. It is also hermetically closed to prevent any leakage of gas. Within this box, equidistant from either end, is placed a cube of platinised porous material, the side of which is about one-third the

entire length of the box; this constitutes the catalytic agent. A longitudinal section of part of the cube is shown in Fig. 2, and a transverse view in Fig. 3. The best results

Fig. 2.

are obtained with blocks manufactured as follows:—Light coloured dense pumice is washed successively with hydrochloric acid, sulphuric acid, and water; it is then dried, pulverised, and mixed with 10 per cent. of dry clay (as free as possible from iron) and 3 per cent. of cork, both

Fig. 3.

being in a finely powdered condition. This mixture is made into a paste with brine of sp. gr. 1.20; it is then air-dried for about 15 days, placed on a stove heated to about 300°–400° C., where it is allowed to remain for 4–5 days, and subsequently baked in a pottery furnace. The block thus obtained is then drilled with holes or passages *a* which do not pass completely through it, but extend from each side to within say 0.8 in. from the opposite side; the passages are about 0.13 in. in diameter and are parallel to one another. After drilling, the block is immersed in a hot 10 per cent. solution of platinum tetrachloride or other suitable platinum salt, which will, when sufficiently heated, deposit finely-divided platinum within its pores; the platinising will usually have to be repeated two or three times. "The boiling in each case continued for three hours." After sufficiently heating, the block is tested with dry steam, and if it fails to decompose the latter, it is again platinised until it does so.

The block is held in position by two steel plates, one of which is shown at B and the other at C; these are perforated with holes coinciding exactly with those of the block. To the ends E and F are fixed the tubes *e* and *f*, conveying carbonic anhydride and ethylene respectively; each tube is furnished with a meter G, a gauge H, and a regulating valve I. Ethylene is passed, under slight pressure, into the chamber V' and carbonic anhydride at about the same pressure into the chamber V". After the lapse of a few minutes the valve *j* is opened and dry steam at about two or three atmospheres pressure is introduced into the chambers through the pipe J. The apparatus now becomes rapidly heated; the supply of gases and vapor is continued for about half an hour, but not so long that the temperature rises above 150° C.; a lower temperature than 100° C. will be found more suitable. The gases mix through the dry substance of the pumice, and on the expiration of the above-mentioned period, the syrup produced, containing 20–25 per cent. of sugar, is run off through the valve *k*. When the apparatus is cool the operation may be repeated. —A. R. L.

*Apparatus for Separating and Utilising Steam from Cane Juice on Leaving a Juice Heater.* A. Chapman, Liverpool. Eng. Pat. 20,221, October 26, 1893.

THE patentee claims the invention and application of an apparatus consisting of a cane-juice heater in combination with an evaporating apparatus, and of a steam and cane-juice separator comprising two or more vessels, the first connected with the second by an inverted siphon pipe, and the second (where a third is employed) similarly connected with the third. The hot juice from the heater is delivered to the first separating-vessel, whence it passes, by the inverted siphon, to the second, and from thence to the third, or to defecators or filters or elsewhere. The steam which is evolved from the juice in the first and second separating-vessels is conducted to and utilised in the evaporating apparatus or otherwise. —A. R. L.

*Improvements in the Manufacture of Animal Charcoal.* C. W. Kriens, London. Eng. Pat. 8112, April 24, 1894.

See under XIV., page 1075.

## XVII.—BREWING, WINES, SPIRITS, Etc.

*Composition of Hops, and their Influence on Wort.* Aubry. Wochenschr. f. Brauerei, 11, 289–296, from Zeits. Gesamte Brauwesen, 1894. Part I.

THE author examined eight samples of hops for moisture (1.2–7.30 per cent.), alcoholic extract (40.87–44.69 per cent.), and aqueous extract (10.2–14.72 per cent.), and then examined the influence of these various hops on the same wort. He found that the values of these determinations gave no criterion of the values of the hops for brewing. Two hops, one a very fine Saaz hop, the other a coarse but healthy and vigorous Al-sace hop, gave the same alcohol and water extracts.

The author found that in extracting the resin of hops by light petroleum, only very little of the tannic acid is removed, and that the aqueous extract from hops contains but little of the nitrogenous matter. The ripeness of the hops does not influence the fermentability of the wort, but only the flavour of the beer. Hopped wort ferments better and more completely than unhopped wort, and yields clearer beer. The percentage of sugar in wort is not influenced by hopping, but the nitrogenous matter (both albuminoid and total) is increased thereby and to the greatest degree by the finest quality of hop. Beer brewed with inferior hops had a more fiery but coarser flavour than when fine quality hops were employed. —L. T. T.

*Finding the Specific Gravity of Barley by means of the Volumetric Barley-Balance.* Wochenschr. f. Brauerei, 11, 290.

BANZOWSKI has recently patented a "volumetric barley-balance," by means of which the specific gravity of barley may be quickly and accurately determined (to third decimal). Wölky and Heine and others have, however, shown that the specific gravity of barley cannot be taken alone as a criterion of value, but that a complete chemical analysis is also necessary.—L. T. T.

*Respiration of Malt on the Malting Floor.* H. Jaeschke. Wochenschr. f. Brauerei, 11, 473—476.

The author has carried out a series of experiments on the practical scale, in order to determine the variation of moisture and of temperature in germinating barley, and how high the percentage of carbonic acid rises in the air of the heap during the ordinary process of malting.

**Steeping.**—Barley containing 15.15 per cent. of moisture was steeped in water (changed as usual) at 46° F. for 70 hours, samples of 1,000 corns being from time to time removed and weighed. The increase of weight (disregarding the very slight loss by aqueous extract) gave the moisture absorbed by the barley. After 24 hours' steeping, the increase in weight (*i.e.*, increase in moisture) was 32.35 per cent., after 48 hours 41.49 per cent., and at the end of 70 hours 48.52 per cent. The barley was then transferred to the malting floor.

**Malting.**—The malting was carried on for nine days, the temperature of the air of the malting chamber being 43—45° F. For the first five days the heap ("piece") was turned twice a day, then once a day. The tests for temperature and moisture were always made at five different places in the "piece." There was a further absorption of moisture during the first two days to a maximum of 55.57 per cent., after which there was a gradual loss of moisture, so that on the third day the excess of moisture over that originally present in the barley was 51.75 per cent., on the fourth day 41.47 per cent., on the fifth 34.51 per cent., on the sixth 33.69 per cent., on the seventh 31.20 per cent., on the eighth 33.04 per cent., and when the malt was removed from the malting floor 28.38 per cent. The moisture in the green malt was thus 33.95 per cent. of its total weight.

The temperature in the middle of the piece gradually rose from 51° F. on the first day to 79° F. on the fourth day, and then slowly fell to 62° F. on the ninth day. The temperature near the floor was generally two or three degrees lower than in the middle of the piece, and during the most active germination (*i.e.*, from the third to the sixth day) the difference was 9° or 10° F., and in one instance 13° F.

The percentage of carbonic anhydride in the air of the piece was determined by inserting a pointed tube punctured

been drawn into the aspirator, it was considered that that in the burette was a fair sample of the air of the piece. The accompanying sketch will render the method employed clear. The average percentage of carbonic acid found, was 5.40 on the first day, rapidly increasing to 19.4 on the morning of the third day, and then falling to 3.8 at the end of the fourth day, and 0.0 on the sixth day. Estimations of oxygen were made in many of the samples, to determine whether the increase of carbonic anhydride was accompanied by a corresponding decrease in oxygen. At first this was the case, but as the percentage of carbonic anhydride increased, the sum of the carbonic anhydride and oxygen exceeded 20.9 more and more, until on the third day, when the germination was most active, the carbonic acid was 19.1 per cent., and the oxygen 4.4 per cent., or an excess of 2.6 per cent. over the normal 20.9 per cent. This excessive formation of carbonic anhydride was also observed by Schütt, and is probably due to chemical processes going on even in the absence of oxygen, by which carbonic anhydride is liberated—a kind of self-fermentation.

—L. T. T.

*The Action of Oxygen on Yeast.* H. van Laer. Wochenschr. f. Brauerei, 11, 353—359

THIS paper consists of a critical discussion of the work published on this subject and especially of that centering round the question of the correctness or the reverse, of Pasteur's two statements, (a) "No alcoholic fermentation can take place without simultaneous formation, development, or increase of cells, or continuous life of already formed cells," and (b) "Fermentation is a consequence of life without air." The author points out that much, at least, of the discrepancy in views of different workers is due to a confusion of the meaning of Pasteur's "fermentative power" (*Fermentativ-vermögen*) with what may be called "fermentative activity" (*Gährthätigkeit*) and with Schützenberger's "fermentative energy." Pasteur gives as the measure of

"fermentative power" the expression  $\frac{S}{Y}$  where *S* represents the total amount of sugar fermented and *Y* the total weight of the yeast obtained. It may in fact be considered as the total fermenting capacity of the yeast-cell, *irrespective of time*, and is quite distinct from the general expression "fermentative activity" which represents the amount of sugar fermented (or alcohol produced) in a *given time*, either per unit weight of yeast or irrespective of the weight of yeast formed, or Schützenberger's more exact expression "fermentative energy" or quantity of sugar fermented in the unit of time by a unit-weight of yeast. Thus, whilst the "fermentative activity"—which is, in a measure, the most important to the brewer—is undoubtedly assisted by the presence, during a part of the fermentation at least, of oxygen, this does not in any way necessarily disprove Pasteur's statements. Thus Pasteur himself says: "Whilst the fermentative power of yeast is greatest when it is growing in the absence of free oxygen, its fermentative activity—that is its capacity of decomposing a given quantity of sugar in a given time—is diminished. The ternary substances will only be very slowly decomposed, because the vital force of the cells is weakened. Yeast produced in the presence of air decomposes more sugar per unit of time than yeast produced under any other conditions."

Another cause of the discrepancy in the conclusions drawn by various investigators, is the fact that often not enough weight is given to the varying conditions under which the different experiments are carried out, and to the influence of factors—sometimes omitted from consideration altogether.

The author draws the following conclusions:—

1. It is definitely proved that alcoholic fermentation can take place, both with and without the formation of new cells.
2. If a yeast is growing in a suitable saccharine liquid its fermentative-power (*i.e.*, the ratio  $\frac{S}{Y}$  of sugar decomposed to yeast formed) is greater the more complete is the aëration.
3. The intensity of the sugar-decomposition in a given time (fermentative energy or activity) is greater when the

with several small holes near the point, well into the piece. The other end was attached to a Bunte or Orsat gas burette, and this to an aspirator. After about a litre of air had

yeast is in contact with air than when it is living in the absence of air.

1. Under otherwise like conditions, yeast grown in the presence of air has a higher fermentative power than that grown in the absence of free oxygen.

5. When a fermenting liquid is aerated, the fermentation is rendered quicker and more complete, and in general more yeast is produced.

6. Yeast growing in a suitable medium cannot increase beyond a certain maximum, even under the most favourable conditions.

7. When a yeast which cannot further increase (*i.e.*, has reached the maximum referred to under 6) is living in a suitable nourishing medium, both the fermentative power and fermentative activity are increased by aeration.

On the other hand the author considers that the following problems still require further experimental investigation.

1. In alcoholic fermentation with formation of new yeast cells is the production of alcohol dependent on this formation of new cells, or is it an effect of the already-formed and non-increasing cells?

During fermentation, with or without new yeast-cell formation, would alcohol be produced if *all* the yeast-cells were exposed to the influence of free or atmospheric oxygen?

3. How do yeast-cells which ordinarily show the greatest reproductive increase, behave in the presence of air?

4. What are the conditions which restrict within certain limits, the increase (reproduction) of yeast in saccharine liquids, especially in beer-worts?

5. Can certain yeast species produce simultaneously more alcohol and more yeast in wort in the presence of air, than under ordinary conditions?—L. T. T.

#### *The Influence of the Compounds of Fluorine on Beer-Yeast.* J. Effront. Comptes rend. **118**, 1894, 1420—1423.

THE author has previously demonstrated (this Journal, 1892, 50) that beer-yeast, when grown in media containing fluorides, may be gradually accustomed to comparatively large doses of the reagent, to quantities in fact large enough to render ordinary non-habituated yeast completely inert. The life-process of such yeast is, however, profoundly modified. Reproduction is greatly restricted, whilst on the other hand, the fermentative power of the cells is largely augmented. Further experiments have shown that the chemical action of the yeast also suffers a change. The fact was demonstrated by making two series of fermentations of sugar solutions, &c., under strictly identical conditions, but using in one series, ordinary yeast, in the other, yeast habituated to fluorides. The results proved in every case that the treated yeast produced more alcohol, and a much smaller proportion of glycerol and succinic acid than ordinary yeast. For instance, in a glucose fermentation, the treated and ordinary yeasts yielded respectively 50.49 per cent. and 48.37 per cent. of alcohol (calculated on the dextrose fermented). The former figure approaches very closely to the theoretical value demanded by Gay-Lussac's simple equation; the latter is almost identical with Pasteur's result. As regards the formation of by-products the following figures are of interest.

#### *The Oxidation of Beer Wort.* P. Petit. Comptes rend. **118**, 1055—1057.

ACCORDING to Reinker, beer wort when it reaches the fermentation vats, contains an approximately constant quantity of dissolved oxygen, about 4 cc. per litre, and taking account of the products of oxidation he estimates that 800 cc. of oxygen is the largest quantity one hectolitre can absorb. The author has examined the gases dissolved in the wort and finds that after it has passed into the refrigerator that it contains large quantities of carbonic acid, and also that the proportions of oxygen to nitrogen dissolved in the wort correspond to the solubilities of these two gases in water, that is to say, about 28.5 per cent. of oxygen to 71.5 per cent. of nitrogen. A sample of the wort kept for a week in a sterilised flask closed with a cotton wool plug gave approximately the same numbers for oxygen and nitrogen, but the amount of carbonic acid had largely increased. The same result was obtained by boiling a sample of the same wort for 1½ hours when it no longer contained any gas. It was allowed to cool, air only being admitted through a very small orifice. After five days the gas was extracted from the wort and gave 13.3 cc., containing 5.7 cc. of CO<sub>2</sub>, the rest being oxygen and nitrogen in the proportion of 28.3 to 71.7 as before. The wort thus required 570 cc. of oxygen per hectolitre for chemical action. It is therefore necessary when using an air injection to regulate it so as not to remove the whole of the aroma from the wort since the latter can be oxidised to an almost indefinite extent by means of air, and even in the cold.

—T. A. L.

#### *The Oxidation of Beer Wort.* P. Petit. Comptes rend. **119**, 1894, 312—343.

IN a former note (see preceding abstract) the author examined the conditions of oxidation of beer wort as it takes place in practice; he now describes his observations upon the oxidation of wort by direct injection of air so as to produce the same phenomena and with a view to ascertaining what are the constituents of the wort that become oxidised. He aerates the wort by passing a measured volume of air through it, and then by aid of a mercury pump extracts the dissolved gases, measures them at 17° C. and 740 mm. pressure, and analyses them. The quantity of air necessary to effect complete oxidation of course varies with the concentration of the wort, and in his experiments he used a wort containing from 10 to 12 per cent. of extract. The following are the results obtained:—

It is seen that the aeration in the case of No. 11, is complete, since the quantity of oxygen dissolved is normal and bears the ratio  $\frac{1}{2}$  to the dissolved nitrogen. The volume of air injected was 110 litres per minute under a pressure of 0.6 kilo, through a volume of 400 litres of wort, and it may therefore be deduced that a sufficient oxidation and oxygenative is arrived at by injecting 750 litres of air at a rate of 110 litres per minute into a volume of one hectolitre of wort either hot or cold. The experiment on wort No. 1, indicates that a portion of the air should be injected into the hot wort, since complete saturation was not obtained after aeration for 30 minutes at 16°.

The author also finds that in the case of wort with hops,  $\frac{1}{2}$  of the carbonic acid in the dissolved gases is due to the oxidation of the constituents of the wort and  $\frac{1}{2}$  to those of the hops. He next proposes to ascertain what are the constituents of the wort thus oxidised.—H. S. P.

*The Diastase of Cereals.* J. Egaroff. Jour. Soc. Ph. Ch. Russe de Saint-Petersbourg, 1893, No. 2.

Fair diastase was obtained by extracting cereals with 30 per cent. alcohol. The extract was precipitated with absolute alcohol three times in succession. The precipitates were then suspended in water and left to settle in fractions. It was, however, found impossible to completely remove the albuminoid matters by this treatment. The elementary analysis of the purest fraction gave the following figures:—10.24 per cent. of C, 6.78 per cent. of H, 4.70 per cent. of N, 0.70 per cent. of S, 1.45 per cent. of P, and 4.60 per cent. of ash. The purification of the diastase by fractional settlement appears to have a great influence upon the reduction of the percentages of nitrogen and ash in the substance. This diastase is a white powder with a faint yellow shade. It assumes a dark blue coloration with guaiacum and hydrogen peroxide. Water rather emulsifies than dissolves it, the liquid formed being slightly opalescent. Alcohol of 75 per cent. and a semi-saturated solution of salt do not extract the diastase from gluten. The reaction of diastase is faintly alkaline, that of the ashes faintly acid. The latter contain potassium, magnesium, calcium, and phosphoric acid.—C. O. W.

*Reichler's Artificial Diastase.* J. Egaroff. Jour. Soc. Ph. Ch. Russe de Saint-Petersbourg, 1893, No. 2.

THE solution, possessing a very considerable degree of activity, which, according to Reichler, is obtained by warming gluten with weak acids ( $\text{HCl}$ ,  $\text{C}_2\text{H}_3\text{O}_2$ ,  $\text{CH}_3\text{CO}_2$ ,  $\text{KH}_2\text{PO}_4$ ) represents a solution of diastase pre-existent in the gluten, but mechanically retained by the latter. The solution of gluten in di-acid potassium phosphate decomposes rapidly whilst its saccharifying power is increasing. Under the microscope this solution is found to be full of bacteria.

A series of experiments made with this and other solutions of gluten demonstrated that they contain no diastase but what is pre-existent in the gluten. The more energetic action of the above-mentioned solution is due to the bacteria contained in it, and which, as Wortmann showed, are capable of converting starch into maltose. Jäger's observations on pancreatic appear to admit of a similar interpretation.—C. O. W.

*The Supposed Occurrence of Free Tartaric Acid in Wine.* A. Carpené. Selmi, 1894, 4, 13.

WHEN tartaric acid is added to a solution of potassium malate, succinate, pectinate, or acetate, or to acid potassium sulphate or phosphate, and also to mixtures of these salts, a precipitate of cream of tartar is obtained. This precipitation continues until all the potassium has combined with tartaric acid. Consequently it is impossible for free tartaric acid to exist in wine along with these salts. Experimenting with 100 wines a precipitate was always obtained.

The ash of a wine treated with a solution containing 3.5 grms. of tartaric acid per litre, contains 0.2–0.3 grm.

less of potassium than the natural wine-ash does. When therefore free tartaric acid is proved to be present in a wine in absence of the potassium salts of the other acids, we may rightly suspect the wine of artificial preparation.—T. A. G.

*The Influence of Cane Sugar on the Valuation of Malts and Worts.* E. Prior, Bayer. Brauerjourn. 1894, 4, 49.

THE total amounts of sugars, reducing sugars, and cane sugars were estimated (according to Meissl's method) in 13 malts. The tabulated results show that 100 parts of wort extract contain 5.59 to 8.69 per cent. of cane sugar. Of two malts containing about the same amount of reducing sugars, the one contained about 2 per cent. more cane sugar and this malt, although in all respects a good brewing malt, gave in practice a higher finished fermentation. This is attributed by the author to the greater percentage of cane sugar present.—T. A. G.

*Quantity of Steam and Capacity of Boiler required in Washing and Boiling Wort.* Wochenschr. f. Brauerei, 11, 323.

EXPERIMENTS made at Schönberg when mashing 5 tons of malt showed that 2.9 tons of steam were required for mashing and 2.2 tons for boiling the wort, or, together, 5.1 tons of steam for 14 hours' boiling. Basing calculations on a production of about 3 lb. of steam per hour per square foot of heated boiler surface, these results show that for every cwt. of malt mashed, 7.75 lb. of steam and 2.5 sq. ft. of heated boiler surface are required.—L. T. T.

*The Influence of Ferruginous Water in Malting.* Kukla. Wochenschr. f. Brauerei, 11, 350. From Oesterr. Brau-u.-Hopf-Zeit. 1894, part 5.

AN otherwise good water, but containing 2 parts in 100,000 of iron oxide caused considerable darkening of the malt, and the latter absorbed so much of the iron (23 mgrms. in 100 grms. of malt) that in mashing it gave up some of the iron to the wort, which then became dark coloured on the addition of the hops.—L. T. T.

*Effect of Alkaline Chlorides on the Flavour of Beer.* Wochenschr. f. Brauerei, 11, 289.

IT is generally considered in England that chlorides, and especially salt, exert an important influence on the flavour, apparent maturity, and brightness of beers, and salt is therefore often added to the brewing water. The recent experiments of Zuntz on "The Physiology of Taste" (Naturw. Rundschau, 7, 619) give support to this view. Zuntz finds that if salt or bitter substances are added to sweet substances in quantity insufficient of themselves to produce a decided taste, the sweetness is apparently increased. Thus, if to a 12–13 per cent. sugar solution, 0.1 per cent. of salt or of quinine sulphate be added, the sweetness of the solution appears much increased. It is thus probable that the presence of minute quantities of salt &c. has an important influence in bringing out other flavours.—L. T. T.

*Some of the Micro-Organisms causing the Diseases of Beer.* F. W. Fellowes, London. Trans. North of England Inst. of Brewing, Manchester. May 1894.

THE normal acidity of beer acts as a strong preservative against the attacks of many of the disease-producing organisms.

Wort contamination is usually due either to atmospheric infection or the use of impure pitching yeast.

Hayduck observed that the lactic ferment has strongly marked stages of fermentative activity, for instance, during 11–12 hours, 0.35 per cent. of acid was formed; 13–14,

0.60 per cent.; 15—16, 0.1 per cent.; 17—18, 0.22 per cent. The percentage of alcohol in the liquor has a marked effect on the vital activity of the ferment; 2 per cent. has practically no effect, whilst 4 per cent. checks it considerably, and 6 per cent. entirely. Mr. Fellowes attributes the excessive production of lactic acid in many beers to a somewhat high rate of nitrogenous matter in conjunction with an abnormal number of lactic bacteria, which, in all probability, had their origin in a highly infected pitching yeast.

A neutral sterile beer infected with *Saccharo bacillus Pastorianus*, as Van Laer has appropriately named this organism, was found at the end of four weeks growth at 25°—30° C., to have produced volatile acid = 3.5 cc. N. alkali, and fixed acid = 24.0 cc. N. alkali per 100 cc.

Van Laer has investigated "ropy" or excessively viscid Belgian beers, and attributes their production to the action of *Bacillus Viscosus*—of which there are several varieties. The fact of "ropiness" in English beers not always affecting an entire brew appears to point to infection having taken place after the primary fermentation.

Illustrating the rapid deterioration which infected yeast may undergo, Mr. Fellowes mentions a case in which ordinary commercial yeast was used for a series of laboratory experiments. The yeast in its fresh state gave a satisfactory fermentation; with, however, a rather high acidity. It was passed through some three or four generations by successive growths in sterile wort. Each successive generation was very strongly reduced in fermentative power, until a stage was reached when it failed to produce more than a slight alcoholic fermentation. In all cases, however, (about three dozen in number) the beer ultimately became turbid and decidedly ropy; the viscosimeter taking 53 seconds to deliver 25 cc. of distilled water at 20° C., and 98 seconds to deliver an equal volume of the viscid beer at the same temperature.

The bacteriological examination of air and water are dealt with, and a new apparatus, introduced by the author and Mr. A. J. Banks, for the culture of anaerobic organisms, is described. This consists of a glass dish having an inner circular wall of lesser diameter than that of the bell-jar. The bell-jar has a tubulated opening at the side, into which a caoutchouc stopper holding a doubly bent glass tube is fixed; this serves as a gas inlet. The top of the chamber

has a similar opening, and is likewise closed by a stopper through which is passed a bent glass tube of sufficient length to reach well below the inner wall of the dish. After the chamber has received its charge of plates, a layer of light colorless mineral oil is run into the outer space until the end of the gas outlet becomes immersed. The inlet tube is connected with a gas generator and a rapid current of nitrogen, hydrogen, or carbonic acid gas passed through until the air is expelled. The apparatus, after being placed in the incubator, is connected with a gas holder from which an almost imperceptible current of gas is forced by means of a suitably regulated siphon affixed thereto.—A. J. B.

*Rectification of Alcohol.* E. Sorel. *Comptes rend.* 118, 1213—1215.

It has been shown by the author in previous papers (*Comptes rend.* 108, 1128, 1205, 1317) that the volatile impurities contained in a liquid undergoing rectification

ascend to higher levels or descend towards the still, according as the difference  $K - \frac{P}{p}$  is positive or negative. In this expression  $K$  is the ratio of the weight of impurity in 1 kilo. of the vapour and in 1 kilo. of the liquid in contact with a given level;  $P$  is the weight of the reflux liquid, and  $p$  is the weight of vapour which traverses the given level in unit time.  $\frac{P}{p}$  is therefore of necessity less than unity; but it is the nearer unity the more concentrated the alcohol. The author has now determined the value of  $K$  for fermentation isomyl alcohol, ethyl formate, methyl acetate, ethyl acetate, ethyl isobutyrate, ethyl isovalerate, isomyl acetate, and isomyl isovalerate. The results are given in tabular form and the following deductions are drawn from them:—The value of  $K$  decreases with the increase of the molecular weight and the rise of the boiling point; but there is no apparent relation between the three variables.—A. R. L.

*Utilisation of Vintage Dregs.* A. Muntz. *Comptes rend.* 118, 1221—1226.

The dregs of the grapes in wine manufacture are more often a source of little profit, and in some cases are a source of actual loss. The author took up the problem of the utilisation of these dregs during the vintage of 1892. The pressed dregs were found to contain 60 per cent. of their weight of wine; it is possible to recover this wine by displacement with water, and the "piquette" thus obtained is superior in strength to that consumed by the farm labourers. The surplus of these "piquettes" when submitted to distillation gives an "eau de vie" of superior value to that obtained by the direct distillation of the dregs. After having separated the wine from the dregs the latter have lost none of their nutritive value, which was proved by the fact that a flock of sheep were fed on the material during the winter.

The author resumed his studies during the vintage of 1893, the operations being conducted in the following manner:—The dregs as they leave the presses are introduced without delay into cylindrical vats, where they are treated with 4—5 per cent. of water to assist the pressing down. When the vat is full, the surface of the dregs is treated uniformly every quarter of an hour with water, which is distributed uniformly over the surface; in the present case there were used every quarter of an hour, 12 litres of water, this being the requisite amount for a cask of 80 hectolitres capacity. The water thus presses out the wine contained in the dregs, and the first runnings which collect at the bottom of the vat consist of wine of excellent quality without admixture of water. The operation is arrested when the liquid only contains 1 per cent. of alcohol which will be attained at the end of four days, the liquid having then but a faint colour. The more concentrated liquors are reserved for direct consumption or distillation; the more dilute are used for the lixiviation of a fresh quantity of dregs.—A. R. L.

### PATENTS.

*Improvements in the Manufacture of Yeast.* W. S. Squire, London. Eng. Pat. 19,843, October 21, 1893.

WHEN distiller's spent wash is heated to a temperature corresponding to about two atmospheres above the atmospheric pressure, it becomes perfectly clear and bright after filtration or subsidence, less viscid, and more suitable for the manufacture of yeast. In the ordinary process of brewing in distilleries the grain is treated with water at, or about, the boiling point, and thus most of the albuminous matters are coagulated and lost for yeast manufacture. To avoid this loss, an albuminous solution is made by treating the grain, before boiling, with ordinary water, spent wash or, preferably, spent wash which has been purified as above described, at a temperature not exceeding 130° to 140° F. Albuminous solutions thus prepared are to be used instead of water or spent wash for mashing malt, rye, or other suitable grain before the addition of the boiled maize, as described by the patentee in Eng. Pats. 12,058 and 12,463 of 1885, and 5457 and 8982 of 1886 (this Journal, 1886 542, also 1887, 297 and 514).

For the manufacture of yeast a mash, made in this manner, should, after the addition of the boiled maize, have a temperature of about 145° F., and when saccharification is complete spent wash or one of the solvents named is added so as to obtain a wort of specific gravity 1.030. The wort is then clarified, cooled to 80° F., yeast is added and air blown in until fermentation is complete. The yeast is collected and pressed, and the resulting wash may be distilled to recover the spirit.—T. A. G.

*An Improved Method of Utilizing and Means for Treating Yeast.* E. W. Greening, Thames-Ditton, Surrey, and E. O. Greening, Lee, Kent. Eng. Pat. 20,960, October 24, 1893.

WASTE brewer's yeast is dried, conveniently, by passing through steam-heated rollers, until the moisture is reduced from the normal amount of 75 or 80 per cent. to less than 10 per cent. The thin flakes thus obtained are scraped from the rollers by suitably arranged knives, cooled in trough conveyors by continual turning and stirring, and then ground into powder or meal of any requisite degree of fineness.

Fresh yeast meal, being exceptionally rich in albuminous matters, and the tonic principle of hops, is serviceable for admixture with other substances, to increase their feeding value and flavour when used as feeding-meals, or cakes, for cattle.

Meal from stale or dirty yeast forms a valuable manure since it is rich in phosphates, potash, nitrogenous matters, &c. It may be used by itself, or mixed with other fertilizers.

—T. A. G.

*A Method of Treating Grain and other Materials for Employment in Brewing and for other useful Purposes.* T. Bayley, Dublin. Eng. Pat. 20,930, November 4, 1893.

GRAIN and other starch containing materials are treated with dilute acid at or below a temperature of 40° C. (104° F.) whereby the starch is, for the greater part, converted into the soluble form, and when the grain is subsequently treated with hot water at 190° F. or upwards, a comparatively limpid solution is obtained, and any undue thickening or viscosity avoided. The time required for conversion depends upon the nature and strength of the acid used and upon the temperature. If rice be digested in the cold with sulphuric acid, diluted with nine times its weight of water, modification of the starch results in 21 days, whilst at a temperature of 100° F. about 48 hours suffice for dilute sulphuric acid and seven or eight days for a saturated solution of sulphurous acid. At the end of the necessary

time the acid is removed, and the rice is well washed with water until the washings are no longer acid. It is then ready for use either in the wet state or after being dried.

—T. A. G.

*Improvements in the Manufacture of Compounds suitable for the Production of Ginger Beer, Herb or Botanic Beers, or other Fermented Beverages.* J. Heron, London. Eng. Pat. 21,332, November 9, 1893.

THE object of the invention is the preparation of solid compounds containing all the necessary ingredients, except the actual water, required for producing "home-brewed" ginger beer or other fermented beverages.

For instance, a ginger-beer compound is made thus:—A solution of solid dextro-glucose is concentrated until it contains only 10 to 12 per cent. of water. Whilst still hot, the ingredients are added, the mixture is cooled to about 70° F. and thoroughly incorporated with fresh, pressed yeast (about two parts, by weight, to 100 parts of glucose). The mixture is run into moulds, where it sets into a hard, compact mass. When required for use it is broken up into small pieces and dissolved in water at a temperature of 70° to 80° F. The water should be previously boiled to destroy any germs which it may contain. After standing 12 hours the beer is ready to bottle. In cases where any of the ingredients can only be extracted by boiling water they are not incorporated with the glucose and yeast, but are boiled in the water, which is then cooled, and the prepared compound is added.—T. A. G.

*A New or Improved Apparatus for Fining Beers and other Liquors in Cask, applicable also for Priming and Filling up Casks.* J. G. Crossman, Cork. Eng. Pat. 2152, January 31, 1894.

THE apparatus consists of a portable hand-pump of which the cylinder is fitted with plunger, piston-rod, and handle. The top cover has a packed joint, and the lower cover carries a projecting nozzle and thimble. The rubber-covered thimble is tapered to fit any bung-hole and ensure a tight joint. An adjusting nut on the piston-rod is used to regulate the volume of contents to be delivered.

In operation the finings are drawn into the cylinder by an instroke of the plunger, the nozzle is passed through the bung-hole into a full cask, the rubber securing a tight joint, and the finings are forcibly injected. The displaced beer simultaneously passes up an annular space between the nozzle and the thimble, and through the side tube into the cylinder, and at the next instroke is forced out again to be received into any suitable receptacle.—T. A. G.

## XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY AND WATER PURIFICATION, DISINFECTANTS.

### (A.)—CHEMISTRY OF FOODS.

*Testing Milks with Rennet.* R. Lezé and E. Hilsont. Comptes rend. 118, 1069.

See under XXIII., page 1099.

*Centrifugal Methods of Milk Analysis.* A. Scott. A Paper read before the Glasgow City Analysts' Soc. Abstracts, No. 4, 1893-94, 9.

See under XXIII., page 1104.

*Soxhlet's Arcometric Method of Determining the Fat in Milk.* H. Zimpe. *Chem. Zeit.* 1894, **18**, 392.

See under XXIII., page 1104.

*Composition of "Honey Dew": Influence of a Summer in which "Honey Dew" is abundant, on the Character of the Honey.* E. von Raumer. *Zeits. anal. Chem.* **33**, 397.

See under XVI., page 1076.

#### PATENTS.

*New or Improved Compositions for Preserving Beer, Wine, Milk, and other Liquids.* J. W. Pickles, Leeds. Eng. Pat. 18,736, October 6, 1893.

THE compositions described contain a mixture of boracic acid, sodium salicylate, and potassium bicarbonate, which has been allowed to absorb sulphur dioxide (produced by burning sulphur), with or without addition of capsicum and primrose yellow, and a mixture similar to the above, but without the sodium salicylate.—T. E.

*Improvements in or connected with the Production of Butter from Cream or Milk.* S. H. Wright, Monmouth. Eng. Pat. 18,708, November 25, 1893.

THE object of the invention is to produce butter from milk or cream by passing a rapid current of air through it. The current of air is produced by exhausting the air over the liquid with a water pump, or by forcing the air into the liquid under pressure. The butter can then be washed in the same apparatus by forcing water through it. The apparatus (which is described and illustrated by three sheets of drawings) is stated to be of an inexpensive nature.—T. E.

*Improvements in or relating to the Roasting of Coffee, Cocoa, and similar Materials.* A. J. Boulton, From C. A. Otto, Dresden. Eng. Pat. 22,645, November 25, 1893.

THE roasting is done by passing the material in small quantities through a helically-wound and heated tube. The improvements claimed are the different pieces of machinery necessary for carrying this out. They consist mainly of the helically-wound rotating tube heated in any convenient way and containing heart-shaped scoops for the purpose of more completely mixing the material passing through the tube, and of a hollow rotating ball, of a capacity which can be varied, by means of which small quantities of the material may be fed into the tube at small successive intervals.

—T. E.

*Improvements in Apparatus specially suitable for Use in Estimating the Amount of Fat in Milk and other Substances.* R. W. Woosnam and the Dairy Supply Co., Lim., London. Eng. Pat. 23,039, November 30, 1893.

See under XXIII., page 1091.

*Improvements in the Means of Using Baking Powder.* W. G. Dunn, East Croydon, and J. A. Brown and J. Polson, Paisley. Eng. Pat. 9183, May 9, 1894.

ANY of the well-known chemical raising agents is ground up with five times its weight of a non-nitrogenous flour, such as corn-flour. The injurious action of the raising agent on the nitrogenous constituents of the flour generally employed in making baking powder is thus avoided. The patentees also state that their preparation keeps better, is more easily distributed uniformly through the dough, and that the addition of corn-flour improves many kinds of bread, especially when milk is used.—T. E.

*Improvements in Compound Edible Fats.* A. W. Winter, Chicago, U.S.A. Eng. Pat. 9526, May 15, 1894.

THE object of the patent is the production of fats which may be used for food, containing about 60 per cent of refined mineral oil mixed with varying quantities of animal or vegetable fats and oils. Eleven claims for different mixtures are made; for details of their composition and preparation the specification may be referred to.—T. E.

*Peptonised Extract of Malted and other Cereals.* Peptine Maltine, Lim., and G. Bartlett, Leicester. Eng. Pat. 12,174, June 23, 1894.

THE cereals are extracted with water at 140° F., and 1 part of pepsin and 1 part B.P. hydrochloric acid to 2,000 parts of albumen added; the mixture is then heated to 104° F. for six hours and evaporated *in vacuo*. The peptones formed render it a powerful digestive agent, and it is said to keep for a considerable period.—T. E.

#### (B.)—SANITARY CHEMISTRY.

*Estimation of Nitrates and Nitrites in Waters.* J. Fraser. Communicated to the Glasgow City Analysts' Society. Abstracts, No. 4, 1893-94, 47.

See under XXIII., page 1095.

*The Removal of Iron from Drinking-Water.* H. Schuster. *Zeits. des Ing. und Arch. Ver. zu Hannover*, 1894, 297; *Proc. Inst. Civil Eng.* 1894, **118**, 34-35.

AT Aurich, in East Friesland, a tube-well 36 mm. in diameter was put down to a depth of 84 metres in alluvial ground, for the purpose of supplying the barracks; but the water, although free from organic matter, was unfit for use on account of the large amount of iron in solution, amounting to 19.2 mgrms. per litre, and, when exposed to the air, became brown and turbid from the formation of ferric hydrate when the carbon dioxide which kept the iron in solution, had escaped. As no other supply could be got, it was decided to purify it by the method adopted by C. Piefke, the separation of the iron being facilitated by breaking up the mass of water into numerous fine streams so as to obtain the largest possible contact with the atmosphere. The apparatus consists of a rectangular iron scrubber 3 metres high, 2 metres long, and 1 metre broad, filled with lumps of coke. The water is distributed by a series of perforated plates uniformly over the top of the coke-column, and passes downward into a collecting chamber below, and from thence through a sand-filter bed 640 mm. thick, with about 11 square metres area, that of the scrubber being 2 square metres. The proportion of iron was diminished from 19.2 to 7.21 mgrms. per litre in the scrubber, and to 1.08 mgrms. after passing the filter. The apparatus was intended to treat 3½ cubic metres per hour, under which condition the rate of delivery per square metre was 1,750 litres in the scrubber and 380 litres in the filter.

The removal of the ochre deposit on the coke is effected from time to time by stopping the communication with the filter and allowing the water from the pump to flow for a short time in a single stream through each of the distributing plates in succession. The strong current thus obtained detaches the deposit. A similar coating accumulates on the top of the filter, rendering it nearly, if not quite, impermeable to water, so that about 2 metres of the upper part must be renewed at intervals of three or four weeks.

#### PATENTS.

*An Improved Device for Filtering Water.* S. Wittman, London. Eng. Pat. 20,259, October 27, 1893.

IN the ordinary filter, charcoal is contained in a vessel into which water is poured and from which it percolates into another vessel or compartment. The novelty consists in making the first vessel itself the filtering medium, by fashion-

ing it out of a mixture of animal charcoal, clay, and ground coke or lignite, and firing it in a closed kiln from which air is excluded. The vessel may be of any shape, preferably egg-shape, and in moulding it starch or sawdust may be substituted for the coke or lignite.—L. A.

*Improvements in the Utilisation of Sewage Sludge.*  
T. Twynnam, Egham, Surrey. Eng. Pat. 21,024, November 6, 1893.

THE patentee proposes to utilise well-pressed sewage sludge by charging it into a blast-furnace making phosphoric pig-iron. "The carbonaceous and volatile matter in the pressed sludge (generally amounting to about 30 per cent.) serve as part of the requisite fuel, the lime and alumina go to form a fusible slag, the iron oxide present being reduced to metal, whilst the phosphoric acid is all reduced to phosphorus, which enters into the pig-iron, being eventually recovered as a valuable manure in the form of basic slag when the pig-iron is used in the manufacture of basic steel. All the ammonia of the sludge passes away in the furnace gases, and is recovered by condensation in the usual manner.

—L. A.

*Improvements in Means for Cremating and Destroying Obnoxious Gases and Fumes from Dust Destroyers and the like.* T. W. Baker, London. Eng. Pat. 21,820, November 15, 1893.

THE inventor proposes to destroy or render innocuous the gases given off by the destructors of town refuse, and also other objectionable gases, by conducting them into the combustion space of the furnaces of steam boilers, so mixing them with the furnace gases at their hottest and burning them, thus utilising the heat given off during the operation.

At present, a special furnace, known as a cremator, has to be employed for rendering the destructor-gases innocuous.

The inventor prefers to use the dry-back marine steam boiler, with two or more furnaces and a common combustion chamber connecting the furnaces with the return tubes; in this case he simply connects the destructor-gas flue to the combustion chamber.

With wet-back marine boilers, the destructor-gases pass through openings made through the stayed space at the back of the combustion chamber or chambers. With Lancashire or with Cornish boilers he inserts between, and at a lower level than, the furnaces, another tube, similar to the third flue of a three-flued boiler, but reaching only to the back of the furnaces, which connects up with the two combustion spaces (this modification is specially claimed).

With water-tube boilers the inventor uses a double back to the furnaces, and leads the destructor-gases through the space between the two backs, into the combustion space, so that fuel-gases and destructor-gases mix above the fuel and also in the spaces between the water-tubes.

In some cases, however, he prefers to pass the destructor-gases through the burning fuel, and in this case introduces them into the closed ash-pit, claiming the use of fans for this purpose.—E. R. B.

*Improved Apparatus for Filtering and Sterilising Water.*  
H. Kowalski, Vienna. Eng. Pat. 15,487, August 14, 1894.

THIS is an apparatus for providing a continuous supply of sterilised and filtered water.

The water flowing into the vessel A, (see figure) and maintained at a constant level by the overflow *a*, passes downwards, through a layer of filtering material in the bottom of A, into the pipe *a*<sup>1</sup>, which conducts it into the compartment B, from which it rises through the pipe *b* into the coil *b*<sup>1</sup>, where it becomes heated by the hot water in F. A portion of the water from B rises between the double walls of the vessel F, and meeting, in the pipe *b*<sup>2</sup>, the water which has passed up the coil, the mingled stream flows into the heater C, whence it overflows, down the pipe *c*<sup>1</sup>, into the bottom of the

boiler D. The water is here boiled by the heat of the furnace E, and overflows through the U-pipe *d*<sup>1</sup>, which terminates in a rose, into the vessel F, where it is partially cooled by the cold water passing up through the space *f* and the coil *b*<sup>1</sup>. At the bottom of F there is a second filtering layer, and, after passing through this, the sterilised water is further cooled by flowing partly between the double sides of the vessel B and partly through the coil *f*<sup>2</sup>, and is finally drawn off through the cock and pipe *f*<sup>3</sup> for use.

IMPROVED APPARATUS FOR FILTERING AND STERILISING WATER.

The steam generated in the boiler D rises through the space *w*, between the chimney *e* and the dome *c*, and, finding an outlet through the pipe *c*<sup>2</sup>, condenses in the water passing down the pipe *c*<sup>1</sup>: any excess of steam condenses in the water which gets through the perforations in the lower part of the outer dome *c*<sup>1</sup>. The cover of the vessel C is left loose to prevent the steam pressure from accumulating, and also to prevent the formation of a vacuum if the boiling should slacken or cease. *d*<sup>2</sup> is a thermometer. The vessels A, B, and F are made of corrugated sheet iron, and are of such relative dimensions that they may be packed one within the other for transport.—L. A.

## (C).—DISINFECTANTS.

### PATENT.

*Improvements in Disinfecting and Fumigating Apparatus.*  
G. G. Crosby, New York. Eng. Pat. 22,820, November 28, 1893.

THIS specification describes a portable box or case containing a mechanical contrivance for fumigating the air of a room. The mechanical contrivance consists of three parts: 1st, perforated trays containing absorbent material saturated

with a disinfectant or perfume; 2nd, an air propeller driven by an electro- or other motor; 3rd, a battery to work the electro-motor. When the motor is set going, air is drawn through an opening in one end of the box, perfumed by passing through the material contained in the trays, and ejected through an opening in the other end of the box.

—L. A.

## XIX.—PAPER, PASTEBOARD, Etc.

### PATENTS.

*Improvements in Apparatus used in the Manufacture of Paper Pulp.* W. H. Caldwell, Loanhead, Midlothian. Eng. Pat. 15,332, August 11, 1893.

THE improvements relate to the arrangement of the knives or blades of a heating or pulping engine. According to the inventor, the fibres, when flattened by pressure, are capable of holding the water on the machine wire longer than when in the original cylindrical form. The object of the invention is to flatten the fibres by pressure while they are passing between the bars or knives of the grinding surfaces, and this is claimed to be accomplished by an apparatus constructed as follows:—Within a cylindrical shell is a heating roll having knives of the ordinary type fixed upon its circumference. Outside this roll is a fixed cylinder having another set of knives which are movable in radial slots, and corresponding to the bed plate of the "Hollander." Upon the exterior surface of this cylinder is a second cylinder constructed of rubber or similar flexible material, and upon which the distal end of the movable knives rest. The space between this latter cylinder and the outer shell is filled with water under any desired pressure, which pressure, acting upon the flexible cylinder, is transmitted to the pulp through the movable knives. The general construction of the apparatus and the mode of driving is of the usual pulp-refiner type.—S. P. E.

*Improvements in Obtaining Useful Products from the Liquors resulting from the Manufacture of Cellulose or Fibres by the Sulphite Process.* C. D. Ekman, London. Eng. Pat. 20,036, October 24, 1893.

THE improvements relate to a method of recovering some of the organic compounds contained in the spent liquor from the manufacture of cellulose fibre from wood by the sulphite process. The waste liquor is first clarified by allowing it to settle or by passing through filter beds, after which it is concentrated, preferably to about 63° Tw. at 85° C., in suitable vessels having an acid-resisting lining, and heated by steam in a leaden coil or jacket. Before evaporating, the liquor may be made alkaline by the addition of any of the caustic or carbonate compounds of the alkaline earths, in which case an acid-resisting lining in the evaporating vessel is unnecessary. To the concentrated liquor sulphuric, hydrochloric, or oxalic acid or an acid salt is added to improve the colour of the product formed, which is somewhat hygroscopic and contains a compound resembling dextrine and which the author has called "dextrone." To obtain this product, soluble salts, as the sulphate or chloride of sodium, &c., are added to the boiling liquor as long as the dextrone separates out, which, rising to the surface, may be easily removed. When cold this substance is a semi-solid, and may be either dissolved in water or dried and reduced to a powder. Mixed with gelatine or glue it forms a substance similar to the *gela-lignosine* described by Messrs. Cross and Bevan, and, like that compound, when dissolved in a suitable solvent, as sulphite of soda, can be employed as a mordant or size for textile fabrics, paper, &c. The liquor remaining after removing the dextrone may be further employed for the production of the *gela-lignosine*-like substance, by adding a concentrated solution of glue or gelatin as long as the compound separates out.

—S. P. E.

*Improvements in the Treatment of Sulphite Pulp used in the Manufacture of Paper and the like from Wood.* E. Partridge, Glossop. Eng. Pat. 3440, February 17, 1894.

THE improvement consists in the addition of liquid hydrocarbon as petroleum, preferably of a specific gravity of 0.800 to 0.850, for the purpose of dissolving and removing any resinous material that may be present in the boiled sulphite wood-pulp, and thus prevent the formation of the black resinous specks that are usually present in the finished pulp and upon the machinery employed. The proportion of petroleum recommended for this purpose is about six to eight quarts to one ton of air-dry pulp, added gradually while the pulp is being "opened" or beaten up in the rag engine, pulp opener, or washing engine.

—S. P. E.

*Improvements in the Manufacture of Parchment.* H. O. Brand, Brentford, Middlesex. Eng. Pat. 14,384, July 26, 1894.

IN addition to the lime-water washing, claimed in a former specification (this Journal, 1893, 946), the parchment is to be treated with alum, the object being to further harden the skin and to prevent the ink from soaking in. The alum is added, in the proportion of half a pound to 90 galls. of water, to the bath or washing of lime-water already referred to. The finishing process is similar to that previously described (*loc. cit.*), save that before the final rubbing with flannel the parchment is cleaned by rubbing with sand or glass paper.—A. G. B.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

*The Essence Ylang-Ylang.* M. A. Reyher, Bull. Soc. Chim. 1894, **11**—12, 576—583.

THIS essence, in which up to the present only benzoic acid has been definitely recognised, contains quite a number of substances. Benzoic and acetic acid (in the form of their esters) appear to be present in the proportion respectively of 9 and 7 per cent. Ylangol constitutes about 30 to 32 per cent. of the essence, and the sesquiterpene present is contained in similar amount. The remaining 20 per cent. comprise the more volatile portions together with the resinoid constituents (polyterpenes, &c.).

With regard to Ylangol, it resembles Licareol (Barbier) in its rotatory power in alcoholic solution ( $[\alpha]_D = -19.3$ ). Oxidation by means of chromic acid mixture furnishes an oil with an odour like citral, and forming a crystalline compound with sodium bisulphite. Ylang-ylang contains, it appears, an alcohol of the geraniol series, with the formula  $C_{10}H_{18}O$ .—W. S.

*The Rhodinol of the Essence of Pelargonium.* Ph. Barbier and L. Bouveault. Comptes rend. **119**, 1894, 334—337.

THE chief part of the essence of pelargonium is a colourless, slightly oily liquid possessing a very strong odour of roses. It boils at 115°—116° under a pressure of 10 mm., its density at 0° is 0.8866, and through a thickness of 20 cm. it gives a deviation of  $-12.28^\circ$ .

That this compound is an alcohol is demonstrated by its easy conversion into its acetic ether by heating to 150°—160° with an excess of acetic anhydride. This acetate boils at 120° under 10 mm. pressure, and has an agreeable odour, and its density at 0° is 0.9458. That it is a primary alcohol is shown by its yielding an aldehyde and an acid on oxidation. The authors have prepared the oximide from the aldehyde, and from this the nitrile, which has the composition  $C_{10}H_{15}N$ ; the aldehyde has therefore the composition  $C_{10}H_{16}O$ . This nitrile fixes one molecule of

bromine. They have also isolated from the oxidation products of the rhodinol of pelargonium, an acid boiling at 149—150°, and have analysed its barium salt. It has the composition  $C_{10}H_{16}O_4$ . A more complete oxidation of the alcohol yields a considerable quantity of dimethylacetone and a crystallised acid which separates in fine needles melting at 100°. The composition of this acid is  $C_{10}H_{16}O_4$ . It distils without alteration above 300° at the ordinary pressure and at 205° under 10 mm. pressure. Its formation is indicated by the formula—

It is a dibasic saturated acid. The authors conclude that it is a methyl adipic acid. The alcohols isomeric with the rhodinol of pelargonium (geraniol, linaldolol), with which it has been confounded until now, readily lose one molecule of water and thus yield terpenes,  $C_{10}H_{16}$ . The alcohol in question, however, behaves differently: acid potassium sulphate converts it into viscous products of very high boiling point, no doubt oxides, and only a very small amount of hydrocarbon is formed. Hydrochloric acid, which etherifies its isomerides in the cold so easily, only attacks the rhodinol of pelargonium when heated, and the hydrochloride then produced, when it is heated with potassium acetate, yields the acetate of rhodinol, whilst the hydrochlorides of the isomerides yield terpenes.—H. S. P.

#### A Natural Unsaturated Ketone in Lemon-Grass Oil.

Ph. Barbier and L. Bouveault. *Comptes rend.* **113**, 983—986.

ACCORDING to Dodge (*Amer. Chem. J.* **12**, 553; this Journal, 1891, 158), oil of lemon-grass contains an aldehyde,  $C_{11}H_{16}O$ , to which he gave the name citridic aldehyde, but which was subsequently found to be identical with geranaldehyde (Semmler, *Ber.* **24**, 201—211; this Journal, 1891, 382). With a view of obtaining it the authors have distilled a large quantity of lemon-grass oil in a vacuum. After four or five distillations three fractions were obtained, one boiling at 65°—75° C. at 12 mm., the second at 110°—115°, mainly consisting of geranaldehyde, and the third a brown viscous fluid, which was not further investigated. The lowest fraction distils under atmospheric pressure at 170°—175° C., and generally consisted of a mixture of a terpene and an unsaturated ketone, the amount of the former varying from 0 to 50 per cent. of the fraction. The ketone was separated by means of its bisulphite compound, and was found to be methyl-hexylene ketone. Although the physical properties of this ketone are very similar to those of an isomeric compound obtained by Wallach (*Annalen*, **28**, 318) by distilling cinoleic aldehyde, the two substances react differently with zinc chloride.

Tieman and Semmler, by oxidising geraniol and geranaldehyde, also obtained an isomeric compound, which they termed citral. This, according to Tieman and Semmler, gives a well-defined crystalline bromine derivative, whereas the new ketone only gives a yellow viscous mass which will not crystallise. The authors have also examined the terpene which occurs together with the ketone in lemon-grass oil. It was purified by distilling over sodium and boiled at 175° C. Its specific rotatory power is  $\alpha_D^{20} = -5.48$ . It is not a limonene, and the authors are of opinion that the very varying quantities of this terpene in samples of lemon-grass oil, point to its presence as an adulterant.—T. A. L.

#### The Aldehyde of Lemon-Grass Oil.

Ph. Barbier and L. Bouveault. *Comptes rend.* **113**, 1059—1062.

THE authors have studied certain of the reactions of geranaldehyde, as the conclusions they have come to with regard to methyl-hexylene ketone are at variance with those of Tieman and Semmler. On oxidation with a sufficient quantity of bichromate to evolve 4 atoms of oxygen, geranaldehyde is decomposed into a mixture of volatile and non-volatile acids, the former consisting chiefly of acetic and formic acids. By boiling geranaldehyde with three times its weight of glacial acetic acid it is readily converted into xymene. The formula proposed by Tieman and Semmler for geranaldehyde explains

this reaction, but the oxidation of a substance constituted according to them ought to give terebic acid on oxidation. This, however, is not formed, neither does their formula explain the formation of methyl-hexylene ketone, carboxylic acid, or terebic acid. T. A. L.

#### Geraniol from Oil of *Andropogon Schenanthus*.

P. Barbier and L. Bouveault. *Comptes rend.* **118**, 1154—1157.

THE Geraniol of *Andropogon Schenanthus* furnished the same products of oxidation as citridic aldehyde, and the authors therefore admit the truth of Tieman and Semmler's observation that the citridic aldehyde is really the aldehyde of the geraniol of *Andropogon Schenanthus*.

The results of experiments with the essence of Pelargonium all point to the conclusion that this essence is absolutely different from the essence of *Andropogon Schenanthus*. Hence the alcohol of the essence of *Andropogon Schenanthus*, must no longer be termed "Geraniol," and the authors propose the name "Lemonol," which indicates its relation to citridic aldehyde, to which the name "Lemonal" might be given, thus indicating its origin (essence of lemon grass, *Andropogon citratus*) as well as its chemical functions.

#### The Physiological and Therapeutic Action of the Homologues of Quinine.

E. Grimaux and Laborde and Bourru. *Comptes rend.* **118**, 1294, 1303—1306.

GRIMAUX and Arnaud have shown (this Journal, 1891, 723, 770; 1892, 631—632) that quinine is the methyl-ether of cupreine. Since then other allyl derivatives of cupreine have been prepared and their relative physiological and therapeutic values have been investigated by Laborde and Bourru respectively. The results in general prove that the activity of these homologous bases increases as the series is ascended.

**Physiological Action.**—Cupreine administered subcutaneously to guinea-pigs, &c., produces local anaesthesia persisting for several days, and an increase in temperature of about 1° C. Its toxic influence is about half that of quinine.

**Ethyl Cupreine** resembles quinine in its action, but has a more marked effect, producing "quinine intoxication," stupor, bilateral tremor, and an average decrease in temperature of 2°—3° C. 0.15 gm. caused death in the case of a guinea-pig weighing 400 gm.

**Propyl Cupreine** is analogous to the above, but its action is still more intense. An injection of 0.025 gm. reduced the temperature of a guinea-pig by 2° in 15 minutes, 5° in 2 hours, and produced stupor, collapse, &c.; whilst 0.05 gm. was fatal, death being due to epileptic convulsions and suffocation.

**Therapeutic Action.** Cupreine administered internally in various fever cases exerted only a very slight and transient antiperiodic action.

**Ethyl cupreine** employed as basic sulphate (0.5 to 0.75 gm.) was found to have an excellent anti-periodic influence. Notably in two instances of fever, complete exemption from further attacks was secured by 3—4 doses of ethyl-cupreine, although repeated use of quinine had failed to afford relief. The toxic action of the drug when employed at the above rate was nil.

**Propyl Cupreine** has a still more powerful antiperiodic function, and exerts a very marked influence on temperature. In a case of typhoid fever, doses of 0.5 gm. administered from the third to the eighth day, gradually reduced the temperature from 103.3 to 37°—4. The base is, however, very toxic, and in every instance caused nausea, dizziness, &c.

It appears, therefore, that ethyl-cupreine might with advantage be employed where the quinine fails; whilst propyl-cupreine might find application as a potent antithermal remedy in continuous fevers.—H. T. P.

*The Technical Production of Bodies rich in Nicotine.*  
Th. Schloesing, jr. Comptes rend. **118**, 1053—1055.

THE process hitherto employed for preparing these extracts has consisted in evaporating an aqueous extract as far as possible, but due regard has not been paid to the amount of nicotine contained, which is the essential principle. Extracts of tobacco are largely used as a preservative against the ravages of certain plant insects, but by far the largest use is as a sheep-wash in cases of scab. The Argentine Republic imported in one year more than 3,000,000 kilos, for this purpose. With a view of obtaining nicotine extracts of known strength, the aqueous tobacco extracts are distilled with steam in a column apparatus. The resulting solution has approximately the same nicotine strength as the original extract, but is to be preferred to it as it is nearly colourless. Moreover, by passing the steam charged with nicotine from the exit of the column through a tower down which a slow stream of sulphuric acid is allowed to fall, the nicotine is absorbed and passes on to the tower in solution as nicotine sulphate. It is not advisable to work to a higher strength than to 200 grms. of nicotine per litre on account of the poisonous nature of the alkaloid. The liquor thus obtained contains a small quantity of ammonium sulphate, and the solution coming from the tower ought to be neutral or slightly alkaline. If acid it must be neutralised with sodium carbonate and is then coloured with tobacco extract and diluted with water until it contains about 100 grms. of nicotine per litre. This solution diluted with 80 times its volume of water kills the scab mite, or diluted with 50 times its volume of water it kills the eggs of this insect, whilst solutions containing 0.01 per cent. of nicotine are of a convenient strength for horticultural purposes. The method proposed by the author renders it possible to prepare, on a manufacturing scale, colourless nicotine solutions of known strength, which may be used for medicinal purposes. —T. A. L.

*The Qualitative Composition of Official Beech and Oak-wood Creosotes.* A. Richal and E. Choay. Comptes rend. **118**, 1894, 1332—1342.

"OFFICIAL creosote" is designated as that fraction of wood-tar which distils over between 200° and 220° C., this range being adopted because it comprises the extreme limits laid down in the pharmacopœias of various countries. Specimens of creosote answering to this requirement were prepared by the distillation of beech and oak "heavy oils" and were subsequently exhaustively examined. It was found that qualitatively the two creosotes were identical. The following phenolic bodies were definitely recognised:—Phenol, *o*-, *m*-, and *p*-cresol, *o*-cetylphenol, two *m*-xyleneols (1:3:4 and 1:3:5), guaiacol, rosol, and ethylguaiacol,

Besides these, traces of sulphur derivatives, probably thiophenols, were detected, as well as a substance resembling, but not identical with, Reichenbach's "pittacal."—H. T. P.

*The Stability of Aqueous Solutions of Mercuric Chloride.*  
E. Bureker. Comptes rend. **118**, 1894, 1345—1347.

THE following observations were made:—

1. When mercuric chloride is dissolved in ordinary service water, a portion of the salt is immediately decomposed; but under the combined influence of air, light, and the mineral and organic substances present in the water, or derived from the atmosphere, decomposition goes on indefinitely, resulting in the formation of a brownish, crystalline precipitate which contains mercury, chlorine, ammonia, and organic matter.

2. Further decomposition is, however, almost entirely arrested when the solution is completely protected from contact with air and light.

3. Solutions of mercuric chloride in distilled water suffer only an insignificant change, even when freely exposed to the air and light.—H. T. P.

*Stability of Dilute Solutions of Corrosive Sublimate.*  
L. Vignon. Comptes rend. **118**, 1099—1101.

THE alterations which dilute solutions of corrosive sublimate undergo on keeping (see this Journal, 1894, 171) are due principally to the presence of alkaline substances, which may either be derived from the water with which the solutions have been prepared, from the air, or from the glass vessels containing the solutions. It is also to be remembered that dust or organic substances with which the solutions may come into contact bring about a certain amount of reduction.—A. R. L.

*Physical Properties of Pure Nitrous Oxide.* P. Villard. Comptes rend. **118**, 1096—1099.

NITROUS oxide after treatment with appropriate absorbents still contains air and nitrogen. It may be freed from these impurities by the preparation, from the impure gas, of the hydrate of nitrous oxide (Comptes rend. **118**, 646), which, although scarcely decomposed below 0° C. under the ordinary pressure, furnishes about 200 times its volume of gas when warmed above this temperature. A more rapid process of purification consists in rectifying the nitrous oxide contained in a gasometer, or, better still, the liquefied gas in an iron cylinder. To this end the gas is passed through appropriate reagents contained in a long tube of resistance glass or of ordinary glass incased with copper, whence it issues deprived of those impurities which are capable of being absorbed. It is then led into a glass tube, where it is liquefied by cooling. The pressure rises progressively, showing that the superincumbent atmosphere is rich in nitrogen; this is allowed to escape from time to time, and the release of pressure causes the liquid to boil, thereby removing from it the major portion of dissolved gas. After this the tube is reversed, and the liquid is passed into a recipient tube; the first portions, which serve to wash out this tube, are rejected. A prolonged ebullition effects the purification, and the tube is closed. The whole operation is carried out in a gas-tight apparatus without joints; the cocks used were of metal. About 20 grms. of pure nitrous oxide may thus be prepared in one operation.

From experiments described in the paper, the author deduces the critical temperature of nitrous oxide as 38°·8 C., a value notably higher than any hitherto recorded (35°·4 Dewar, 36°·4 Jansen). The volume and density are then 0·00436 and 0·454, and the critical pressure 77·5 atmospheres.—A. R. L.

## XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

*The Photographic Properties of Vanadium Salts.* A. and L. Lumière. Monit. Scient. 42, June 1894, 427.

From the position of vanadium in the series of metals, and its general properties, the authors concluded that its salts should be acted on by light. This they have verified as a fact, and give the results they have obtained, though both the cost of vanadium compounds and the feebleness of their photographic properties are likely to prevent their practical employment.

On reducing a solution of vanadic acid in sulphuric acid by zinc, the red colour first formed becomes blue, green, and lastly violet. This violet hypovanadious sulphate is an energetic developer, working even in a strongly acid solution.

Vanadic salts, obtained usually in unstable solution, by acting on vanadic anhydride with acids, are sensitive to light. The chloride, phosphate, and potassium vanadic tartrate have given the best results. The chloride is obtained by acting in the cold on vanadic anhydride with strong hydrochloric acid, and the tendency to dissociation is lessened by adding alcohol. With this a sensitive film can be prepared, giving after short exposure a faint picture which can be fixed and intensified by aromatic amines, as the authors have shown in the case of manganic salts. The phosphate, made by the action of phosphoric acid on vanadic anhydride at 150° C., is more stable than the chloride, but less sensitive to light. The potassium tartrate, easily made by shaking vanadic anhydride in solution of cream of tartar, gives films which are very sensitive and yet can be kept some weeks without change. The authors have tried to increase the differences between the vanadic salts and their reduction products, and thus add to the intensity of the pictures, but hitherto without success.—J. T. D.

### PATENTS.

*A New or Improved Process for Separating Photographic Gelatine Films from Celluloid Supports or Bases.* A. A. Barratt, Esher, and A. J. E. Hill, Surbiton. Eng. Pat. 19,810, October 20, 1893.

This process consists in soaking the celluloid negative in a solution of one part of amyl acetate or acetone in six parts of water, which penetrates the gelatin film and attacks the celluloid support, thereby loosening the film, which may then be stripped or floated off on to a glass plate and dried. If "enlargement" of the film be desired, an acid, preferably citric, tartaric, or acetic, may be mixed with the above solution, or, the stripped film may be treated with the acid in a second operation, suitable chemicals being employed to preserve the density of the image.—J. C. C.

*Improvements in or relating to Photography in Colours.* J. Joly, Dublin. Eng. Pat. 14,161, July 23, 1894.

The object of this invention is to obtain, by means of a single exposure, a representation of an object in its natural colours, or in colours appearing to be so to the eye.

A film sensitized for the red rays is exposed beneath a parti-coloured screen bearing lines ruled in transparent pigments: these lines are of three tints: Chrysoidine orange for the red-selecting line, Ethyl green and Chrysoidine orange for the green-selecting line, and Soluble blue for the blue-violet selecting line, being mentioned as suitable colours. The lines are about 200 or more to the inch, and the tints are in regular order. From this negative after development a positive transparency is printed by contact, and on this, if viewed through a screen bearing lines ruled of the same dimensions, but of the three primary colours, red, green, and blue-violet, the image is seen in its natural colours. Many modifications of this process are described, such as the various methods of ruling the lines, or having a pattern in place of lines on the screen, also modifications in the pigments used, the method of ruling, &c.—J. C. C.

## XXII.—EXPLOSIVES, MATCHES, Etc.

*Smokeless Powder.* Annual Report of the Chief of Ordnance for 1893. Washington, U.S.A. 24—23; 245—265; 276—278; 303—306; 395—405.

During the year ending June 30, 1893, the following smokeless powders for small arms have been experimented with:—Peyton, Leonard, Du Pont, Axtell, Alters (all of American manufacture), Wetteren (Belgian, made in 1891), Troisdorf (German), B. N. F. (French), and Rifleite, S. R. and S. V. (English).

The best results were obtained with the Peyton and Leonard powders, but the number of experiments has not, so far, been sufficiently great to decide which of the two is the better one. It would appear, however, that the Peyton powder gives somewhat lower pressures for the same velocities, and is less affected by heat and moisture, whilst the Leonard powder with very reasonable pressures gives much greater uniformity of velocity.

The following tables give the results obtained in a 0.30-cal. rifle under ordinary conditions, and after the powders had been exposed to heat and moisture. The exposure to moisture was effected on a screen over water, in a closed receptacle, for 24 hours. The exposure to heat was for 24 hours at a temperature of 120° F.

The S.R. powder was tested in a 0.45-cal. rifle and in a 0.45-cal. carbine: in the latter it gave satisfactory results, but in the former it was inferior to ordinary black powder. S.V., a revolver powder, gave good results. The results from the Axtell and the Alters powders were quite unsatisfactory.

The recoil when using smokeless powders was found to be less, as was anticipated, than with black powder. This must not be attributed to the more progressive action of the former, but to the lighter charge required to give the same velocity.

The smokeless cannon powders tested were the French B.N. powder, the German smokeless, U.S. Navy smokeless, Cordite, Troisdorf, and Leonard. Details of the tests are given, but as they were not all conducted in the same size and type of gun, a direct comparison is not possible.

The Leonard powder is stated to have given remarkably good results. In a 5" gun in which the length of travel of the shot was 34.3 calibres and its weight 63 lb., a 21-lb. charge of Leonard powders gave a muzzle velocity of 2,874 ft.-sec., with a chamber pressure of 46,000 lb. per sq. in., which is claimed to be the best result yet obtained. An account of the general principles on which smokeless powders are manufactured is given. The measurements of velocity were made with a Boullengé chronograph, and of pressures with Rodman cutter gauges in large guns, and by crusher gauges in a special "pressure-rifle," which is illustrated, for small arm powders. The laboratory for the chemical examination of powders is described and illustrated.

—R. B. P.

The Agglomeration of Explosive Substances. P. Vieille.  
Comptes rend. 118, 1894, 912–915.

THE dry agglomeration of black powders in a state of fine sub-division under increasing pressures in steel moulds, shows that there are four periods corresponding to different degrees of compression. *First*, under feeble pressure, the various grains still remain practically surrounded with interstitial spaces, which ensure the rapid ignition of the component particles; so that the rapidity of combustion is independent of the thickness of the mass. *Secondly*, the individual grains are partly united into groups, under higher pressures, but these groups, instead of the grains themselves, are separated by minute spaces, and a species of large grain cellular structure is obtained; and although the rapidity of combustion decreases with increasing density, it is still independent of the thickness of the agglomerate. *Thirdly*, under still higher pressures, the cavities are more nearly obliterated, and the groups of granules more nearly approximate to the size of the moulded grain; the rapidity of combustion still varies with density, but the influence of thickness is more and more clearly seen. *Fourthly*, under the highest compression, the time of combustion of the compact material is practically proportionate to thickness, and almost independent of density. The rapidity of combustion was found by firing the powders in closed vessels, in such a manner that the gas pressure finally increased to an extent equal to that obtaining in a gun at the time of discharge (see this Journal, 1894, 659).

In the following table are given the mean rapidities of combustion of different powders fired under pressures increasing from 100 to 2,500 kilos. per sq. cm. All samples, excepting the colloidal powders, were primarily powdered, sifted through silk gauze, and then agglomerated undre

pressure sufficient to insure combustion by parallel surfaces (fourth period of compression). The charges were made up

of plates geometrically similar, but of different thicknesses:—

#### AGGLOMERATION OF EXPLOSIVES.

Type.	Explosive. Class.				Density of Compressed Substance.	Rapidity of Combustion in C.m. per Second.
		KNO <sub>3</sub>	S.	C.		
Black or brown powders.	Mining powder .....	62	20	18	> 1.900	5.09
	French brown powder .....	78	3	19	"	1.45
	German brown powder (R.W.P.) .....	78	3	19	"	5.70
	French black powder ( <sup>26</sup> / <sub>31</sub> ) .....	75	10	15	"	8.50

	English ecobite (nitro-glycerin base) .....				" "	20.40
	French B.N., commercial, with nitrates .....				" "	7.58
	Nobel's ballistites .....				" "	20-40*
Various .....	Nitro-mannite .....				1.765	23.3
	Hexanitratèd diphenylamine .....				1.620	6.19
	Pieric acid .....				1.708	5.32

\* Varying with the sample employed.

Hence it is seen that in regard to rapidity of combustion, black or brown powders are similar to the colloidal cotton powders, whether pure or nitrated, but are greatly inferior to the nitro-glycerin colloids. The fact that to obtain equal ballistic results colloidal powders are substituted for service black powders of much larger grain, shows that these latter do not behave like the compact bodies of the fourth class above alluded to, but is another evidence of the disaggregation described in the previous paper (*loc. cit.*). It is also clear that among black powders of the same type the rapidity of combustion varies with the degree of trituration of the ingredients, and with the nature of the charcoal. The latter circumstance agrees with the slower action of the service powder containing lightly carbonised wood instead of charcoal.—W. G. M.

#### PATENTS.

*Improvements in Explosives.* K. C. Edmunds, Calcutta, India. Eng. Pat. 23,416, December 5, 1893.

THE inventor claims the use of mixtures of potassium nitrate, pieric acid, sulphur, Prussian blue, sawdust, or nitrated wood pulp, potassium chlorate and chloride, and silica in various proportions.—W. M.

*Improvements in Matches and Striking Surfaces for Use in connection therewith.* W. Herz, Vienna, Austria. Eng. Pat. 14,979, July 21, 1894.

THIS is an invention for "matches free from poison, and without heads, manufactured by treating splints of wood having rounded ends with a solution of phosphate of ammonia and alum, subsequently drying them, and then dipping their two ends in an ignition mass, of a gelatinous consistency, composed of a solution of chlorate of sodium, sulphate of alumina, sulphate of potassium, hyposulphite of soda, and saltpetre, to which is added tragacanth, gum arabic, and dextrin, again drying them, and then coating them with a solution of india-rubber, benzine, camphor, and

paraffin, and once more drying them," and "a friction surface for igniting matches forming the subject of the first claim, such friction surface consisting of a mixture of amorphous phosphorus with water, fish glue (syndeticon), sulphide of antimony, chalk, and manganese, which are well triturated together, and then painted upon the box, substantially as described."—W. M.

*Explosive Compounds.* G. J. Buechert, San Francisco, U.S.A. Eng. Pat. 15,887, August 21, 1894.

THIS invention relates to a compound consisting of ammonium chloride or sulphate, sodium nitrate, wood pulp, and nitro-glycerin. To prevent the ammonium salt from being in contact with the sodium nitrate and being transformed into ammonium nitrate, its particles are coated with some protective substance, such as aluminium oleate.

—W. M.

### XXIII.—ANALYTICAL CHEMISTRY.

#### APPARATUS, ETC.

*Apparatus for Obtaining a Constant 50-mm. Water Pressure during the Estimation of the Freezing Point of Oils.* F. Ganter. Zeits. anal. Chem. **33**, 1894, 343-344.

THE method of using this apparatus is apparent from the figure: the tube containing the oil is attached to the apparatus by the india-rubber tube *c*. It is advisable to surround the flask with felt to prevent the influence of draughts, &c. By means of this apparatus any required pressure may be readily maintained.

—L. T. T.

## PATENTS.

*An Apparatus for Notifying the presence in the Air, of Gases such as Fire-Damp.* E. Hardy, Dreux, France. Eng. Pat. 15,329, August 11, 1893.

THE principle of this invention is based upon the fact that the musical sound emitted by an organ-pipe, varies as the density of the vibrating air or gas contained therein. Two similar organ-pipes are employed, which are in perfect unison when sounded with the same gas or air, and arranged so that one is always blown with pure air, while the other receives the mixture of air and gases to be tested. According to the extent the air is mixed with other gas, so the density varies, and the sound emitted by the pipe supplied by the mixture differs proportionally from that fed with pure air. When the two pipes are sounded together, one with air and the other with the mixed gases, a greater or less number of musical beats are produced in a given time, which may be graphically indicated by the ordinary acoustical methods. The construction of the apparatus and method of working are such as to adapt themselves to the utilisation of the above principle for the purpose above set forth. The apparatus described may be used for testing the gases of flues, as well as those of mines.—S. P. E.

*Improvements in Apparatus specially suitable for Use in Estimating the Amount of Fat in Milk and other Substances.* R. W. Woosnam and the Dairy Supply Co., Lim., London. Eng. Pat. 23,039, November 30, 1893.

THE apparatus is designed to be used by unskilled persons. It consists of a two-necked bottle, containing sulphuric acid or hydrochloric acid dissolved in amyl alcohol, to which is attached a small burette and an india-rubber ball. By pressing the latter a definite volume of liquid is filled into the burette by an automatic siphon arrangement. This

volume of acid is then added to the milk to be tested, which is contained in a small bottle, into the neck of which a divided glass tube can be fitted by means of a ground joint. In the shoulder of this bottle a small perforation is made. The bottle being charged, is placed in a metal vessel containing hot water and caused to rotate in a centrifugal machine, the hot water enters by the above mentioned small perforation, and the specifically lighter fat collects in the divided tube.—T. E.

## INORGANIC CHEMISTRY.—QUALITATIVE.

*Detection of Hydrochloric Acid.* A. Villiers and M. Fayolle. Comptes rend. 118, 1152—1154.

THE method proposed by the authors is based on the difference of the action of halogens on an acid solution of aniline. Iodine does not produce an apparent reaction, or at all events gives a colourless soluble product; bromine forms white, insoluble substitution derivatives, and chlorine gives coloured oxidation compounds—black and insoluble if the quantity is large; but if it is small, reddish-violet in the hot, and blue, becoming red after some time, in the cold. The solution must be acid, but should not contain a large quantity of mineral acid or the reaction will fail to take place. The following solution is recommended as one which can be kept for an indefinite period in yellow glass vessels without becoming coloured:—Saturated aqueous solution of aniline (100 cc.), glacial acetic acid (100 cc.).

The liquid to be tested is brought to a volume of 10 cc. a mixture (5 cc.) of equal volumes of sulphuric acid and water, together with a saturated solution of permanganate of potassium, added. This mixture is heated, and the evolved gas is led into 3—5 cc. of the above-mentioned reagent contained in a tube kept cool by water. In the absence of bromine and iodine there is obtained with 0.0001 grm. of hydrochloric acid a bluish coloration, which slowly changes at a low temperature, rapidly at a high temperature into a rose coloration. When the amount of hydrochloric acid is augmented, there is obtained a very intense coloration or a black precipitate. When hydrobromic and hydriodic acids are present and the proportions above indicated are used, the iodine is completely oxidised and does not pass over; bromine is retained by the reagent as a precipitate; a certain quantity, however, enters into combination with the chlorine, the brominechloride considerably reducing the delicacy of the reaction. The results are shown in the following table:—

HI only .....	No reaction.
HBr .....	White precipitate colourless liquid.
0.05HI + 0.05HBr + 0.05HCl	{ Very intense blue liquid, the { rich violet; black precipitate.
" " + 0.01HCl	{ Liquid and precipitate blue, { then intense rose.
" " + 0.003HCl	Bluish tint then clear rose.
" " + 0.001HCl	{ Appreciably tint—rose after { some time.

—A. R. L.

*Detection of Hydrochloric Acid.* A. Villiers and M. Fayolle. Comptes rend. 118, 1204—1206.

THIS paper is supplementary to the former (last abstract). To obviate the vitiating effect of bromine when this halogen is present, the acids are precipitated with silver nitrate, and the washed precipitate is digested for some hours with a solution containing ammonia diluted with 10 parts of water. This dilution of ammonia does not dissolve silver iodide, only dissolves silver bromide sparingly, but dissolves the chloride readily. The ammonia is expelled from the filtrate by boiling and an excess of a solution of hydrogen sulphide added; the filtrate is then boiled and concentrated to 10 cc., the remainder of the operation being conducted as already described.

Simple cyanides when present are decomposed by dilute sulphuric acid, the hydrogen cyanide being expelled by evaporation, but ferrocyanides and the like are distilled with

dilute sulphuric acid until fumes of sulphuric anhydride appear. Water is then added to the residue and the distillation repeated; the distillates are then united and the hydrogen cyanide expelled from them by evaporation.

When the haloid acids are not precipitated with silver nitrate as in the method described in the former paper (last abstract), ammonium salts, when present, should be eliminated, because of their action on chlorine.—A. R. L.

*Testing for Hydrobromic Acid.* A. Villiers and M. Fayelle. *Comptes rend.* 1894, **118**, 1265—1268.

The authors describe the uncertainty attending the method of testing for small quantities of bromine in the presence of much iodine, which depends upon the successive absorption by, and coloration of, carbon bisulphide in contact with the halogen compounds, when they are attacked slowly by dilute chlorine water. They then give details of a process which is applicable to the indication either of large volumes or mere traces of bromine mixed with any proportion of iodine. A solution of the haloid salts, free from nitric acid, is mixed with a sufficient excess of ferric chloride free from chlorine (it should not impart colour to carbon bisulphide in presence of alkaline bromides), the proportion being about 5 cc. of semi-normal ferric solution to 0.1 grm. of iodine. The mixture is then evaporated to dryness on a water-bath. Thus the iodine is completely liberated and sublimed; the bromides on the other hand are absolutely unattacked. A few drops of water are added to the dry residue, iron is precipitated by an alkali and filtered off, an excess of hydrochloric acid is added to the filtrate, with some carbon bisulphide, and chlorine water is slowly introduced. The coloration or non-coloration of the bisulphide is a certain indication as to the presence of bromine. For general analysis, the haloids are precipitated as silver compounds; hydrocyanic acid is separated, as described in a previous paper, dealing with chlorine determination (see previous abstract); the precipitate is treated with hydrogen sulphide; excess of the gas is boiled off; and the liquid is ready for treatment as above described. The process may be used for the detection of free bromine in presence of iodine, by previously converting the halogens into hydrogen acids by means of aqueous hydrogen sulphide.—W. G. M.

*The Detection of Traces of Chlorine.* A. Villiers and M. Fayelle. *Comptes rend.* **118**, 1894, 1413—1414.

In a previous communication (see p. 1091, "Detection of Hydrochloric Acid") the authors have described a method for the detection of chlorine in presence of bromine and iodine, based on the fact that chlorine (liberated by means of potassium permanganate and sulphuric acid) when passed into an acid solution of aniline, converts the latter into coloured oxidation products. It appears, however, that the sensitiveness of the reaction varies greatly with different samples of aniline. Pure aniline yields with traces of chlorine only a comparatively slight brownish tint; whilst with certain commercial anilines a fine blue coloration changing gradually to reddish-violet is obtained; and so intense in character that less than 0.1 mgrm. of chlorine produces a distinct effect. This high sensitiveness has been traced to the presence in commercial aniline of certain impurities, especially *o*-toluidine. It is, therefore, recommended to make up the test solution as follows:—

	Cc.
Saturated aqueous solution of aniline (colourless) . . . .	100
Saturated aqueous solution of <i>o</i> -toluidine . . . . .	20
Glacial acetic acid . . . . .	30

—H. T. P.

*A Delicate Reaction for Copper Compounds.* P. Sabatier. *Bull. Soc. Chim.* 1894, **11**—12, 683—685.

The author has shown that cupric bromide, according to conditions of hydration, or of combination with hydrobromic acid, may give a blue, green, brown, or purple colour in solutions. The present paper deals with the formation of the purple salt, the hydrobromide, in its applications as a

sensitive means of detecting the presence of copper. A drop of the solution to be tested for copper is added to about a cubic centimetre of colourless concentrated hydrobromic acid; if the solution contains 1 atom of copper in 4 litres of fluid, a brilliant purple colour develops; a drop of a solution 100 times more dilute gives a lilac colour, and the reaction is still appreciable with 1 atom of copper in 2,000 litres solution, equivalent to 1 part copper in 30,000 of water. The amount of copper thus revealed in the drop of liquid tested, did not exceed 0.015 mgrm. If free bromine be present in the test solution it must be expelled by boiling.

Concentrated hydrobromic acid may be replaced by a saturated solution of orthophosphoric acid containing crystals of potassium bromide. A drop of the cupric solution is added, and on cooling, after heating to near 100° C., the coloration appears. This process answers with insoluble copper salts, as the sulphide, phosphate, and silicate. If the quantity of copper be very small, a little bromine is added, and the excess expelled by ebullition. The author states that the reaction is more delicate than with other quick methods, citing especially the reactions with potassium ferrocyanide and hydrogen sulphide as inferior in delicacy. Small proportions of gold, nickel, or cobalt in the solution to be tested for copper do not interfere. The reverse is the case if much iron be present, in which case the solution is electrolysed, so that any copper may be deposited on a piece of platinum foil, which is then moistened with a drop of nitric acid, then with sulphuric acid, and, after drying, is treated with hydrobromic acid. The author discusses the bibliography of the subject, and points out that, although previous observers had noticed the same or a similar reaction, they had failed to interpret it correctly, or to indicate the requisite conditions for its success.—E. S.

## INORGANIC CHEMISTRY.— QUANTITATIVE.

*Reliability of Magnesium Pyrophosphate for Estimating Phosphoric Acid.* H. Neubauer. *Zeits. anal. Chem.* **33**, 1894, 362, 370—from *Inaug. Dissert.* Rostock, 1893.

Phosphoric acid determinations made according to the usual methods of Abesser, Jani, and Marcker, or of Peitsch, Rohn, and Wagner, almost invariably give too low results. The author has made a long and careful investigation of the whole subject, and finds that the low result is caused by the volatilisation of phosphoric acid during ignition of the magnesium phosphate. His investigations have led to the following conclusions:—

1. If the ammonium magnesium phosphate is formed in a neutral or ammoniacal solution containing no excess of magnesium salt, the precipitate contains less than its normal amount of magnesium. On ignition some metaphosphate is formed, which, on continued heating in the blowpipe flame, is converted into pyrophosphate with volatilisation and loss of some phosphoric anhydride.

2. If the precipitate is formed in the presence of an excess of magnesium salt, and during its formation an excess of ammonia is never present, the normal precipitate  $MgNH_4PO_4$  is alone formed. This on ignition yields pure magnesium pyrophosphate, and no loss of phosphoric acid occurs.

3. If the precipitate is formed in presence of an excess of magnesium, and an excess of ammonia is also present, the precipitate always contains some trimagnesium phosphate.

In the case of 1, the analytical result would be too low; of 2, correct; and of 3, too high. It is, however, impossible in practice to maintain the conditions of 2. The best results are obtained by a slight modification of the Wagner method and the use of corrections which have been carefully determined by the author.

The precipitation with molybdate and washing of the yellow precipitate is carried out as usual, but care must be taken to prevent the precipitation (by heating or too long standing) of free molybdic acid. The washed precipitate is dissolved in 100 cc. of cold 2½ per cent. ammonia and

magnesia mixture added drop by drop with stirring until about as many cc. of the mixture have been added as there are centigrams. of  $P_2O_5$  present. The addition of 10 cc. of the magnesia mixture should take not less than a minute. The precipitate is once well stirred up and then allowed to stand for three hours. In igniting the precipitate, the heat must be increased slowly, and not allowed to exceed a dull red till the last trace of carbon of the filter paper has

disappeared. The precipitate is then heated in the blow pipe till half an hour's heating causes no further loss of weight.

The corrections are given in the accompanying table, in which the abscissæ represent the weight, in grms., of pyrophosphate found, the ordinates the weight, in mgrms., of pyrophosphate (equivalent to the loss of phosphoric anhydride) to be added.

TABLE OF CORRECTIONS FOR PHOSPHORIC ACID DETERMINATIONS.

It is never advisable to attempt to estimate phosphoric acid by direct precipitation by magnesia, as the intervention of the molybdenum precipitate allows the proper conditions to be more certainly maintained.—L. T. T.

**Standard Solutions.** J. L. Buchanan. Communicated to the Glasgow City Analysts' Society. Abstracts. No. 4, 1893-4, 14.

As, generally, the whole series of normal solutions used in acidimetry and alkalimetry depends upon tests made against pure sodium carbonate, the author endeavoured to prepare a normal acid solution directly, which would not require standardising, by using potassium tetroxalate which has been recommended for the purpose. The salt is very readily prepared in a pure state, and does not lose its water of crystallisation in the desiccator; but owing to its limited solubility, a stronger solution than N/5 cannot be prepared. Phenolphthalein is the only indicator available for use with it, so that altogether its usefulness is very circumscribed. Potassium bitartrate, recommended by Borotraeger, has all the disadvantages of the tetroxalate and is still less soluble. Therefore the author concludes that no substance yet proposed is a satisfactory substitute for sulphuric acid.

Sodium carbonate, purchased as pure, cannot be relied upon, and is troublesome to purify. The author recommends the use of borax instead. Pure borax is easily prepared by recrystallising the commercial salt and drying the crystals in the air until constant in weight. It is quite stable in the air, but loses water in the desiccator. The air-dried salt contains 47.12 per cent. of water (10 mols.). Simple ignition over the Bunsen flame, which expels all this water, serves to determine whether the salt is of normal composition. In standardising an acid, a suitable quantity of the salt should be weighed out, dissolved in water, tinted with methyl orange, and the standard acid added until the first tinge of red appears. Owing to the high molecular weight of the salt, it is obvious that an error in weighing the borax affects the result far less than the same error in weighing sodium carbonate.—L. A.

**The Estimation of Iodine.** A. Villiers and M. Fayolle. Comptes rend. 118, 1894, 1332-1335.

THE estimation of iodine in presence of chlorine and bromine is a somewhat difficult operation, and the various methods adopted for the purpose are all more or less faulty. The author has devised a volumetric process, which he claims to be very accurate and of which the following are

the details:—The solution to be examined, which must be free from nitric acid, is placed in a stoppered separator, carbon bisulphide added, and then 5 cc. of a N 10 solution of ferric chloride for every decigram of iodine supposed

to be present. The mixture is then gently warmed (the heat of the hand is sufficient), thoroughly shaken, and the carbon bisulphide drawn off and replaced by a fresh portion, the extraction process being repeated four times in all. The united carbon bisulphide extract is subsequently shaken in another separator with water to remove traces of ferric chloride, finally transferred to a stoppered bottle, and the dissolved iodine titrated in the usual way with a standard solution of sodium thiosulphate. A double bulbed separator, as shown in the accompanying drawing, may conveniently be employed. The extraction with carbon bisulphide is effected in the upper bulb, and the subsequent washing in the lower one. In analysis, where the three halogens are precipitated in combination with silver, the hydroacids are best regenerated by means of sulphuretted hydrogen, the excess of the latter being expelled by boiling the (dilute) solution.—H. T. P.

*The Analytical Separation of Chlorine and Bromine.*  
M. R. Engel. Comptes rend. 1894. 118, 1263—1265.

Ammonium persulphate may be made to separate the whole of the bromine from sufficiently dilute solutions of mixed bromides and chlorides without influencing the chlorine. From 1 to 2 grms. of the mixture of the alkaline haloid salts are dissolved in 150 to 200 cc. of water; from 3 to 5 grms. of the ammonium persulphate are then added, the liquid is heated to 70—80° C., and the liberated bromine is driven over by a current of air into a solution of sulphurous acid, the bromine being afterwards determined gravimetrically as silver bromide or volumetrically by titration with silver nitrate, with a potassium chromate indicator. The operation is complete in an hour, and the separation is theoretically perfect. The sulphurous acid is to be preferred to potassium iodide for the reception of the bromine, as the gases are apt to contain traces of ozone or of persulphuric acid sufficient to liberate 0.006 to 0.007 grms. of iodine in the hour. In a blank experiment with commercial sodium chloride, using silver nitrate instead of sulphurous acid, a just perceptible cloudiness of the nitrate is observed after a quarter of an hour, which may be due to hydrochloric acid or to a trace of bromine, or to a mixture of the two (not yet ascertained), but the error thus introduced cannot exceed one-tenth of a milligramme of salt in any experiment. Ammonium persulphate may be used to separate iodine from iodides in presence of chlorides and bromides, by operating in the cold with the addition of sodium acetate; the iodine is then separated by carbon bisulphide and titrated with sodium thiosulphate. At higher temperatures, some iodic acid is formed which invalidates the result.—W. G. M.

*The Estimation of Silica.* A. Cameron. Communicated to the Glasgow City Analysts' Society. Abstracts, No. 4, 1893-94, 22.

THE author, by experiments made with silica purchased as pure, but found to contain 98.5 per cent. of  $\text{SiO}_2$ , has confirmed the conclusions of previous investigators that repeated evaporations to dryness with hydrochloric acid are necessary in order to render the whole of the silica insoluble after fusion with alkaline carbonates. His experiments showed that these repeated evaporations lead to no useful result unless the silica rendered insoluble by the first evaporation be first removed by filtration; on evaporation of the filtrate more silica will be obtained, and for accurate work it is necessary to continue evaporating the successive filtrates until no appreciable quantity of insoluble matter is left on dissolving. The author found it preferable to evaporate the filtrate from the main silica with hydrochloric acid, rather than use sulphuric acid, as the results were quite as accurate, and, when iron and aluminium are present, sulphuric acid is apt to cause the formation of difficultly soluble salts. Fusion with potassium bisulphate gives too low results. (See also this Journal, 1892, 215—217.)—L. A.

*The Estimation for Industrial Purposes of Boric Acid in Boronatrocalcites.* G. A. Le Roy. Monit. Scient. 42, July 1894, 520—522.

THE author avails himself of the difference between Poirrier's Orange 3 (ammonium dimethylamidoazobenzene-sulphonate) and Poirrier's Orange 2 (sodium  $\beta$ -naphthol-azobenzene-sulphonate) as indicators; the latter is affected by boric acid, the former not. The method of procedure is as follows:—From 2.5 to 5 grms. of the powdered sample is treated, in a flask furnished with a reflux condenser, with a few cc. of sulphuric acid diluted with an equal volume of water, and a little hydrochloric acid. On cooling, the whole is thrown on a filter, the residue (silica and calcium sulphate) washed with acidulated water, the filtrate and washings neutralised with soda and boiled, to precipitate ferric oxide, alumina, &c., the filtrate and washings from this precipitate acidified with hydrochloric acid, boiled to expel carbon dioxide, and made up to a known volume. 20 cc. are placed in a beaker on white paper, beside 20 cc.

of water in a similar beaker. A 10 per cent. solution of Orange 3 is added in equal quantities to both, till the water is tinted orange-yellow. Normal soda solution is added to the acid liquor, till the cherry-red tint changes to that of the water. This gives the amount of hydrochloric acid. A second 20 cc. treated similarly, but using Orange 2, gives the total hydrochloric and boric acids, the boric acid being of course obtained by difference. The change of tint in the second case is not so sharp as in the first, but can be observed well enough when working in a good light and with the water-comparison vessel. The soda solution must be quite free from carbonate, silicate, or aluminate, and cannot be substituted by potash or ammonia.—J. T. D.

*The Volatility of Alkaline Salts in Connection with the Determination of Alkalis in Fire-clays, Manures, &c., &c.* A. Cameron. A paper read before the Glasgow City Analysts' Society. Abstracts, No. 4, 1893-94, 7.

0.5 GRM. of pure sodium sulphate heated in a platinum capsule lost nothing at the highest temperature attainable with the Bunsen flame, nothing in the muffle, but 0.4 per cent. every 10 minutes in the blow-pipe flame. The same weight of pure potassium sulphate lost nothing at a dull red heat, 0.4 per cent. in one hour at the highest Bunsen flame temperature, nothing during 10 minutes in the muffle, but 1.4 per cent. every 10 minutes over the blow pipe. A mixture of 0.2 grm. of each of the pure salts lost 0.25 per cent. in one hour at a bright Bunsen flame temperature, and 1.25 per cent. every 10 minutes in the blow-pipe flame, but after 40 minutes the loss ceased. This result was confirmed by a fresh experiment.

These results, obtained with the pure salts, led the author to experiment further with mixtures, such as are obtained in the estimation of alkaline salts in manures, &c. The influence of ammonium sulphate was determined by heating a mixture of 0.2 grm. each of pure sodium and potassium sulphates and 1 grm. of ammonium sulphate at a dull red heat till the weight was constant, which took one hour. The loss of alkaline sulphates amounted to 2.2 per cent. Considering the prolonged heating here employed, and the small amounts of alkaline salts usually found, this result is regarded as showing that ammonium sulphate does not injuriously affect the accuracy of the results. The influence of organic matter was ascertained by further experiments in which the ammonium sulphate was replaced by 1 grm. of gelatin, when the loss observed was 0.75 per cent., and by 1 grm. of sugar, when the losses in two experiments were 1.5 and 1.75 per cent. respectively.

The process in which the alkaline chlorides are evaporated with oxalic acid, ignited, and weighed as carbonates, is almost as accurate as the sulphating method. 0.2 grm. of each of the pure chlorides, evaporated and ignited with 1 to 2 grms. of oxalic acid, showed a loss, in three experiments, of 0.5, 1.25, and 1.75 per cent. during 10 minutes' ignition.

The method of estimating alkalis in fireclays by evaporating the solution of the chlorides and igniting without sulphating, as recommended in Thorpe's Dictionary, is said to be quite unreliable. 0.2 grm. each of pure sodium and potassium chlorides heated to dull redness lost 6.37 per cent. every 10 minutes during one hour's heating.

The three methods were tried with a sample of artificial manure, the experiments being made in duplicate. There were obtained—

	Na <sub>2</sub> O per Cent.	
	A.	B.
By the sulphating method .....	3.86	3.86
By the carbonating method .....	3.31	3.31
By the chloride method .....	3.16	3.18

Continued heating caused a steady loss in the chloride method. The author does not account for the discrepancy

between the other two methods, but recommends the first, since with it, precautions as to heating need not be taken, and none of the usually occurring substances affect the accuracy of the results.—L. A.

*The Influence of Various Substances on the Estimation of Potash by Tatlock's Process.* H. Dods. A Paper read before the Glasgow City Analysts' Society. Abstracts, No. 4, 1893-94, 12.

SOME years ago (1877) a committee appointed by the British Association recommended Tatlock's process as the best all-round method for estimating potash. (See Chem. News, 1877, 36.) Its characteristic feature consists in washing the chloroplatinate precipitate first with platinic chloride solution (containing 7 grms. Pt per 100 cc.), then with alcohol of about 85 per cent. strength, drying at 100° C. and weighing. For the following experiments pure salts were prepared, except in the case of calcium sulphate, the commercial quality of which was used.

**Potassium Chloride.**—A standard solution of the pure salt was made, which, by the process, gave a yield equal to 100.5 per cent. of KCl, a result which was repeatedly confirmed.

**Potassium and Sodium Chlorides.**—In presence of 5 per cent. of NaCl the result was 99.85 per cent. of the KCl taken, while with 50 per cent. of NaCl the result was only 99.40 per cent. These results confirm those of the B. A. Committee, who suggested that the  $K_2PtCl_6$  precipitate is soluble in a solution of sodium chloroplatinate.

**Potassium Sulphate.**—The results obtained were very low, an average of only 99.13 per cent. being obtained. The author doubts the purity of the salt used.

**Potassium Bichromate.**—The results of two experiments were 99.16 per cent., which the author regards as satisfactory for this class of salt.

**Potash Alum.**—A mixture of 0.183 grm.  $K_2SO_4$  and 0.73 grm.  $Al_2(SO_4)_3$  gave 99.81 per cent. of the "calculated percentage of potash," but great care is necessary to wash out all the aluminium sulphate with the platinic chloride solution, before washing with alcohol. (See Chem. News, 1877, 36, 47—48; also see whole Report.)

**Calcium Phosphate.**—It is frequently requisite to estimate potash in presence of calcium phosphate; as, for instance, in the analysis of vinegar. A mixture of 50 per cent. of pure precipitated and ignited  $Ca_3P_2O_8$  and 50 per cent. of KCl, was dissolved in excess of hydrochloric acid and evaporated with platinic chloride. The results of two experiments were exactly 99.98 per cent. of the KCl taken.

**Calcium Sulphate.**—The author's experiments gave 121.8 and 130.5 per cent. of the  $K_2SO_4$  taken, showing that the  $CaSO_4$  had not been washed out, although in one experiment, additional hydrochloric acid was used for the purpose. The author is making further experiments.—L. A.

*Estimation of Nitrates and Nitrites in Waters.* J. Fraser. Communicated to the Glasgow City Analysts' Society. Abstracts, No. 4, 1893-94, 17.

In searching for a rapid and accurate method, the author tried Harrow's process (this Journal, 1891, 727), but in numerous experiments such results were obtained as finding nitrates and nitrites when none were present, besides variations in duplicate tests, showing the process to be unreliable. Horsley's process, in which pyrogallol, sulphuric acid, and common salt are used, which has been recommended as extremely delicate, was also found to indicate nitrates and nitrites strongly when none were present. In using the nitrometer, it has been suspected that oxides of nitrogen may be lost during evaporation of the water owing to the reduction of nitrates by organic matter. The author has proved that this does occur, by evaporating a solution of potassium nitrate, yielding 5.5 cc. of NO when treated directly in the nitrometer, with 500 cc. of a water containing 3 grains per gallon of oxidisable organic matter, and on treating the concentrated solution in the nitrometer only 3.1 cc. of gas were obtained. When 1 cc. of normal caustic

soda was first added to the water before evaporation, 4.2 cc. of gas were obtained. An attempt to oxidise the organic matter before evaporation with neutral potassium permanganate was not entirely successful, but acid permanganate completely solved the difficulty. The author recommends the following procedure:—To 250 cc. or 500 cc. of the water add 10 cc. of normal sulphuric acid, and then enough permanganate to render the liquid pink. Heat for about 1 hour, adding more permanganate if required. Now add rather more than 10 cc. of normal caustic soda, and evaporate to a small volume. Filter off the precipitated manganese oxide and transfer the concentrated filtrate to the nitrometer. Three tests by this method with known quantities of potassium nitrate gave exactly correct results in each case.—L. A.

*Analysis of Pyrites with Sodium Peroxide as Oxidising Agent.* C. Glaser. Chem. Zeit. 18, 1894, 1448.

THE author does not find it so easy as Hoeftel anticipated it would be, to substitute with success the sodium peroxide process proposed by Hoeftel, for the older fusion method with carbonate and nitrate, and so to avoid the repeated evaporations with hydrochloric acid necessary for the expulsion of nitric acid.

A pyrites containing 41.12 per cent. of sulphur, by Hoeftel's method only indicated 38.37 per cent. On acidifying the filtrate from the lixiviated fused mass, it was found that some sulphur had separated, and an odour was developed which indicated the presence of decomposition products of hyposulphurous acid.

In subsequent experiments more peroxide was consequently taken, and at last the proportion was adopted of 5 grms. of  $Na_2O_2$  with 4 grms. of  $Na_2CO_3$  to each amount of 0.5 grm. of pyrites weighed out. In order to anticipate any danger of subsequent losses, a few cc. of brominated hydrochloric acid were added, before the more complete acidification with hydrochloric acid. The mixture was then boiled until nearly all the bromine was expelled. Precipitation with barium chloride followed. The result indicated 41.13 per cent. To avoid the destruction of the nickel crucible it is recommended that a flame as small as possible be employed, so that the mixture in the crucible merely softens and cakes together. The heat is then raised for from 15 to 20 minutes, by the use of a strong flame. Towards the close of the process complete liquid fusion must be brought about, by which an oscillatory motion of the liquid contents of the crucible is induced. If this climax be not attained, it will be subsequently found that the brown metallic oxides become black on lixiviation through re-formation of more or less iron sulphide, and on testing the residue on the filter after a separate treatment with brominated hydrochloric acid, it is found that a considerable quantity of barium sulphate is formed. When the thorough liquid fusion indicated, has been brought about however, the filtrate will be found colourless, and without the addition of brominated hydrochloric acid, there appeared merely a slight separation of sulphur, the insoluble residue proving to be quite free therefrom. The following directions must therefore be kept well in mind:—1. Gentle heating at the beginning of the fusion. 2. Towards the conclusion, heating strongly till complete liquid fusion with swinging motion is attained. 3. Oxidation by means of brominated hydrochloric acid. By observing these precautions a determination may be made in from 2 to 2½ hours.

Sodium peroxide is conveniently employed for determining the sulphur in burnt ores. One gramme of the ore is taken, 0.5 grm.  $Na_2O_2$  and 2 grms. of  $Na_2CO_3$ , and the mixture is heated in a nickel crucible for 15 minutes over a moderate flame.

The melt is easily lixiviated. Nevertheless, it is advisable before acidifying with hydrochloric acid, to add a few drops of brominated hydrochloric acid. This is followed by precipitation with barium chloride. Watson's method, strongly recommended by Lunge, is stated not to be applicable for American burnt pyrites, though yielding good results with burnt Spanish ores. This apparent enigma is probably solved in the fact of the strongly siliceous character of American pyrites.—W. S.

*Quantitative Estimation of the Impurities most commonly found in Commercially Pure or Rolled Nickel.* T. Fleitmann. *Zeits. anal. Chem.* **33**, 1894, 335—338.

THE most commonly occurring impurities are iron, copper, cobalt, zinc, and manganese. These may be easily and quickly estimated as follows:—About 5 grms. of the nickel are dissolved in nitric acid, and the excess of the latter destroyed by repeated evaporation with hydrochloric acid. Any carbon or silica is of course left on solution of the residue in water, and may be estimated if desired. By the slow and careful addition of dilute sodium carbonate and subsequent boiling, the iron (generally not more than 1 per cent.) may be precipitated without the admixture of weighable quantities of copper or nickel. The separation is assisted by the addition of a drop of acetic acid before boiling. The iron precipitate is dissolved in hydrochloric acid, precipitated by ammonia, and weighed as oxide. If any copper has been precipitated with the iron it is left in the ammoniacal filtrate, and may be precipitated in the ordinary way and added to the subsequent copper precipitate. To the filtrate from the iron a drop of hydrochloric acid is added and then a solution of sulphuretted hydrogen drop by drop as long as copper sulphide is precipitated. Care must be taken to avoid any excess of sulphuretted hydrogen, or some of the zinc or nickel may be precipitated. After filtering off the copper sulphide, sulphuretted hydrogen is passed into the cold filtrate to precipitate the zinc. The zinc precipitate is dissolved in hydrochloric acid, precipitated as carbonate, and weighed as oxide. The filtrate from the zinc is boiled to expel the sulphuretted hydrogen, neutralised, heated to 60–80° C., and a slightly alkaline solution of sodium hypochlorite slowly added. The manganese is first precipitated as brown oxide, the cobalt next as brownish-black peroxide, and the nickel last as deep black peroxide. As soon as the precipitation of nickel begins—which is also noticeable by a marked evolution of oxygen—no more hypochlorite is added, and the mixture is boiled and filtered. In this way the quantity of nickel precipitated can easily be restricted to about that of the cobalt present, and the further separation of the manganese, cobalt, and nickel may readily be effected in the usual way.

Any traces of arsenic, antimony, and tin are precipitated with the iron, traces of lead with the copper.—L. T. T.

*Note on the Estimation of Iron.* C. R. Mitchell. Communicated to the Glasgow City Analysts' Society. Abstracts, No. 4, 1893–94, 11.

THE author has examined the modification of the bichromate process, in which the ferric chloride solution is

reduced by the addition of stannous chloride in slight excess, the overplus of stannous salt being destroyed by adding excess of mercuric chloride, and the liquid then titrated as usual. He finds that the mercurous and stannic chlorides formed by the action of the mercuric chloride on the excess of stannous salt do not affect the bichromate at all, and that the results are equally correct, no matter what excess of mercuric chloride is used or at what temperature—cold, warm, or hot—the titration is performed.

—L. A.

*The Various Methods of Estimating Carbon in Iron.* Göttig. *Verhandl. Ver. zur Beförd. des Gewerbel.* October 1893.

THE author has investigated, from the technical point of view, the various methods used, proposing especially the inquiries, whether oxidation in the dry way without previous separation of the carbon gives the whole of the carbon, whether wet methods in which the carbon is not first separated are exact, and whether, when the iron has been treated with a copper salt, the metallic copper must be removed before oxidising the carbon. He gives a résumé of usual methods, grouping them into those where the carbon is not separated from the iron before oxidation, and those in which it is: each group being sub-divided into dry and wet methods. The dry methods of the first group are all combustions of the finely-divided metal with copper oxide, lead chromate, potassium chromate, potassium chlorate, or varying mixtures of these, with or without a current of oxygen; the wet methods consist in oxidation with chromic acid and sulphuric acid of various strengths (sometimes with a preliminary treatment by a copper salt in the same vessel), the carbon dioxide evolved being either weighed in potash bulbs or measured over water. The dry methods of the second group agree in converting the iron into volatile chloride by chlorine, hydrochloric acid gas, or mercuric chloride, the carbon remaining being then burnt as in the first group; in the wet methods the iron is dissolved by the action of a copper salt, iodine or bromine, moist silver chloride, or hydrochloric acid aided by a voltaic current, and the carbonaceous residue oxidised by wet or dry methods, with or without previous removal of the copper or silver. The author has tested these methods on graphitic and non-graphitic irons and steels, containing varying amounts of carbon, manganese, and silicon. His results, for graphitic irons, are given in three tables, which are again summarised in a condensed table given below:—

TABLE I.

Method.	Nature of Metal.	Total Carbon found.	Total Carbon, Actual.
Direct combustion in the dry way (ultimate analysis) .....	Grey pig. ....	2·946	3·395
Direct oxidation in wet way (Gmelin, Jüptner, Rürup, Wiborgh).....	" .....	3·326	3·395
	" .....	4·069	4·0735
Combustion in oxygen of the carbonaceous residue separated in dry way (Wöhler, Deville) .....	" .....	3·153	3·395
	" .....	3·464	4·0735
Oxidation in wet way of residue separated by copper salt, without previous separation of copper (Ulrichsen, Clausen),	" .....	3·361	3·395
As above, but copper salt previously removed (Elliot).....	" .....	3·333	3·395
Oxidation of residue got by dissolving metal in HCl with a voltaic current passing (Weyl, Binks).	" .....	3·36	3·395

The author's conclusions are:—The combustion methods give discordant results; the end of the operation is difficult to recognise, and the grains of metal are apt to become coated with oxide, which protects them from further action: this is avoidable only if extreme care be taken to regulate the heat and prevent the fusion of the oxide; the operation,

too, takes a long time. As to the wet methods of group I., those of Gmelin and Jüptner (oxidation by chromic and sulphuric acids) give low figures, unless the sulphuric acid be strong, the amount of acids plentiful, and the attack continued for a sufficient time; Rürup's method (the same oxidiser, with previous separation of carbon by a copper

salt, in the vessel) gives good results, and there is no danger of production of sulphur dioxide if the sulphuric acid be of density not higher than 1.1; Wiborgh's method (similar to Rurup's, but the carbon dioxide is measured over water instead of being weighed) does not give regular results, no doubt owing to the absorption of carbon dioxide by the water. The dry methods of group II. are inexact. Of the wet methods, that of Ullgren, modified by Claassen

(separation by copper sulphate, and oxidation of washed residue by chromic and sulphuric acids) gives good results; most of the others can be made to furnish accurate results, but demand in that case extreme care, a long time, or both.

For non-graphitic irons, the author gives four tables of results, which are again summarised in the following table:—

TABLE II.

Method.	Nature of Metal.	Carbon Found.	Carbon, Actual.
Ultimate elementary analysis .....	White pig .....	3.324	4.301
	Cast steel .....	0.988	1.075
Direct oxidation in the wet way (Gmelin, Japtner, Rurup, Wiborgh) .....	White pig .....	4.342	4.301
	" .....	4.296	..
Combustion in oxygen of the residue separated in the dry way (Wobler) ...	Bessemer steel ..	0.4715	0.474
Ultimate analysis of residue got by a copper salt, without previous separation of the copper (Langley, Parry) ..	White pig .....	4.249	4.301
As above, with previous removal of the copper (Berzelius, Sprenger, Pearse and Creath) ..	" .....	4.279	..
Oxidation in the wet way of residue got by copper salt, without previous separation of copper (Ullgren, Claassen) ..	" .....	4.308	..
As above, but with previous removal of copper (Elliot) ..	" .....	4.268	..
Solution in iodine or brominated hydrochloric acid, and combustion of carbonaceous residue (Ergert, Brandt) ..	" .....	4.304	..
	Bessemer steel ..	0.478	0.474
Solution with mercuric chloride: residue weighed before and after combustion (Boussingault) ..	White pig .....	4.355	4.301
	Thomas steel ..	3.980	4.105
	Forged iron .....	0.284	0.290
	Bessemer steel ..	0.1465	0.174
Oxidation of residue got by electrolytic decomposition (Weyl) ..	Fine steel .....	1.0865	1.098
	Cast steel .....	1.059	1.075
	White pig .....	1.275	4.301

TABLE III.

Method.	Nature of Metal.	Graphite found.	Graphite, Actual.	Remarks.
Dissolved in HCl at a gentle heat; residue washed with water, potash, alcohol, and ether; oxidised by $\text{CrO}_3$ and $\text{H}_2\text{SO}_4$ ..	Grey pig ....	3.224	3.104	Attacked for six hours.
	" .....	3.193	3.104	" " five "
	" .....	2.890	2.855	" " three "
Dissolved in boiling HCl; residue washed with warm water; oxidised by $\text{CrO}_3$ and $\text{H}_2\text{SO}_4$ ..	Grey pig ....	3.306	3.104	Attacked for one hour.
	" .....	3.030	3.104	" " two hours.
	" .....	3.135	3.104	" " three "
Dissolved in $\text{HNO}_3$ ; residue washed with potash (no alcohol or ether); oxidised by $\text{CrO}_3$ and $\text{H}_2\text{SO}_4$ ....	Grey pig ....	3.140	3.104	Attacked for five hours.
	" .....	2.944	3.104	" " one hour.
Dissolved by prolonged boiling in $\text{HNO}_3$ ; residue washed with warm water; oxidised by $\text{CrO}_3$ and $\text{H}_2\text{SO}_4$ ..	Grey pig ....	3.169	3.104	Attacked for one hour.
	" .....	3.080	3.104	" " two hours.
	" .....	2.821	2.855	" " one hour.
Dissolved in boiling dilute $\text{H}_2\text{SO}_4$ ; residue washed with boiling water; oxidised by $\text{CrO}_3$ and $\text{H}_2\text{SO}_4$ ..	Grey pig ....	3.558	3.104	Attacked for two hours.

In the case of non-graphitic irons, the author's chief conclusions are:—The combustion methods give results too low; but when the oxidising material is infusible and porous, higher figures are got than when it is a fusible body. The same remarks as made above in the case of graphitic irons apply here, too, to the wet methods of the first group, though they are here more easily carried out, and need less time; the author recommends Wiborgh's method where approximate results are sufficient, on the

ground of its ease and rapidity. The dry methods of group II. are not recommended, save for rough work; and where many samples have to be treated by them successively, large tubes must be employed to avoid choking by condensed chlorides. As to the wet methods, that of Ullgren-Claassen gives good results, though an almost imperceptible quantity of hydrocarbon gas nearly always comes away during the solution of the iron; no evolution of sulphur dioxide takes place if there is enough chromic acid present;

the absorption of carbon dioxide by sulphuric acid is quite negligible. Eggertz' iodine method gives good results in all cases; 24 hours should be given for the solution of the iodine. Weyl's electrolytic method also gives good results, provided the current is not too strong, and provided the metal is homogeneous, so that any fragment can be used as a fair sample for analysis.

In an appendix to the paper, the author deals with the determination of the graphite. His work is summarised in Table I. I. :—

He concludes that: the washing with water, potash, alcohol, and ether is shortened if the boiling with acid is sufficiently prolonged; nitric acid gives slightly lower results than hydrochloric, no doubt because it oxidises a small portion of the graphite; yet nitric acid is preferable, because, in a much shorter time than hydrochloric acid, it yields a residue free from non-graphitic carbon.—J. T. D.

*The Determination of Lead in Small Quantities.* J. A. Williamson. A paper read before the Glasgow City Analysts' Society, Abstracts, No. 4, 1893-94, 16.

As phosphoric acid is largely used instead of tartaric and citric acids in manufacturing mineral waters, it is of importance to note that in the ordinary colorimetric test free phosphoric acid seriously prevents the formation of lead sulphide, but if the free acid be neutralised by ammonia the results are accurate. The neutralisation is best effected by adding to a measured volume of the liquid some methyl orange and a dilute solution of ammonia to neutrality. The same volume of the ammonia solution is then added to another equal volume of the liquid without methyl orange, and the quantity thus neutralised is used for the test. Excess of ammonia does not interfere with the lead reaction, but if lime be present in the liquid it causes a cloudiness.

Iron has no effect on the modified test. Copper must be estimated separately and allowed for, unless excess of ammonia can be used, when the interference of copper can be prevented by adding a little potassium cyanide and tartaric acid. Hydrochloric and nitric acids injuriously affect the estimation unless previously neutralised. Free acetic acid does not affect the result.—L. A.

## ORGANIC CHEMISTRY.—QUALITATIVE.

*The Distinction between Coal Tar and Blast-Furnace Pitches.* D. G. Buchanan. A paper read before the Glasgow City Analysts' Society, Abstracts, No. 4, 1893-94, 21.

Pitch is graded commercially as "hard," "medium soft," and "soft." A common test is to place a small piece in the mouth, and after a minute or so to try to force the teeth into it; if it breaks and crumbles it is considered to be hard; if the teeth mark it with difficulty it is medium soft; if one can chew it, it is soft. The author has examined all these varieties.

The chief difference between the coal-tar and blast-furnace pitches lay in the amount of ash, which in the coal-tar pitches never reached 0.1 per cent., whilst in the blast-furnace pitches it varied from 6.8 to 11.1 per cent. As it does not seem practicable to remove the dust before collecting the tar from the blast-furnace gases, a sample containing less than 1 per cent. of ash may at once be put down as a coal-tar pitch. In cases where the amount of ash renders the denomination of a sample doubtful, an analysis of the ash should be made to see if it corresponds with that from blast-furnace pitch. Coke was estimated in the different kinds of pitch. Hard pitch yielded about 38 per cent.; medium soft, 30 per cent.; soft, 26 per cent. The yields from some samples of coal-tar and blast-furnace pitches were almost identical. The melting point or softening point was determined by warming a piece of the sample and placing it on the end of a thermometer, the latter being then fixed in a test-tube and the tube heated in a beaker of water. The pitch glazes when it begins to soften, and shortly after begins to fall—this is taken as the melting point. Hard pitch melted at about 80° C., medium soft at

about 55° C., and soft at about 50° C. Blast-furnace pitch has a somewhat higher melting point than coal pitch. The solubility in ether and gasoline (petroleum spirit) gave no means of distinction. Ether dissolved about 77 per cent., and gasoline about 44 per cent. of soft pitch from both sources. The colour of the ether solution is rather darker in the case of the blast-furnace pitches, and this is suggested as the basis of a confirmatory test.—L. A.

*Some Blue Lakes derived from Dibromogallanilide and some Blue Reactions of the Polyphenols.* P. Cazeneuve. Comptes rend., 118, 1046—1048.

On carefully adding ammonia, potash, or soda to a solution of dibromogallanilide an unstable blue precipitate is obtained, easily changed by excess of air or of the base, becoming green and then yellow. Lime or baryta water give a white precipitate, which rapidly changes on shaking with air to a beautiful blue, which is stable below the surface of the water. The addition of a weak acid, even a current of CO<sub>2</sub>, is sufficient to decompose the lake and liberate the free acid which is of a reddish colour, and thus in its turn is destroyed by an excess of an organic acid. These calcium and barium lakes are so unstable in air that they cannot be filtered off, but it has been possible to prepare and analyse the corresponding zinc lake, the constitution of which has an important bearing on the blue products derived from gallic acid, dibromogallie acid, methyl dibromogallate, gallanilide, pyrogallol, purpurogallin, and pyrogallolquinone. The zinc lake is prepared by adding an excess of an aqueous solution of zinc acetate to a dilute aqueous alcoholic solution of dibromogallanilide in the proportion of about 2 molecules of the former to one of the latter. The precipitate, at first white, rapidly turns blue in the air, and can be filtered off and dried in a vacuum over sulphuric acid. It has the formula—

or else that of a compound containing the two groupings—

connecting two molecules by oxygen as in the case of purpurogallin and pyrogallolquinone. The spontaneous decomposition of these lakes by oxygen, which no doubt removes the hydrogen of the phenolic group and causes further condensation, is always accompanied by the production of a bromide. In this case zinc bromide is formed. The final yellow product is in all probability a quinone or polyquinone. It is noteworthy that all the polyphenols derived from pyrogallol give blue coloured bodies. Gallic acid, dibromogallie acid and its ethers, and gallanilide give blue colouring matters with baryta or lime water, which are stable under water, that from dibromogallie acid being the least stable. Purpurogallin and pyrogallolquinone give unstable blue products with ammonia.—T. A. L.

*A Reaction of the Aldehydes. Differentiation of Aldoses and Cetroses.* A. Villiers and M. Fayolle. Bull. Soc. Chim. 1894, 11—12, 691—693.

The authors show that the recoloration of a solution of magenta decolorised by sulphurous acid is not affected by both aldehydes and acetones, but by aldehydes only. Ordinary specimens of acetones produce the coloration owing only to the presence of impurities. Urine containing acetone gives the reaction because aldehydes are almost always formed simultaneously with acetone. The authors obtain the reagent in a highly sensitive state by avoiding

the use of excess of sulphurous acid, a day being then needed to complete the gradual and exact decoloration of the magenta solution, which must be preserved in closed tubes, as a red colour appears on prolonged exposure to air.

Ordinary sugar, maltose and lactose, gives no coloration with the reagent, until after several days, when the colour develops, as under the influence of water, aldehyde-glucoses are formed, such glucoses having the property, like aldehydes, of producing an intense coloration. Glucose, invert sugar, galactose, and reduced dextrins colour the reagent, whereas pure levulose and sorbine are without action. The presence of acids, interferes with the reaction of aldehyde-sugars, so that neutral solutions must be used, and the reagent should be prepared in the manner described above.—E. S.

*Examination of Chloroform for Phosgene.* Zeits. anal. Chem. 1894, **33**, 488.

THE pharmacopœias direct for this purpose that the sample shall be shaken with water and the aqueous liquid tested for hydrochloric acid, which is one of the decomposition products of phosgene with water.

According to Scholvién (Ber. pharm. Ges., **3** 213) this method does not always yield trustworthy results. He adopts a direct test for the detection of phosgene. To carry this out a drop of amidophenetol is dissolved in benzene (the benzene must be quite dry and free from carbon bisulphide) and the suspected chloroform added to this solution. If phosgene is present, there is produced an immediate turbidity, and later crystals of diparaphenetol carbamide separate out; these are insoluble in chloroform. Instead of amidophenetol, aniline may be used; in that case diphenylcarbamide being formed.

—A. R. L.

*A New Reaction of Colchicine.* E. Barillot. Bull. Soc. Chim. **11**—**12**, 1894, 514—516.

THIS reaction, which affords a very reliable test for the detection of colchicine, morphine, and codeine, is obtained by mixing the alkaloid in the state of free base very intimately with 0.25 gm. of oxalic acid and 1 cc. of sulphuric monohydrate. This mixture is sealed up in a small glass tube, which is kept at 120° C. for one hour. Subsequently the tube is opened, the colour of the mixture observed, and excess of alcoholic soda added. By operating in this way the following results are obtained with the above-named alkaloids:—

Alkaloids.	Coloration in the Cold.	Coloration after Heating.	Observations.
Colchicine.	Golden yellow.	Dark red-dish-brown, not modified by addition of water.	On treating the aqueous solution with an alkali and reacidifying a yellow precipitate is obtained, which is soluble in chloroform, and, on addition of nitric acid of sp. gr. 1.4, is precipitated from this solution in the form of a powder at first yellow and then peach-coloured.
Morphine.	Light blue	Reddish-brown.	On addition of a large volume of water the colour sometimes changes into blue. Treating this solution with caustic potash and alcohol, then acidifying it, and shaking it with chloroform, the latter assumes a blue colour. Ether takes a purplish-red colour. On evaporating these two solvents morphine-blue remains behind.
Codeine...	Bright blue.	Greenish-blue.	Like morphine.

None of the ptomaines shows any similar reactions. With 1 mgrm. of colchicine the above reaction can be repeated ten times.—C. O. W.

*The Detection of Abrastol in Wines.* L. Briand. Comptes rend. 1894, **118**, 925—926.

TO 50 cc. of the wine add 1 cc. of pure sulphuric acid, shake well, introduce 25 grms. of lead peroxide, agitate for five minutes and filter. Shake 40 cc. of the filtrate with 1 cc. of chloroform for the space of 1 minute. In the presence of abrastol the chloroform becomes yellow in colour (sensitive to 0.01 gm. per litre), whilst with natural wines it remains colourless. On evaporating the yellow chloroform solution, a yellow crystalline residue is left, which gives a fine green colour when treated with a few drops of sulphuric acid, the latter reaction being obtainable from wines containing 0.02 gm. of abrastol per litre. (This Journal, 1894, 548.)—W. G. M.

*Testing Milks with Rennet.* R. Lozé and E. Hil-sont. Comptes rend. **118**, 1069—1071.

THE authors in their investigations on the coagulation of milk by rennet have observed that the operation takes more or less time according as circumstances, and the properties of the curd chance to vary. They have devised a practical method for analysing milk based on their results. This consists in adding a certain quantity of rennet to 100 cc. of milk at a temperature of 35° C. and noting the time required to coagulate it. Commercial rennet is usually employed of such a strength that 1 litre would coagulate 10,000 litres of pure fresh milk at 35° C. in 10 minutes. The rennet solution employed by the authors is ten times this strength, so that the addition of 1 cc. of their rennet solution to 100 cc. of normal milk causes coagulation in four minutes. The time is taken by a seconds counter and the authors have investigated the effect of various influences, such as temperature, or the presence of carbonic acid, fatty matters, solid bodies (sawdust, starch) and water, which accelerate or retard the coagulation and as a result of their experiments they arrive at the following conclusions. A good milk is coagulated by the rennet solution referred to in 3½ to 4 minutes and the curd is clear, white and homogeneous. If, however, it does not possess these properties but is cloudy and separates in clots and requires a much longer or shorter time than 4 minutes, the milk is doubtful and ought to be further examined. The addition of water or of an alkaline salt considerably retards curdling, but it must be remembered that boiling produces the same effect. Milks which rapidly coagulate either contain foreign substances or have begun to decompose and a milk which coagulates in less than two minutes should be unhesitatingly rejected either as a fool, or for technical purposes.—T. A. L.

*A Natural Unsaturated Ketone in Lemon-Grass Oil.* P. Barbier and L. Bouveault. Comptes rend. **118**, 1893.

See under XX., page 1086.

ORGANIC CHEMISTRY.—QUANTITATIVE.

*Volumetric Estimation of the Three Isomeric Cresols and also of Xylenol.* F. Keppler. Archiv. f. Hygiene. Zeits. anal. Chem. **33**, 473.

THE method employed by the author is a modification of Koppeschaar's method of estimating phenol.

Into a flask, furnished with a well-fitting stopper and of such a capacity that the volume of liquid to be mentioned fills it to about two-thirds, is introduced a mixture of 50 cc. of potassium bromide solution (5.94 grms. per litre) and 50 cc. of potassium bromate solution (1.667 grms. per litre); to this mixture 5 cc. of concentrated sulphuric acid are added. A measured volume of a solution of cresol in caustic soda lye is then added, the quantity of the latter being so adjusted that a small amount of bromine remains in the free state. The mixture is now well shaken for about 10—15 minutes, when the precipitate subsides. The liquid is then filtered through glass wool, and an

aliquot portion of the filtrate treated with potassium iodide, the free iodine being titrated with  $\frac{N}{10}$  or  $\frac{N}{100}$  thio-sulphate solution and starch in the well-known way. A calculation then gives the excess of bromine; this is deducted from the amount of bromine set free from the potassium bromide and potassium bichromate (0.24 gram. Br.), and the difference gives the amount of bromine which has entered into reaction with the cresol; the percentage of the latter may then be arrived at by the equation:— $C_6H_3(CH_3)OH + 6Br \rightarrow C_6HBr_5(CH_3)OH + 3HBr$  from which it is found that 1 gram. of bromine corresponds to 0.225 gram. cresol. These directions must be obeyed in order to obtain good results; if the liquid containing the bromo-cresol be treated with potassium iodide direct without filtering, inaccurate values are obtained on titrating the free iodine.

The estimation of xylenol is carried out in the same manner, 1 gram. of bromine corresponds with 0.2542 gram. of xylenol.—A. R. L.

#### *Analysis of Sealing Wax.* C. Mangold. Zeits. anal. Chem. 1894, 33, 477–478.

The substance (5 grms.) is boiled with alcohol (150 cc.) and the solution, after cooling, diluted with alcohol to 250 cc. After settling, 50 cc. of the clear liquid are withdrawn and the iodine number of the resinous constituents contained therein determined by Hübl's method. The portion insoluble in alcohol is filtered off, washed, dried at 110 C., and weighed. It consists of inorganic matter and resin, the latter being mostly a mixture of shellac and colophony (rosin). The iodine number may be used to calculate the relative amounts of these two constituents. The percentage of the constituents is calculated from these data by the formula—

$$i = \frac{k \cdot i_1}{100} + \frac{S \cdot i_2}{100} \text{ and } S = 100 - k,$$

whence—

$$k = 100 \cdot \frac{i - i_2}{i_1 - i_2},$$

in which  $i$  is the found iodine value,  $i_1$  the iodine number of the colophony, and  $i_2$  that of the shellac;  $k$  is the percentage of colophony and  $S$  that of the shellac.

It may be remarked that a difficulty arises when the shellac has become, as it sometimes does, partially or wholly insoluble in alcohol.—A. R. L.

#### *Studies in Oil Analysis.* H. Ballantyne. A Paper read before the Glasgow City Analysts' Society. Abstracts. No. 4, 1893–94, 6.

SIMULTANEOUS exposure to sunlight and air lowers the iodine absorption of vegetable oils, and increases the temperature reaction and specific gravity (this Journal, 1891, 32). Determination of the specific temperature reaction is preferable to the simple Mauméné test (this Journal, 1891, 233). The author finds that the Hübl reagent loses iodine far less rapidly than has been stated by Fabron: thus Fabron observed a loss of 17 to 23 per cent. of active iodine in 8 days, whereas the author observed a loss of only 5 to 8 per cent. in 38 days. Raising the temperature to 25 C. made no appreciable difference. Contrary to statements made by some, the use of starch solution in determining the end reaction was found to have no influence upon the results, whether the solution used were unfiltered or filtered, the quantity large or small, or the solution added at the beginning or near the end of the titration. Experiments also showed that the age of the iodine solution has no effect upon the results provided sufficient excess of iodine be used. The titration of a blank quantity, containing the same volume of Hübl reagent as that added to the oil, does not obviate all error due to the loss of active iodine on standing, because the blank quantity contains more free iodine, and consequently loses more on standing, than the test-quantity; hence the results are too low, the error increasing with the time of

standing. Dieterich (this Journal, 1893, 381) has shown how to partly compensate for this, but the author is endeavouring to find a more satisfactory method.—L. A.

#### *Valuation of Wool-fat.* E. v. Cochenhausen. Dingl. Polyt. Jour. 292, 1891, 51–96; 112–116.

On the basis of the well-known quantitative methods practised in fat analysis, and further with due regard to the peculiar properties of wool fat and its fatty acids, already demonstrated by Lewkowitsh (this Journal, 1892, 135), the author gives the following outline of the operations adopted by him in the valuation of wool fats:—

*Foreign substances*, insoluble in ether, are determined in the usual way.

*Water* is best found by difference, since dehydration of the free fatty acids partially takes place on drying.

*The acid value*, i.e., the number of mgrms. of KOH required to saturate the free fatty acids of 1 gram. of wool fat, is determined in the usual manner.

*The free fatty acids* are separated as described (this Journal, 1892, 136), with the modification that the neutralised wool fat is shaken with 30 per cent. alcohol, and the soap solution boiled down to dryness, dissolved in 50 per cent. alcohol (Spitz and Hönig, this Journal, 1891, 1039), and exhausted with petroleum ether. But also in this process insoluble soaps of higher fatty acids separate between the two layers as flocculent matter and must be filtered off (this Journal, 1892, 136). The molecular weight of the free fatty acids is then ascertained in the usual manner.

*Saponification Value of Wool Fat.*—From experiments published by Herbig (see page 1068), the conclusion is drawn that wool fat contains certain ethers that are easily saponified by alcoholic potash (see also Eng. Pat. 14,114, this Journal, 1892, 928), and that working under certain conditions constant numbers for these easily saponifiable ethers are obtained. The remainder of the ethers can, as is well known, only be saponified by alcoholic potash under pressure (this Journal, 1892, 137). The author, neglecting the proportion of the latter compounds, adopts as saponification value the number obtained by boiling the wool fat with half-normal alcoholic potash for one hour in a flask connected with an inverted condenser.

*The volatile fatty acids* are determined by saponifying the wool fat with half-normal alcoholic potash under the conditions just stated, and subjecting the mass, termed “decomposed wool fat”—(analogous to the term “decomposed wax” in the Hübl-Benedikt-Mangold process for the analysis of bees' wax, although the “decomposed wool fat” still contains unsaponified ethers)—to Reichert's distillation process. There is, however, this modification introduced, that the “decomposed wool fat” is distilled until 1,000 cc. have passed over. The values thus obtained are still considered too low, and a correction is made subsequently by the author.

The residue left in the distilling flask is weighed and returned as the sum of the *total non-volatile fatty acids*, of the *alcohols*, and of the *unsaponified ethers*.

Next the acid value of the “decomposed wool fat” is determined, and now the total non-volatile fatty acids may be isolated as described above for the free fatty acids. Finally the molecular weight of the total non-volatile fatty acids is determined.

From the data thus obtained the composition of the sample may be calculated. The wool fat examined by the author yielded the following results:—

	Per Cent.
Free fatty acids (hydrated) molec. weight, 292 .....	25.77
Combined fatty volatile .....	2.20
acids..... non-volatile molec. weight, 348 ...	39.74
Free and combined alcohols, plus unsaponified substance .....	33.486
Water and foreign substances .....	1.20
	102.396

The author acknowledges himself that this process is too tedious for commercial analysis; it is, however, recommended in case of dispute, or for arbitration purposes.—J. L.

*Estimation of Saccharose.* Zeits. anal. Chem. 1894, 33, 474—475.

A. BORNTRAGER (Zeits. angew. Chem. 1893, 600) has given instructions for the preparation of a solution of invert sugar for the control of Fehling's solution (see this Journal, 1893, 1063). To standardise Fehling's solution 10 cc. of the latter are diluted with 40 cc. of water, boiled, and the invert-sugar solution run in. If the liquid be boiled for two minutes, 10 cc. of Fehling's solution require exactly 10.3 cc. of 0.5 per cent. invert sugar solution.

Samelson (Zeits. angew. Chem. 1891, 267) recommends estimating the exact titre in copper of Fehling's solution, as 50 cc. of this solution will only correspond with 0.2375 gm. of sugar when it contains 0.4420 gm. of copper. Employing Fehling's solution standardised in this way, the author contends that volumetric determinations of cupric-reducing power are as accurate as gravimetric determinations.

J. Jais (Zeits. gesamt. Brauw. 1893, 349) has carried out experiments on the estimation of saccharose in mixtures of maltose, isomaltose, and dextrin, using a method similar to that of Meissl. Meissl dissolves a quantity of sugar corresponding to 10 grams. of invert sugar in 700 cc. of water, inverts with 100 cc. of  $\frac{N}{5}$  HCl for half an hour on the water-bath, and, after neutralising, makes up to 1,000 cc. He thus employs for the inversion 1.4 per cent. solutions and for the reduction 1 per cent. solutions of invert sugar. The author worked with solutions of at most 1 per cent. concentration. The duration of boiling before inversion was 4 minutes, and after inversion 2 minutes; 50 cc. of Fehling's solution diluted with 25 cc. of water were employed for every 25 cc. of invert-sugar solution. The author's results may be summarised as follows:—

1. The reducing power of mixtures of maltose, isomaltose, dextrin, and saccharose is equal to the sum of the reducing powers of the single constituents.

2. Solutions of maltose, isomaltose, and dextrin, separately or in mixtures, give no increase in reducing power when inverted by Meissl's method. Hence these sugars are unaltered under the circumstances.

3. When saccharose solution is added to the above solutions and the mixture inverted by Meissl's method, the increase in the cupric-reducing power is in accordance with the saccharose added. From this increase, moreover, the saccharose may be calculated by Wein's table (No. IV.).

4. Added quantities of saccharose may be estimated by Meissl's inversion process in unhopped worts as also in beer worts, together with the quantity of saccharose already present in them.

5. Neutralisation is not necessary for the determination of the reducing power after inversion by Meissl's method.

6. Inversion by Meissl's method in malt extract solutions more concentrated than 1 per cent. (up to 8 and 9 per cent.) with the corresponding quantity of  $\frac{N}{5}$  HCl, gave on 100 cc. of wort the same results as 1 per cent. solutions.—A. R. L.

*The Estimation of Sugar: the Sugar Content of Tanning Materials, Tanning Extracts, Tanning Liquors, and Weighted Leather.* Von Schroeder, A. Bartel, and W. Schmitz-Dumont. Dingl. Polyt. J. 1894, 293, 229—237, 252—260, 281—287, 297—304.

Of late, increased attention has been called to the function of the non-tannins as a source of organic acids in liquors used for tanning (this Journal, 1894, 650 and 964), and it has been shown that it is the sugar, or at all events the compounds capable of reducing Fehling's solution, which, by fermentation, gives rise to these acids. The weighting of heavy leather with sugar is no novelty. The object of the authors of this paper is to ascertain the normal content of Fehling-reducing compounds in leather.

Comparative experiments were made on the use of lead acetate and magnesia as precipitants for non-sugars in extracts of various tanning materials, it having been stated by Kohnstein (Gerber, 1886, 253) that the latter precipitant is the better. In each case the liquor which had been

treated with lead acetate showed a higher sugar-content by the use of Fehling's solution, than that which had been treated with magnesia.

For most technical purposes it is held that the excess of lead present in a solution which has been treated with lead acetate, does not interfere with the subsequent estimation of sugar, unless the excess be large. Experiments made to ascertain whether this is true for tanning extracts gave no very definite conclusion, but it seemed on the whole that the results were better when the excess of lead was precipitated, and the best precipitant for the purpose proved to be sodium or potassium sulphate. It was further proved that the addition of lead acetate and the subsequent removal of the lead as sulphate, either in the presence or absence of tannin, had no appreciable effect upon the percentage of sugar found; thus, when working with a solution of glucose of predetermined sugar-content, there was found as a mean of several experiments 100.5 per cent. of the sugar present.

As a further objection to the magnesia method it is urged that when this precipitant is used the cuprous oxide invariably contains magnesia, a fact which entails the dissolution of the oxide in hydrochloric acid and the precipitation of the copper as sulphide before it can be weighed.

A series of experiments was next undertaken to prove whether the sugar in a sample of leather can be completely extracted from the powdered and fat-exhausted sample by water, and whether hide powder, when employed in analysis to remove tannin, absorbs any sugar from a saccharine solution. The results show that hide fibre is not, in this sense, capable of absorbing sugar.

It is next shown that for the estimation of sugar in tanning materials a longer heating with the Fehling's solution than that recommended by Allihn is necessary, on account of the presence of unknown and slowly reducing sugars, 30 minutes having been found to give the best results. This alteration of method renders Allihn's table useless, so that another has been constructed showing the mgrms. of glucose corresponding with mgrms. of copper weighed, when the Fehling's solution is heated with the sugar solution for 30 minutes. The mean experimental values for the construction of the table are given below; the rest of the table is filled in by interpolation from these values.

		Mgrms.			
Anhydrous glucose,	248.8	223.5	198.3	173.6	148.7
Copper, weighed ...	469.1	431.3	388.5	345.5	299.5
<hr/>					
Anhydrous glucose,	123.9	99.4	57.2	24.5	9.0
Copper, weighed ...	252.4	205.2	120.0	56.2	22.0

The following procedure is adopted when it is desired to determine the sugar in a solid tanning material. The weighed quantity of the ground material (see below) is extracted with 1 litre of water at 100° C. in the apparatus described by Kech (this Journal, 1888, 528), the process occupying two hours. 600 cc. of the filtered extract are concentrated to 200 cc., and the tannins, &c., are precipitated from this solution by the addition of 20 cc. of lead acetate solution (see below); after 15 minutes, during which time the flask has been frequently shaken, the liquid is filtered through a dry filter, and to 100 cc. of the filtrate, 10 cc. of sodium sulphate solution (equivalent to the lead acetate solution) are added; the lead sulphate is removed by filtration through a dried filter and 25 cc. of the filtrate are taken for the estimation of the sugar. There are mixed in a beaker, 30 cc. of copper sulphate solution, 30 cc. of alkaline Rochelle salt solution (both prepared according to Allihn's directions), and 80 cc. of water. The whole is heated to boiling and the 25 cc. of extract are added; the beaker is then placed in a boiling water bath for 30 minutes. The cuprous oxide is filtered, dried, heated, and reduced in the usual manner. Should the tan-stuff be poor in sugar, or, in case the method is applied for the analysis of a leather, this be not weighted with sugar, a larger volume

than 25 cc. may be taken for the estimation, but a correspondingly smaller volume of water must be added to the Fehling's solution, in order that the total volume from which the cuprous oxide is to be precipitated may not exceed 145 cc.

The quantity of material extracted must vary with its nature, as follows:—

	Grms.
Oak-wood, chestnut-wood, and spent bark .....	30
Oak-bark, willow-bark, pine-bark, fir-bark, larch-bark, &c. ....	20
Quebracho-wood, sumach, rove, cayota-bark, garonille, canniers, .....	10
Myrabolans, valonia, knoppern .....	7-10
Mimosa-bark .....	5-10
Divi-divi, algarobilla and trillo .....	5

In the examination of extracts, 8-20 grms. of the sample are dissolved in 250 cc. of water, and 200 cc. of this solution, without filtration, are treated with lead acetate, &c., exactly as described above, the sugar determination being made with 25 cc. or more of the final filtrate under the conditions already given. Tanning liquors must generally be concentrated before the precipitation with lead acetate.

In estimating the sugar in a leather it is usual to use the 20 grms. of the finely-divided sample which have already served for the estimation of moisture, and have been extracted with carbon bisulphide for the estimation of the fat. This portion is extracted in a Koeb's apparatus at the ordinary temperature in the manner described above. The litre of extract is concentrated to 500 cc., and 200 cc. of this solution serve for the precipitation with lead acetate, &c. Some 40 cc. of the final filtrate are used for the sugar determination.

The lead acetate solution for this work is prepared by mixing 300 grms. of lead acetate with 100 grms. of litharge and 50 cc. of water, heating on the water-bath, with replacement of evaporated water, until the mixture is white, digesting with a litre of cold water, and filtering.

A large number of figures showing the percentage of tannin and of substances capable of directly reducing Fehling's solution, summarised under the name sugar, in commercial tanning materials and extracts, is quoted. The values in each case are calculated for the mean water-content of the material (see page 1072). In this place it is only possible to give a tabular summary of these numbers.

	Mean		"Sugar"-Content.			Proportions of Acid-yielding Substances to 100 Tannin.
	Tannin-Content.	Mean.	Minimum.	Maximum.		
	Per Cent.	Per Cent.	Per Cent.	Per Cent.		
Pine-bark extract .....	25.00	7.84	4.58	9.44		31.4
Pine-bark .....	11.63	3.53	2.65	4.47		30.4
Oak-bark (young) .....	10.10	2.65	1.75	3.46		26.2
Divi-divi .....	41.50	8.39	7.98	8.83		20.2
Algarobilla .....	43.00	8.23	6.24	10.49		19.1
Myrabolans .....	30.09	5.35	3.15	7.05		17.8
Sumach (Italian) .....	28.00	4.53	..	..		16.2
Oak-bark extract (Slavonic) .....	28.00	3.07	2.47	3.92		11.0
Chestnut-wood extract (normal liquid) ....	30.00	2.87	2.61	3.53		9.6
Valonia .....	28.80	2.60	1.21	3.57		9.3
Cayota-bark .....	22.00	1.65	..	..		7.5
Trillo from Valonia .....	43.50	2.41	..	..		5.5
Garonille .....	25.00	1.00	0.67	1.51		4.0
Rove .....	29.00	1.13	..	..		3.9
Quebracho extract (solid) .....	70.00	2.41	1.04	3.80		3.4
Mimosa-bark .....	32.00	0.91	0.33	1.57		2.8
Knoppern .....	30.00	0.65	0.54	0.71		2.2
Quebracho-wood .....	22.00	0.25	0.10	0.65		1.1

The materials mentioned in the body of the paper, but not included in the above list, apparently because of their slight importance in the German market, are as follows:—

	Tannin.	"Sugar."	"Sugar": 100 Tannin.
	Per Cent.	Per Cent.	
Willow-bark .....	10.00	2.16	21.60
Hemlock-bark* .....	12.32	6.71	5.76
Canazze .....	30.00	6.24†	20.80
Gambier‡ .....	47.18	1.85	3.92
Catechu§ .....	39.89	0.50	1.25

\* Water, 11.50 per cent.

† Water, 17.19 per cent.

‡ Sugar-content varies greatly.

§ Water, 20.00 per cent.

An inspection of the table will show that those materials which contain a high ratio of sugar to tannin are those which have always been used for the tanning of such leather as requires an acid liquor for the production of full weight. It must not be forgotten, however, that although there is direct evidence that the Fehling-reducing compounds give rise to acid, there is not yet evidence that they are the sole cause of acidity; starch under certain conditions can give rise to acids. Furthermore, the influence of the temperature of extraction and of the presence of the tan-stuff itself in the layers, on the production of acid, and the influence of the nature of the acid in producing the plumping effect, have yet to be elucidated.

Several useful remarks as to the application of extracts in Germany are to be found in the original paper.

A number of figures is quoted to show that in the process of tanning the sugar decreases and the acid increases in the liquors as the hides pass from pit to pit.

The following analyses of extracts are of interest:—

	Water.	Tannin.	Organic Matter, not Tannin.	Extract Ash.	Insoluble Matter.	Sugar.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Chestnut wood extract .....	69.73	26.19	19.13	0.27	2.98	2.61
" " (probably adulterated) .....	49.17	25.64	21.47	0.29	3.43	11.70

\* Contains sugars capable of directly reducing Fehling 1.76 per cent.; sugar capable of inversion, calculated as cane sugar, 13.86 per cent.

To an acid liquor from a tan yard there was added some glucose; the liquor was examined from time to time during 10 days, when it was found that the total acidity (calculated as acetic acid) had decreased from 0.453 grm. to 0.436 grm. per 100 cc., whilst the sugar had decreased from 0.415 to 0.053 grm. per 100 cc.; at the same time the non-tannins in the liquor had decreased from 1.101 to 1.095, the tannins and ash remaining constant. From this it would seem that the sugar in a liquor is capable of direct conversion into gaseous or very volatile products without passing through the stage of an acid. The authors have never found more than 0.5 per cent. of total acid in a tanning liquor.

The authors conclude with a table showing the minimum, maximum, and mean sugar content of 14 different classes of air-dried leather.† The sugar-content in any particular class of leather does not seem to be characteristic; it will suffice, therefore, to say that the mean content as shown by 171 analyses is 0.22 per cent., and that the maximum in any individual is 1.40 per cent., the minimum being a trace. In weighted leather from 1.50 to 16 per cent. of sugar has been found.—A. G. B.

#### *The Quantitative Separation of Amorphous Nitrogenous Organic Compounds contained in Beer Wort. II. Schjerning. Zeits. anal. Chem. 33, 1894, 263—299.*

THOUGH the results of various workers have been somewhat divergent, there is little doubt that beer worts contain true albumens, hemialbuminoses or propetones, and peptones, but no satisfactory method for the separation of these groups has yet been found. In this paper, the author describes a process, which, though not yet fully worked out, seems to him an advance on those yet used. As precipitants he employs caustic soda, barium hydrate, stannous chloride, normal lead acetate, ferric acetate, uranium acetate, and phosphomolybdic acid in the order named. Each precipitant precipitates (with but slight exceptions which are noted) the whole of the nitrogenous compounds of those preceding it, and in addition a special class which the author denominates its own "absolute precipitate." The precipitates are collected on a filter which has been washed with hydrofluoric acid, and the nitrogen estimated by Kjeldahl's method. If Schleicher and Schüll's 11 c.m. hydrofluoric washed filters are used, the correction necessary for the nitrogen contained in the filter is 0.2 cc. of decinormal acid. It is necessary to keep strictly to certain conditions as to quantity of reagent used, temperature of liquid, time allowed for precipitation, and liquid used for washing the precipitate, &c., and these have been ascertained by the author by careful experiments.

**Caustic Soda Precipitation.**—2—4 cc. of a 10 per cent. solution of caustic soda is added to 100 cc. of wort and the

whole allowed to stand for 20—24 hours. The precipitate, which is crystalline, is then collected on a filter, and washed with cold water. The nitrogen in the precipitate is estimated by Kjeldahl's method, and a correction of 0.27 cc. of decinormal acid made for every 100 cc. of liquid + wash-water.

**Barium Hydrate Precipitation.**—25—50 cc. of wort are treated with one-third to one-half that quantity of 5 per cent. solution of barium hydrate and left to stand for 20 hours out of contact with the air. The precipitate is washed with 1.2 per cent. barium hydrate and a correction of 0.05 cc. decinormal acid for every 25 cc. filtrate + washing solution made to the nitrogen determination.

**Stannous Chloride Precipitation.**—50 cc. of the neutral or slightly acid (with HCl) wort are treated with 10 cc. of stannous chloride solution, the mixture allowed to stand for at least 6 hours at the ordinary temperature and the precipitate washed with cold water. No correction is needed. The stannous chloride should be made in the following way:—50 grms. of granulated tin are dissolved in concentrated hydrochloric acid and the excess of acid evaporated till the residue weighs 120—130 grms. This residue is diluted with water to 1 litre and should give a perfectly clear solution, which should be kept over tin.

**Lead Acetate Precipitation.**—25—30 grms. of neutral or very slightly acid wort are mixed with one-fifth to one-third of the bulk of a 10 per cent. normal lead acetate solution, the mixture heated to boiling, allowed to cool again, and filtered. The precipitate is washed with cold water. The correction to be added is 0.15 cc. decinormal acid for each 100 cc. of filtrate and wash water.

**Ferric Acetate Precipitation.**—20—25 cc. of slightly acid (with acetic acid) wort are mixed with one and a half to twice the volume of ferric acetate, and the mixture heated to boiling, and if necessary a drop or two of sodium acetate added. The precipitate is at once collected and washed with cold water. No correction is needed. The ferric acetate solution is prepared by dissolving 25 grms. of pure ferric acetate in 1 litre of water and adding 25 cc. of 45 per cent. acetic acid.

**Uranium Acetate Precipitation.**—25 cc. of neutral or very slightly acid wort are mixed with 20 cc. of a 10 per cent. solution of uranium acetate, the mixture heated to boiling, and then allowed to stand for 20 hours at the ordinary temperature. The precipitate is washed with a 1 to 2 per cent. solution of uranium acetate, and a correction made of 0.1 cc. of decinormal acid for each 100 cc. of filtrate and wash water.

**Phospho-molybdic Acid Precipitation.**—25 cc. of wort are mixed with 5 cc. of 10 per cent. sulphuric acid and 25 cc. of 10 per cent. phospho-molybdic acid. The mixture is left at the ordinary temperature for 20 hours, the precipitate washed with 1 per cent. sulphuric acid, and a correction

† In bark-tanned leather the results are calculated on the basis of 18 per cent. of water in the air-dried leather.

made of 0.5 cc. deci-normal acid for each 100 cc. of filtrate and wash-liquid.

*Character of the Precipitates.*—The caustic soda precipitate consists of a part of the ammonia present in the wort, combined with magnesium, lime, and phosphoric acid also present. It generally also contains some calcium or magnesium saccharate. About one-quarter of the ammonia of the wort is so precipitated. The examination of the other precipitates has not yet been definitely ascertained, but some information thereon has been obtained. The baryta precipitate contains the same ammonia precipitate as the soda, and in addition a precipitate (the absolute baryta precipitate), containing probably the nuclein-like, acid decomposition products (denuclein) from diastase. The tin precipitate does not contain the soda precipitate, and is probably identical with the absolute baryta precipitate. The lead precipitate does not contain the soda precipitate, but consists of the barium precipitate and a precipitate containing probably mucodin or an acid albumin. The ferric acetate precipitate does not contain the soda precipitate, but consists of the lead precipitate plus its own special precipitate containing probably propeptones. The uranium precipitate contains the soda and iron precipitates plus the true peptones and the phospho-molybdic acid precipitate, the whole of the ammonia, the iron precipitate, and the true peptones.—L. T. T.

*Centrifugal Methods of Milk Analysis.* A. Scott. A paper read before the Glasgow City Analysts' Society. Abstracts No. 4, 1893-94, 9.

THE author's experience with the Leffmann-Beam process is very satisfactory; out of 38 tests, the difference between duplicate tests varied from 0.0 to 0.15 per cent. Examples are given to show that the results obtained by this process are the same as by the Adams process.

With the Lister-Babcock process, out of 130 tests, the difference between duplicate tests was never greater than 0.1 per cent., and the deviation from results yielded by the Adams process was never greater than 0.12 per cent. The machine used was of the new low form, and Embrey's directions were followed. The author finds the correction, + 0.3 per cent., a practically constant figure, though, with milks containing only 1 to 2 per cent. of fat, + 0.35 seems in many cases a better correction. The author believes the necessity for the correction is due both to the method of graduating the bottles and to some of the fat remaining in the acid liquid; thus more fat was obtained both by longer and by more rapid whirling. That the graduation has something to do with the necessity for the correction is shown by the fact that a separated milk, which, by the Adams process, gave 0.24 per cent. of fat, gave 0.2 per cent. in six tests by the Lister-Babcock method, no correction being applied. All bottles should therefore be standardized with a sample of milk which has been tested by Adams' process.

The author regards the two centrifugal processes as equally accurate; but he prefers the Lister-Babcock machine because it is the better design, free from danger, cheaper, and does not involve the use of fusel oil.—L. A.

*Soxhlet's Areometric Method of Determining the Fat in Milk.* H. Timpe. Chem. Zeit. 1894, 18, 392-394.

THE author investigates the causes of discrepancy between the results obtained by Soxhlet's areometric method for the determination of the fat in milk, and those given by the Adams' gravimetric process. He points out that the amount of ether forming the upper layer after the usual process of shaking out the fat direct from the milk, depends both on the quantity of ether used and on the quantity of water in the aqueous layer below the ether, the solvent action of the water and the ether being mutual. Thus, adopting the usually accepted figures for the solubility of ether in water and of water in ether, viz., 1 part in 12 and 1 in 35, respectively (at 17.5° C.) the amount of aqueous ether left

as a separate layer and containing the fat of the milk in solution, is expressed by the equation—

$$X = \frac{132W}{419} - 36W \quad \text{I.}$$

where X is the quantity of aqueous ether, A that of dry ether and W that of water free from ether. It is obvious that a variation will be produced when a milk containing more or less water than the average is used, and the total quantity of aqueous liquid will thus be affected and the amount of ether which it takes into solution, correspondingly influenced. This variation becomes appreciable when rich milks (containing more than 5 per cent. of fat) are treated by Soxhlet's method, as in their case it is usual to dilute the sample with a known amount of water before analysis. The diminution of the volume of aqueous ether which is thus brought about, causes a rise in the specific gravity of the ethereal solution of fat and a plus error in the final result. This error may amount to as much as 0.1 per cent. It is evident, therefore, that allowance must be made for the actual percentage of water in any given sample of milk, when precise results are required. This can be done by means of one of the formulæ connecting the total solids with the fat and specific gravity of the milk, e.g. Fleischmann's. From this it follows that W in the equation given above is a function of the specific gravity *s* of the milk and of the specific gravity *S* of the ethereal solution of fat. As always the same quantity of ether is used, *X* is constant and the resulting amount of aqueous ether *N* is simply a function of *s* and *S*.

Assuming therefore that no alteration of volume takes place on dissolving fat in ether, the percentage of fat *Y* can be calculated from the quantity of ether, and the specific gravity of the ethereal solution of fat, the specific gravity of the fat itself being taken as constant; the following equation represents these relations—

$$Y = \frac{X(S - 0.7211)0.93}{0.7211(0.93 - S) \frac{rs}{100}} \quad \text{II.}$$

*X* being the quantity of ether calculated according to equation I, *S* the specific gravity of the ethereal solution of fat, *r* the volume of milk taken, *s* its specific gravity, and the constants 0.7211 and 0.93 the specific gravities of the aqueous ether and of the fat at 17.5° C. respectively. Seeing that *X* is a function of *S* and *s*, this equation can be written—

$$Y = \frac{f(Ss)(S - 0.7211)0.93}{0.7211(0.93 - S) \frac{rs}{100}} \quad \text{III.}$$

Whence it appears that the percentage of fat in the milk is only dependent on the specific gravity of the milk and on that of the ethereal solution of fat. It is therefore practicable to construct a table by means of which the percentage of fat can be arrived at with great exactitude when these two factors are known. The author gives a voluminous table showing that alterations of the quantities of milk, ether, and water used, have but a small effect on the percentage of fat found. The results are, however, uniformly lower than those given by the unmodified Soxhlet method, the difference increasing with the content of fat.

—B. B.

*Estimation of the Total Alkaloids in Cinchona Bark.* C. C. Keller. Apoth. Zeit. 8, 542; Zeits. anal. Chem. 1894, 33, 490-491.

THE author has modified Haubensack's method (this Journal, 1892, 779) as follows:—The dry powder (12 grms.) is shaken in a medicine glass with ether (120 grms.) and 10 per cent. ammonia (10 grms.) added thereto. The shaking is then repeated and continued for half an hour; water is then added (10 grms. for *Cinchona Succirubra*, and 15 grms. for *Cinchona Calisaya*), and the mixture shaken very vigorously for a minute. Of the clear ethereal solution, 100 grms. are poured off, and very vigorously shaken with 3 cc. of dilute sulphuric acid and 37 cc. of

water. The greater portion of the ether is then decanted, and the residual liquid introduced into a separating funnel, the acid solution of the alkaloids is run off and the flask and separating funnel washed with 10 cc. of water. The aqueous solution, after being freed from ether, is shaken with a mixture of chloroform (30 grms.), ether (10 grms.), and ammonia (5 grms.). The extract is run off and the extraction repeated with chloroform (15 grms.) and ether (5 grms.). The combined extracts are then filtered through a filter moistened with chloroform to effect their partial drying, into a tared flask from which the solvent is then distilled. From *Calisaya* bark the alkaloids usually remain in the crystalline condition; from *Succirubra*, however, in the form of a varnish, which persistently occludes chloroform. In this case the residue is treated with 3–5 cc. of absolute alcohol, which is boiled off on the water bath. The alkaloids then remain in the crystalline condition and may be easily dried.—A. R. L.

*Estimation of the Alkaloids in Nux Vomica Seeds.* C. C. Keller. Apoth. Zeit. 8, 542; Zeits. anal. Chem. 1894, 33, 491–493.

15 grms. of the well-dried and finely-powdered substance are freed from fat as follows.—The material (15 grms.) is introduced into a tube 12 c.m. long and 25 mm. wide, which at its lower end is drawn out to 7 mm. wide and 5–6 c.m. long, the point terminating obliquely: within the constricted portion of this tube is placed a loosely-fitting wad which must be free from fat. The sample is then washed with ether until the ethereal washings no longer give a residue on evaporation. By careful manipulation about 100 cc. of ether are requisite. The ethereal solution contains, however, some alkaloid which is recovered by treatment with 5 cc. of N hydrochloric acid and shaking repeatedly with 10 cc. portions of water until the aqueous extract amounts to 25 cc. The fat-free powder is then introduced into a flask, mixed with a sufficient quantity of ether, so that the whole weighs 100 grms., together with 50 grms. of chloroform and 10 grms. of 10 per cent. ammonia, the whole being shaken for half an hour. The acid solution of the alkaloids (mentioned above) is now added, and after well shaking and allowing to subside, 100 grms. of the ether-chloroform solution are filtered into a tared Erlenmeyer's flask, from which the solvent is distilled, leaving the alkaloids as a varnish. The residue is treated two or three times with absolute alcohol, which is evaporated off on the water bath: the alkaloids are thus obtained in the crystalline condition, and after drying at 95°–100° C. may be weighed. The purity of the bases may be established by titration with alkali and iodoquin. It is absolutely important not to employ more chloroform than above prescribed: if more chloroform be taken the alkaloids will be contaminated by the glucoside Loganiin, whilst if too little chloroform be used a loss is to be feared, for inasmuch as the alkaloids are sparingly soluble in pure ether, they separate out.

*Strychnos nux vomica* bark is extracted in the finely-pulverised condition first with a mixture of chloroform and ether and subsequently with pure ether: the remainder of the process is conducted as above described.

The author treats "*Extractum strychni spirituosum siccum*." Pharm. Helv. III. Ed., thus:—1.5 grms. of the dry finely-ground extract are introduced into a flask, shaken with 10 grms. of water until the whole is moistened, and 30 grms. of chloroform and 60 grms. of ether are added. After shaking for some time 5 grms. of 10 per cent. ammonia are added, and, after shaking, the mixture is allowed to separate. A known weight (60 grms.) of the chloroform-ether extract is then filtered, and the remainder of the operation conducted as already described. An extract prepared by the author was found to contain 21.2 per cent. of alkaloids.

*Quantitative Separation of Strychnine and Brucine.*—0.2–0.4 gm. of the dry mixture of alkaloids is dissolved in 10 cc. of 10 per cent. sulphuric acid by heating on the water-bath. After complete cooling, 1 cc. of nitric acid of sp. gr. 1.41–1.42 is added and the mixture shaken. The strychnine sulphate which usually separates from the

solution is redissolved on addition of the nitric acid; simultaneously, however, the red brucine nitric acid coloration is developed. After allowing the mixture to remain for 1–1½ hours whereby the brucine is completely destroyed, 40 grms. of chloroform, an equal quantity of ether, and 10 cc. of 10 per cent. ammonia are added, and the whole shaken. Forty grms. of the extract are filtered into a tared flask, from which the mixture of chloroform and ether is distilled. The residual strychnine is dried at 95°–100° C. and weighed. The author found as a mean value 47.16 per cent. of strychnine in *strychnos nux vomica* seeds.

—A. R. L.

*New Method for the Estimation of Salicylic Acid and Salicylates.* L. Barthe. Bull. Soc. Chim. 11—12, 1891, 516–522.

This new method is based upon the observation that salicylic acid can be accurately estimated by titration with caustic soda, using phenolphthalein as indicator, and further that salicylates are completely decomposed by hydrochloric acid, a slight excess of which is without effect upon the salicylic acid at the temperature of the water-bath. In carrying out the new method the salicylate is decomposed with hydrochloric acid in slight excess, the whole then being evaporated to dryness on the water bath at a temperature not exceeding from 50 to 60° C. The residue is dissolved in boiling water and the free salicylic acid titrated with caustic soda in the presence of phenolphthalein. This titration being finished, some nitric acid is next added and the hydrochloric acid present estimated by titration with silver nitrate, yellow potassium chromate serving as indicator. The amount of hydrochloric acid thus found is equivalent to the amount of base present in the salicylate. This method answers well for the analysis of the salicylates of the alkalis and alkaline earths. In the salicylates of manganese and bismuth the metal is best estimated by ignition, in those of zinc and lead by the general methods. *Mercuric salicylate* is analysed by first dissolving it in a moderate excess of caustic soda, acidifying with hydrochloric acid, and evaporating to dry mass at a temperature not exceeding 45° C. The dry mass is then dissolved in a definite volume of one fifth normal potassium iodide, and the amount of salicylic acid present estimated by titration with standard soda. The quantity of mercury contained in the solution is then determined by titration according to Personne's method, the rose colour of the phenolphthalein having been removed by the least possible quantity of hydrochloric acid. For the analysis of the salicylates of the alkaloids this new method is not generally applicable, but on the other hand it may be mentioned that it answers very well for the analysis of the alkaline benzoates.

—C. O. W.

*Investigation of Certain Commercial Forms of Artificial Musk.* Bericht von Schimmel and Co., October 1893. Zeits. anal. Chem. 1894, 33, 487–488.

The properties of Baur's artificial musk have been described (this Journal, 1891, 1024).

The sample examined, melted at 108° C., and dissolved somewhat readily in hot water, but only very sparingly in petroleum spirit. It was extracted about 20 times with boiling petroleum naphtha, the residue being dried and crystallised 6–8 times from boiling water. It proved to be acetanilide.

To estimate the amount of adulteration in this sample, a determination of nitrogen existing as nitro-groups (NO<sub>2</sub>) was made by Spindler's modification (Annalen, 224, 288) of Liempicht's process (Ber. 11, 35). This gave 3.25 per cent. of NO<sub>2</sub>, corresponding with 6.67 per cent. of trinitrobutyltoluene.

Acetanilide is used as a vehicle in the cases of other odorous products made by the same firm which manufactured this particular sample of artificial musk.—A. R. L.

### PATENT.

*An Improved Process for the Extraction and Estimation of Eucalyptol.* L. R. Scammell, Adelaide. Eng. Pat. 14,178. July 23, 1894.

A SOLUTION of phosphoric acid, preferably of sp. gr. 1.785, is added to the oil containing eucalyptol. A crystalline precipitate of eucalyptol phosphate is thus produced, which is collected and decomposed by hot water, the quantity of liquid eucalyptol thus separated is easily measured.—T. E.

### ANALYTICAL AND SCIENTIFIC NOTES.

*Remarks on the Heating and Spontaneous Combustion of Hay.* M. Berthelot. Bull. Soc. Chim. 1894, **11**—12, 810—812.

THE spontaneous combustion of heaped up and badly dried hay has been often attributed to a peculiar kind of fermentation; but the author refers to his work, on this subject, of 1855, showing that all fermentation is based upon an exothermic chemical reaction, the ferment itself acting only to start the reaction, the combustion which may follow being due to an oxidation process. Herbs, heaped up as soon as cut, rot from excess of moisture, without much rise of temperature, and become unfit for use as cattle-food; but if they are spread out, they die, and then lose rapidly the water which they obstinately retain while living. At the same time they undergo oxidation and set free carbonic acid, such being the case with good hay, when stacked. But if the hay be heaped up before being sufficiently dry, it is subject to alterations of another kind, with considerable evolution of heat, due to fermentation. Ferments, however, cease to act at 40° C.; yet the temperature may continue to rise, even to 100° or more, with absorption of oxygen from the air, as the author has proved by direct experiment. The oxidation which goes on, increases with the rising temperature, and is of a purely chemical character, empyreumatic products being generated, giving the taste and odour recognisable as emanating from "heated" hay. At a temperature far below a red heat, combustion may ensue. Such spontaneous combustion has occurred in hay contained in a stove maintained at 140°. Charcoal prepared for making powder has been observed to give off carbonic acid at 100°; and some specimens, after cooling in a close vessel, will inflame on contact with air. All such phenomena belong to the same order. The conclusion is, that the rise of temperature leading to the spontaneous combustion of hay, results from purely chemical reactions, in connection with products modified by previous fermentations.—E. S.

*The Crystallisation of Cellulose and the Chemical Composition of the Vegetable Cellular Membrane.* E. Gilson. Bull. Soc. Chim. **11**—12, 1894, 590—591.

THIS work, originally a microscopic investigation of vegetable morphology, has led to an interesting chemical research. In treating microscopic sections by Schweitzer's reagent, and then by ammonia, the author has obtained crystals presenting all the characteristics of cellulose. He has prepared cellulose in quantity by Schulze's method, employing the stalks of young cabbages, and has proved its identity with the crystals before prepared, since when treated first with the copper solution and then with ammonia it was completely converted into a crystalline mass; further, on treating a great number of sections with Schweitzer's solution and ammonia to cause the cellulose to crystallise, and then submitting them to Schulze's treatment for the preparation of pure cellulose, nothing was left but crystals of cellulose. The cellulose thus obtained is the

only hydrate which in the membrane is coloured by iodised chloride of zinc, and which by hydrolysis gives exclusively dextrose.

In certain cases the author found, besides cellulose, another carbohydrate, which he names "paramannane," and which was prepared as follows:—Coffee, after treatment with ether, dilute potash, and dilute sulphuric acid, was dissolved in Schweitzer's solution. Through this solution, containing an excess of ammonia, a current of carbon dioxide was passed, when the cellulose was precipitated, whilst the paramannane remained in solution. This last solution was rapidly evaporated and washed with very dilute acid. Paramannane thus prepared is a white powder resembling sperm, insoluble in water and alkalis, soluble in concentrated sulphuric acid, but attacked with difficulty by dilute sulphuric acid. Hydrolysed it yields manna. Microscopically it is seen in the form of sphere-like crystals.

The researches of the author shew that cellulose is always found in the interior of cells and that it is not removed completely by Schweitzer's reagent. This explains why Frémy admits a variety of cellulose (paracellulose) which only dissolves after first acting on it with dilute acids.

—A. W.

*A Novel Application of Bichromated Gelatin.* Izarn. Comptes rend. **118**, 1894, 1314—1315.

THE author recommends coating silvered surfaces in general, and the mirrors of astronomical telescopes in particular, with an extremely thin film of bichromated gelatin in order to protect them from atmospheric tarnish. Such films are stated to be very adhesive, durable, and transparent; and it was found by experiment that surfaces thus protected remained perfectly bright, even after prolonged contact with sulphuretted hydrogen. The process has been applied to the mirror of a telescope at the Toulouse observatory with very satisfactory results, the sharpness of definition, &c. of the instrument being in no way deteriorated.—H. T. P.

*Cobalt Nitrate as an Antidote for Cyanide Poisoning.* Eng. and Mining J. **58**, 1894, 418.

COBALT nitrate is found by Dr. Johann Antal, a chemist, of Hungary, to be an antidote to prussic acid and cyanide poisoning. First he tried the cobalt on animals, and then, presumably at different times, on 40 living persons who had been accidentally poisoned by prussic acid, and in all cases the results are reported to have been satisfactory.

### New Books.

THE RISE AND DEVELOPMENT OF ORGANIC CHEMISTRY. By CARL SCHORLEMMER, LL.D., F.R.S., late Professor of Organic Chemistry in the Owens College, Manchester. Revised Edition. Edited by ARTHUR SMITHELLS, B.Sc., Professor of Chemistry in the Yorkshire College, Leeds. London and New York: Macmillan and Co. 1894. Price 5s.

SVO VOLUME, bound in cloth, and containing, as frontispiece, an excellent photo-engraving of Schorlemmer, with his autograph beneath. The work commences with a biographical sketch of Schorlemmer by Professor SmitHELLS, a bibliographic list of his investigations, preceded by a brief Preface, a Table of Contents, and the text of the work, covering 268 pages. The work is greatly enhanced in value by the addition of an alphabetical index

of names of investigators and authors, and also of subject-matter, a means of guidance lacking in the original. In the Table of Contents, the sub-division of the text, or analysis of the matter, is made clear. Chapter I. Chemical Knowledge of the Ancients, sketched down to the times of Lavoisier, Berzelius, and Gmelin. II. Vital Force. First Artificial Production of an Organic Compound. Theory of Substitution, &c. III. Dumas's Theory of Types, &c. IV. Introduction of Radicals, Types, and the Beginning of the Theory of Valency. V. Compound Radicals, inorganic as well as organic. Definition of Organic Chemistry, &c. VI. Organic Analysis. Calculation of Formulae. VII. Constitution of Organic Compounds. Isomerism. VIII. Isomeric Paraffins. Alcohols. Unsaturated Compounds. IX. Aromatic Compounds, Kekulé's and Ladenburg's Views. Geometric Isomerism, Kolbe's Views. X. Synthesis of Organic Compounds. XI. Synthesis of Aromatic Compounds. XII. Synthesis of Indigo, and Problems still to be solved.

**CHEMIKER-KALENDAR, 1895.** Ein Hilfsbuch für Chemiker, Physiker, Mineralogen, Industrielle, Pharmazeuten, Hüttenmänner. Von Dr. RUDOLF BIEDERMANN, Sechszehnter Jahrgang. Mit einer Beilage. Berlin: Verlag von Julius Springer, 1895. London: H. Grevel and Co., 33, King Street, Covent Garden. Price 4s. 6d. Post free.

THIS well-known pocket-book and vade mecum for chemists and analysts, has now appeared for 1895. It is strongly bound in cloth, and contains an almanack for 1895 inside the cover, and a table of frequently used atomic weights and their multiples. Among the additions and improvements in this edition for 1895, may be mentioned Lunge's completed tables of reductions of gas volumes. Knietzsch gives the results of his work on liquid chlorine. Brendel contributes a valuable table on the Frigorific Mixtures investigated by him, whilst Stohmann adds many new results of his in Thermo-chemistry. In matters relating to Solubility, Heats of Formation, Refraction of Light, Diffusion, &c., partly the original work and partly the Physico-chemical Tables of Landolt and Börnstein have been laid under contribution. Among the "Chronological Investigations," there will be found important additions to and extensions of the Tables of Colouring Matters, as well as new data bearing reference to the fats and tanning materials.

A Chronological Table of the principal events in the History of the Physical Sciences is given, and also a Notebook Calendar with blank pages for the different days of the year, in which observations, data, facts, &c., may be entered up and recorded. Then follows tabulated matter of Specific Gravities, of Gases and Liquids, Salts and Alcohols, Tables of Solubilities, Properties of Chemical Substances, Analysis, Volumetric Analysis, Spectrum Analysis, Gas Analysis, Physiological Chemical Analysis, and Technological Investigations relating to:—I. Water. II. Assaying. III. Fuels. IV. Sulphuric Acid. V. Alkali. VI. Bleaching Powder. VII. Nitre and Explosives. VIII. Textile Fibres, Paper. IX. Photography. X. Starch and Sugar. XI. Colours, &c. XII. Fats and Oils. XIII. Tanning Materials. XIV. Ceramics. XV. Glass. XVI. Mortars and Cements, Mineralogy.

#### BEILAGE ZUM CHEMIKER-KALENDAR. 1895.

THIS forms a supplement of useful tables of a more thorough-going technological character:—I. Leading Foreign Money Currencies. II. Series of Mathematical Tables. III. Weights and Measures. IV. Tables of Heat and Cold Measurements. V. Expansion and Contraction. VI. Tension of Vapours. VII. Barometry. VIII. Sound. IX. Light. X. Electricity. XI. Magnetism. XII. Diffusion and Capillarity. XIII. Elasticity, &c. XIV. Specific Gravity.

**A TREATISE ON CHEMISTRY.** By SIR H. E. ROSCOE, F.R.S., and C. SCHÖDDEMMER, F.R.S. Vol. I. THE NON-METALLIC ELEMENTS. New Edition, completely revised by Sir H. E. Roscoe, assisted by Dr. H. G. Colman and A. Harden. With 374 illustrations and a Portrait of Dalton, engraved by C. H. Jeens. London and New York: Macmillan and Co. 1894. Price 21s.

THIS is a new, completely revised and reprinted edition of Volume I. of this work of Roscoe and Schödemmer's. Compared with Volume I. of the previous edition, it has grown considerably in bulk. It contains besides the Prefaces (the latter one for this, the third edition), also a list of contractions of the names of journals referred to in the text, the table of contents, and 875 pages of subject-matter. The book ends with a complete alphabetical index of subject-matter. The text is profusely illustrated with admirable engravings, and the technical bearings of the science have received careful attention.

Turning to the divisions of the work, the opening chapter forms an HISTORICAL INTRODUCTION. It is followed on page 41 by another division of the work devoted to GENERAL PRINCIPLES OF THE SCIENCE, and dealing with *Properties of Matter, Elementary of Compound Bodies, Properties of Gases, Boiling Points of Liquids, Laws of Chemical Combination, Experimental Methods for the Determination of Molecular Weights*. On page 126 commences the description of the NON-METALLIC ELEMENTS, among which—following the Compounds of Carbon with Hydrogen, the Halogens, Oxygen, Sulphur, and Nitrogen—are descriptions, theoretical and technical, of Coal-Gas, Wood-Gas, Oil-Gas, Water-Gas, with a chapter on the Nature of Flame, including a description of the experiments of Smithells. A tolerably full account of the Elements of the Science of Crystallography and of its applications fills pages 827 to 873.

**EINFÜHRUNG IN DAS STUDIUM DER QUALITATIVEN CHEMISCHEN ANALYSE.** VON CARL FRIEDHEIM, PH.D., Privatdozent an der Universität Berlin. Ste gänzlich umgearbeitete Auflage von C. F. Rammelsberg's Leitfaden der qualitativen chemischen Analyse. BERLIN: Carl Habel, Verlag-buchhandlung, Wilhelm-Strasse 33, S.W. (48). LONDON: H. Grevel and Co., 33, King Street, Covent Garden. 1894. Price 7s. 6d.

THIS work on Qualitative Analysis is dedicated by the author to Professor Clemens Winkler. It takes the form of an 8vo volume in paper cover, containing preface, table of contents, 335 pages of text, and a full alphabetical index of subject matter. The book really consists of a completely renovated edition of Rammelsberg's "Leitfaden der qualitativen chemischen Analyse." The subject-matter is sub-divided as follows:—I. GENERAL RULES IN CARRYING OUT QUALITATIVE ANALYSIS. II. SYSTEMATIC DEVELOPMENT. III. REACTIONS.

**A.—METALS.** (1.) Group of the Alkali Metals. (2.) Group of the Alkaline Earth Metals. (3.) Metals proper. (3a.) Metals not precipitated by sulphuretted hydrogen from acid solution, but precipitated by ammonium sulphide. (3b.) i. Metals precipitated by sulphuretted hydrogen from acid solution, the sulphides being insoluble in ammonium sulphide. ii. Metals precipitated by sulphuretted hydrogen from acid solution, the sulphides being soluble in ammonium sulphide.

**B.—METALLOIDS.** 1. Acids precipitated by barium chloride from neutral solution. 2. Acids precipitated by silver nitrate from acid solution. 3. Acids precipitated neither by barium chloride nor silver nitrate.

**IV. Employment of foregoing methods.** 1. Analysis of simple substances. 2. Analysis of complex mixtures. 3. Analysis of Alloys. 4. Analysis of Metallic Sulphides and Arsenides. 5. Analysis of Silicates.

**APPENDIX I.** Reactions of Rare Metals. **APPENDIX II.** List of necessary Reagents, and the usual impurities of injurious character to be found in them.

**DIE MASCHINELLEN HILFSMITTEL DER CHEMISCHEN TECHNIK.** Bearbeitet von A. PARNICKE, Civil-Ingenieur, vormals Ober-Ingenieur der Chemischen Fabrik Griesheim. Mit 337 Abbildungen. Frankfurt a. M.: Verlag von H. Bechhold. London: H. Grevel and Co., 33, King Street, Covent Garden. 1894. Price 10s.

This is a text-book for students of chemical technology desirous of acquiring a sufficient book-knowledge of descriptive chemical engineering. It contains a description of the construction and modes of employment of the large scale apparatus used in the chemical factory. The work consists of a large 8vo volume containing Preface, Table of Contents, and Subject-matter, filling 314 pages. An alphabetical index of subject-matter ends the book. The text is illustrated by 337 excellent engravings of all manner of plant and apparatus used in chemical factories.

The subjects treated of in the work, described and illustrated, are as follows:—

General. Packing and laying lines of pipes. Packing material for economising heat. Packing of Stuffing-boxes. Lubrication of Apparatus and Machinery. Taps and Cocks. Valves, &c. I. Sources of Power. II. Transmission of Power. III. Apparatus for Transport or Transmittal of Materials and Products. IV. Pulverising and Disintegrating Apparatus. V. Mixing Machines, including Towers and Columns for Absorbing, Denitrating, &c. VI. Melting, Dissolving, and Lixiviating Apparatus. VII. Concentrating Apparatus. VIII. Arrangements and Plant for Mechanical Separation, Extraction, and Fractionation. IX. Drying Plant. X. Apparatus for estimating Weight, Temperature, Pressure, Power of Draught, and Tensile Strength. XI. Legal Enactments.

**DIE FABRIKATION VON SCHWEFELSAURE THONERDE.** Von Dr. KONRAD W. JURISCH. Dozent an der Königl. Tech. Hochschule zu Berlin. Berlin: Fischer's technologischer Verlag. Fischer und Heilmann, Köthener Strasse 44. London: H. Grevel and Co., 33, King Street, Covent Garden. 1894. Price 5s.

LARGE 8vo volume, with a full description of the modes of manufacture of sulphate of alumina. The work contains a brief Preface, Table of Contents, and subject-matter covering 113 pages. The work is subdivided as follows: Natural Occurrence of Sulphate of Alumina. Historical Development and Patent Statistics. Manufacture from Cryolite. Manufacture from Clays. Manufacture from Bauxite. Bauxite. Manner of Working. Description of Manufacture. Calcining, Melting, Lixiviating, Filtering the Liquors. Carbonating. Filtering off the Alumina. Solution. The Product. Analysis of Sulphate of Alumina. Properties. Pure Aluminium Sulphate. Basic Aluminium Sulphate. Commercial Sulphate of Alumina. Examination of Sulphates of Alumina. Employment of the Salt. Economy. Statistics.

At present the import has not only completely ceased, but it would not even be astonishing to find that Austrian cement is imported into England and France.

There are many cement factories at the present time in Austria, established mainly on account of the high price of the English article. These factories produce cement of different qualities, but, quality for quality, the Austrian article is stated to be equal to the English cement.

At the present time the price of Austrian cement at Trieste is very nearly the same as that of English cement in England; there is therefore no inducement to import the latter, because of the import duties and freight.

It appears that all or nearly all the Austrian cement factories have adopted the principle of delivering their speciality at the same price in any place in the Empire, themselves paying the difference in the carriage rates. With this system, which is remunerative owing to the very low rates of the railway tariff, and being given also the increased cost of maritime freight and the securing of a return freight by English vessels, it would be sufficient for a demand to arise in England for Austrian cement to be exported with profit to that country.

On the other hand, it is asserted that the abolition of the free port of Trieste has been the last blow to the importation of foreign cement through that port.—*Board of Trade Journal*.

#### ALGERIAN PHOSPHATE DEPOSITS.

Under date of August 11, 1894, our consul at Algiers, Africa, Mr. Charles T. Grellet, writes to the Department of State as follows:—

Ever since the year 1886, the French explorers of Tunisia have mentioned the existence, in the western part of that country, of numerous and important phosphate lands. Some two years ago similar discoveries were made in the "Department of Constantine" (in the "Djebel Dir") (Eastern Algeria), "Djebel Kouik" (Djebel—native for mountain), and at Kissa in the region of Tebessa, 250 km. south of Bone. The Tebessa fields are situated in the north-west of that city, extending over an area of several hundred miles (square), and are said to be almost inexhaustible. The fertiliser, mostly composed of bones and teeth of sharks, is found in a semi-pulverulent state, in strata from 5 metres to 3 metres (10 ft.) thick, intercalated in white marl and siliceous limestone; its grade averages from 60 per cent. to 70 per cent, and at places reaches as high as 85 per cent. of tri-calcic phosphate of lime. Owing to the character of the deposit, the mining of the phosphate is exceedingly easy and cheap; the freight by railroad from the mine to Bone is from 2.31 dols. to 2.50 dols. per ton, and it is calculated that, including all expenses, the cost to the miner free on board vessel at the lading port does not exceed 4.63 dols. per 2,240 lb. The cost of transportation from Bone to the principal countries of Europe, and more particularly Great Britain, France, and the Baltic and Mediterranean ports, is at present per ton as follows:—

	Dols.
To England .....	1.94
To France (northern ports) .....	2.19
To Baltic ports .....	2.67
To France (Mediterranean ports) .....	1.46
To Italy .....	1.66
To Austria .....	1.46

The approximate cost of the phosphate delivered f.o.c. at the port of destination would thus be:—

	Dols.
To England .....	6.57
To France (northern) .....	6.82
To Baltic ports .....	7.30
To France (Mediterranean ports) .....	6.09
To Italy .....	5.72
To Austria .....	6.09

The phosphate is as a rule sold on the basis of the unit of tri-calcic phosphate of lime per 1,000 kilos., delivered

## Trade Report.

### GENERAL TRADE NOTES.

#### PORTLAND CEMENT INDUSTRY IN AUSTRIA-HUNGARY.

An article recently published in the Brussels *Bulletin du Musée Commercial*, deals with the subject of the development of the Portland cement industry in Austria-Hungary. The opinion is expressed that at an early period it will compete with the Russian and French factories.

A few years ago the import of Portland cement through the port of Trieste was considerable; the larger part of the cement imported came from Newcastle, but Dunkirk also sent a small quantity.

f.o.b. at the ports of arrival, and the prices obtained at present in Great Britain and Italy average according to grade of mineral from 14 to 14½ cents per unit.

The phosphate lands of Tebessa, as they stand at present, are under the control of three firms, two of which are English. A railroad 12 km. long has been built to connect at Morsott with the Bone Guelma Railroad from Tebessa to Soukarras. The Djebel Dir mine is 15 km. north-east of Tebessa and 1,500 metres above sea level. It can turn out from 200 to 300 tons daily.

The beds of Djebel and Kouik are in the hands of the Constantine Phosphate Company, with head office at Leith, Scotland. This layer is situated some 25 km. north-west of Tebessa, 1,000 metres above the sea level. The quantity of phosphate existing there has been estimated at 40,000,000 tons; the works are not in full operation, and the connection of the mine with the main line at Tebessa will require the construction of a railroad of about 20 miles in length. The third field, that of Kissa, is in the direct vicinity of Djebel Dir, and is the property of Colonel Corp. But little has been done up to the present date; the work is, nevertheless, progressing steadily.

The general output of these mines was about 5,000 tons in 1893; it will reach at the least from 30,000 to 35,000 tons during the present year, the firm of Crookstone Brothers being the largest contributors.

Other fields have lately been discovered in the same district, and numerous claims been filed, with the view of obtaining from the French Government the concession of these lands. Beds of phosphate have also been found in other parts of the colony, in the Department of Oran, in the region of the Rio Salado, close to the boundary of Morocco, and at Inkermann, 254 km. east of Oran, on the railroad from that place to Algiers. Here the deposits are of a different character, and are generally found in a solid rock. The mineral is also of a lower grade. The output has amounted to very little if anything. In fact, the Tebessa mines are at present the only ones worth mentioning.

As to general conclusions with regard to the industry in Algeria and the effects it will have upon American phosphates, it may be fairly said that the discovery of phosphates in Algeria in almost incredible abundance and of the highest value is indeed a notable event in the history of the colony, and it cannot be doubted but that in the very near future the North African phosphates will prove serious competitors against our American fertilisers in the European markets.—*Engineering and Mining Journal*.

#### SECURING THE FOREIGN MARKETS.

In his general commercial report to the British Foreign Office, Sir C. Oppenheimer, Consul-General at Frankfurt-am-Main, makes some remarks which are intended especially for English manufacturers. We give the following extracts from these remarks:—

"It might be of interest for English trade to study in many directions the business tactics of German merchants and industrials, and to adopt from it what is good and what has proved successful. It would promote English export if its representatives accustomed themselves to facilitate for customers the purchase of goods, as the Germans do; by shipping or consigning them to their warehouses, freight and duty free; by having the goods packed and made up according to the local taste of the customers; by making their offers in the coinage of the country for which the goods are destined; by sending round travellers to customers who not only know the language but are also acquainted with the customs of the country, and, finally, wherever a special traveller would be too dear, by several non-competing firms clubbing together to send a joint representative at their common expense. All these points mentioned here may be regarded as the articles of faith of German exporters, and every Englishman knows how strange in most instances they still appear to the English merchant.

"One can give an idea in a few words of the difference between the old English and the new German tactics in the

export trade. As long as England possessed an unlimited supremacy in the world's markets as exporter of industrial products, the customers were, of course, obliged to come to her, accommodate themselves as best they could to English customs, English taste, English usages, and the English industrial export trade thoroughly anglicized the world; nowadays, when we have to take into account an over-production in many branches of industry, increased offers in the export, and the competition of foreign states (to use a well-known simile) 'the prophet must go to the mountains,' the exporter must visit the customers and accommodate himself to their wants and habits as much as possible. It will be the task of the English trade to acquire these new tactics in the export trade if it does not wish to be left behind by Germany."

The German manufacturers are taking English trade by systematic efforts, as the Consul's statements show. They are reaching out in many directions, not blindly or in a haphazard way, but carefully and systematically. They take pains to make themselves known to their customers in the first place, then to study their wants, find out the kind of goods they want and their methods of doing business; then they seek to conform to the requirements of the special market, believing that in this way they can not only secure new trade, but can also hold the markets when their goods are once introduced. How well they are succeeding and what inroads they are making into British trade the complaints of English manufacturers and their representatives, the trade papers, show.—*Ibid*.

#### GERMAN IMPORTS AND EXPORTS OF DYES FOR THE FIRST SIX MONTHS OF 1894.

*Ibid.*—A. R. L.

THE GERMAN CHEMICAL TRADE SINCE 1885.

M. Diezmann. *Chem. Ind.* 1894, 388—401 (conclusion).

The variations of the import values are chiefly due to "chemical products not specified," and when excluding these the total import values vary between 22—24·25 million m. One-third of this amount falls on *sulphate of ammonia*, the imports of which, notwithstanding the increased home-production, remain fairly constant at 31,000—35,000 tons, an exception being made in 1893 with 42,600 tons. The chief importing countries are England (two-thirds of the total), Austria, France, &c. The exports reached a maximum of 957 tons in 1891. The average values varied between 22—25 m. per 100 kilos. As regards *iodine*, it is kept separate from potassium iodide and other iodine preparations only since 1888. From this date onward the imports of the latter amounted to 1—6 tons annually; hence the imports of iodine may be assumed as having increased from 70 tons to 157 tons between 1885 and 1889. In 1890 they amounted to 138 tons; 1891, 156 tons; 1892, 169 tons; 1893, 324 tons. The exports of iodine preparations, including iodine, rose from 34 to 74 tons in 1889, and amounted since then to 100—110 tons yearly. They are taken up chiefly by Russia, Austria, England, France, and Japan. The average value of the imported iodine was taken at 2,200 m. per 100 kilos. in 1889, increasing to 2,650 m., and that of the exported iodine preparations also to 2,200 m., and since then to 2,270 m.

*Phosphorus*, not being produced in Germany, the whole of the exports of this duty-free article is in reality transit, and the home consumption is determined by deducting exports from imports. The consumption is thus shown to be—

—	1885.	1886.	1887.	1888.	1889.	1890.	1891.	1892.	1893.
Tons	92	90	208	98	163	142	138	166	176

In the year 1887 the unusual amount of 104 tons is supposed to have arrived from Holland. This may be due to an error of classification. The seeming increase of consumption since 1889 may be due to the manufacture of phosphor bronze. The chief importing country is England, and small quantities arrive from France and Switzerland. The exports are chiefly to Austria and Japan. The average values receded from 500 m. per 100 kilos. in 1885 to 320 m. in 1892, and increased to 420 m. in 1893. The figures referring to the traffic in *borax* and *boric acid* are not easily understood, perhaps owing to the circumstance that raw material and final product are not separated. *Chlorate of potash* and *chlorate of soda* not in capsules, notwithstanding the increase of production in England and in Switzerland, belong to the goods which experienced a strong increase of exports—from 94 tons in 1885 to 682 tons in 1892, and to 850 tons in 1893. The increase of consumption falls on Belgium, the States (with strong variations), England, Austria, and Sweden. The imports from England, France, Austria, and, since 1890, from Switzerland, which, between 1885 and 1889, varied between 730 and 920 tons, decreased in the years 1890—1892 to 550 tons annually, and reached in 1893 again 764 tons. The import values fell chiefly in consequence of increased English competition and of the electrolytic production in Switzerland, from 125 m. per 100 kilos. in 1885, without interruption, to 90 m. in 1890, increasing in 1891 to 95 m., 1895 to 125 m., and 1893 to 135 m. For exports, the values are estimated 10 m. higher, with the exception of 1893 (5 m. higher).

The trade in *chromate of potash* was subject to great variations even before 1885. The imports, chiefly from England, which amounted in 1884 to 3,470 tons, fell in 1885 suddenly to 864 tons, rising up to 1,759 tons, decreasing in 1892 to 796 tons, and to 734 tons in 1893. The exports moved since 1885 between 107 and 276 tons. They are directed chiefly to Austria, Russia, &c. On the other hand, the exports of *chromate of soda* show an uninterrupted increase since 1888, especially for France, amounting to 345 tons in 1889, 686 tons in 1892, and 708 tons in 1893;

whilst the imports show a complete falling off (from about 800 tons round 1889 to 138 tons in 1893). Chromate of soda seems more and more to take the place of the potash salt. Prices were greatly influenced by the arrangements of the German and English producers, varying since 1885, for imports as well as for exports, between 61 and 85 marks per 100 kilos, for chromate of potash, and 50—68 marks for chromate of soda.

The imports of *lime salts*, such as the artificial carbonate and sulphate of acetate, phenolate, citrate, &c., rose from 1,232 tons in 1885 to 7,422 tons in 1892 and 6,184 tons in 1893, chiefly owing to consignments of American origin. The average values decreased gradually from 40 marks per 100 kilos, in 1885 to 20 marks.

Among potash compounds *potassium chloride* is to be mentioned in the first instance. The variations in the consumption of this article, including the year 1893, are given below:—

	Tons.
United States .....	23,284 to 38,107
England .....	8,532 to 14,891
France .....	8,749 to 12,310
Belgium .....	7,131 to 7,903
All other countries .....	11,175 to 16,296

Since 1885 the value of potassium chloride is estimated at 14 m. per 100 kilos., with the exception of the years 1892 and 1893, at 14·25 m.

The chief consumers for potassium sulphate (including potassium-magnesium-sulphate) are the States, as by the following statement, embracing the years 1885 and 1893:—

	Tons.
United States .....	6,580 to 19,257
England .....	1,879 to 5,735
Sweden .....	2,047 to 6,933
France .....	945 to 2,226
All other countries .....	1,655 to 2,068

The great increase in the American exports is due to the exemption from duty by the McKinley tariff. The average value amounted in 1885 to 10 m. per 100 kilos.; 1886, 7 m.; 1887, 9 m.; 1888 to 1891, 8·5 m.; 1892, 13·25 m.; and 1893, 13 m.

The chief consumer of *sulphate* is England, taking since 1889 annually between 3,368 and 5,349 tons, out of a total of 8,100 to 10,100 tons. The values, both for imports and exports, vary since 1885 between 38 and 42 m. per 100 kilos.

A remarkable feature in the *potash* trade is the increase of the exports to the States (from 243 tons in 1889 to 2,154 tons in 1893), and the gradual ascension of Austria over France in the imports; both countries export chiefly molasses. The export values were estimated at 35 m. in 1885, 34 m. in 1886 per 100 kilos., increasing gradually to 41 m. The import values are less by 2 m. up to 1888, and by 4 m. since then.

*Prussiate of Potash* was in request in 1892, in which year the English demand rose to 444 tons, only to decrease to 96 tons in 1893, and the total exports to 219 tons. There was an unprecedented demand for *potassium cyanide*, chiefly used for extracting gold. The exports rose uninterruptedly from 17 tons in 1885 to 164 tons in 1892, and 720 tons (value 2,087,000 m.) in 1893.

The considerable progress made in the German soda industry is evinced chiefly by the decrease of imports and the increase of exports. Thus the imports of *soda ash* amounted at the beginning of the last decade to 8,000—9,000 tons annually; they are now reduced to a few hundred tons. But the exports rose from 2,000—3,000 tons to more than 30,000 tons. Chief consumers are Switzerland, Italy, Sweden and Norway, Belgium, Holland, and, since 1890, in increasing measure, the United States. The Austrian and Russian markets, however, are almost completely lost. The estimated values per 100 kilos. were: 11 m. in 1885, 8·5 m. in 1888, and 12·5 m. in 1893. Similarly the imports of *caustic soda*, amounting to 8,000 tons in 1880, 3,260 tons in 1885, receded gradually to 400 tons; whilst the exports, which consisted of 240 tons in 1880, 1,100 tons in 1885, and 1,800 tons in 1890, suddenly increased to 3,190 tons in 1891

and 5,820 tons in 1892, and falling back somewhat to 4,910 tons in 1893. The increased exports of the last few years were taken up chiefly by Belgium, Russia, and Spain, and the decreased consumption of the two last named countries caused the falling back noticed in 1893. The export value of caustic soda amounted to 25 m. per 100 kilos. in 1885, 22 m. in 1888, and 27 m. in the last three years.

The exports of *saltcake* amounted to 15,000 tons in 1885 and 37,100 tons in 1893, the chief consumers being Belgium and Austria. The average values per 100 kilos, were 5 m. in 1885, 3·5 m. in 1889, 4·5 m. in 1890, and 3·5 m. in 1893.

The imports of *ammonium carbonate*, including sal ammoniac and liquor ammoniac, are chiefly of English origin, and remain since 1889 at between 1,360 and 1,590 tons. The exports again rose, almost without exception, to 3,094 tons in 1893, a demand being created by the United States in 1892 and by Russia in 1893. The average values for imports remained between 60—75 m. per 100 kilos.; for exports they are fixed at 5—13 m. less.

There is a continual increase in the exports of *alum*, including sulphate, acetate, palmitate of alumina, &c., especially for England, the United States, Belgium, Switzerland, and Holland. Estimated value up to 1890: 15 m., then falling to 13 m., and reaching 10 m. per 100 kilos. in 1893.

The exports of *copper sulphate* vary as a rule from 2,100 to 2,300 tons, reaching 3,009 tons in 1889 and 4,323 tons in 1890, chiefly owing to its extensive use against the phylloxera; this demand fell off in 1891, and with it the exports to 1,368 tons. About 300 tons are sent for amalgamating purposes to Mexico and Chili. The imports from England and Austria amount, as a rule, to 400—600 tons. Prices varied from 35 marks per 100 kilos, in 1885, to 29 marks in 1887, 40 marks in 1888, 46 marks in 1889, 29 marks in 1892, and 31 marks in 1893.

*Sulphuric acid* is imported chiefly from Austria, Holland, and Belgium, in quantities varying from 8,708 tons in 1888, 6,712 tons in 1889, 8,801 tons in 1890, to 5,747 tons in 1893. The exports amount of late years to 18—20,000 tons, and are taken up in Holland, Belgium, France, Switzerland, and Argentina. The average values fluctuate between 6·5 and 8 marks per 100 kilos.

Considerable variations are noticed in the exports of *tartaric acid*, amounting to 1,056 tons in 1885, 1,598 tons in 1889, 1,021 tons in 1890, 777 tons in 1891, and about 1,160 tons in the next two years. The chief consumer is England, with 500—800 tons; next follow Russia and France. The average values receded from 330 marks per 100 kilos. in 1886 to 210 marks in 1893.

*Salicylic acid* is exported in steadily increasing quantities to the United States, England, and Japan (for conserving "saki"), but prices fell, owing to the expiration of the patents, from 1,300 marks per 100 kilos. in 1889 to 900 marks in 1893.

An upward movement is experienced in the exports of *tannic acid*, chiefly owing to the demand for England, Russia, Austria, and France. The values show a decrease from 300 marks per 100 kilos. to 240 marks.

The trade returns of the class here spoken of were greatly influenced by *manufactured products and preparations, not specified, of the chemical industry and pharmacy*. The imports rose almost without break from 1,371 tons in 1885 to 5,938 tons in 1892, falling back to 3,177 tons in 1893. The average values were 150 marks per 100 kilos. The exports show a continuous increase from 3,550 tons in 1885 to 10,525 tons in 1893, the average values being 250 marks per 100 kilos.

The values of the *essences* (scented waters and fats, and perfumes not named) vary considerably for each year, both for imports and exports. The chief importing countries are Austria and France, and lately China, whilst the exports are taken up in the United States, Austria, Russia, France, Spain, England, and Argentina.

*Mineral waters* are exported chiefly to Holland (for Java) and to Belgium. Average values: 28 marks per 100 kilos. for imports, 19 marks for exports.

## II. B.—ETHERS, ESSENCES, MEDICINES, AND PERFUMES.

	Imports.		Exports.	
	Tons.	Thousand Marks.	Tons.	Thousand Marks.
Essences.....	190 up to 252	3,684 up to 5,172	197 up to 365	2,968 up to 6,208
Mineral waters.....	4,813 „ 6,900	1,361 „ 1,582	25,331 „ 36,383	4,813 „ 4,909
Quinine.....	6 „ 41	1,287 „ 1,416	104 „ 226	5,680 „ 9,326
Other alkaloids.....	7 „ 33	1,900 „ 2,345	10 „ 66	1,078 „ 6,066
Sap, scented.....	75 „ 107	1,150 „ 1,215	1,168 „ 1,370	1,753 „ 2,055
Perfumes.....	187 „ 263	1,191 „ 1,608	1,077 „ 1,371	5,989 „ 6,674
Others.....	512 „ 770	1,216 „ 1,507	573 „ 814	863 „ 1,376
Total.....	6,954 „ 6,932	9,270 „ 12,345	28,778 „ 40,235	26,575 „ 33,168

The exports of *quinine* rose gradually from 104 tons to 226 tons in 1892, falling back suddenly to 135 tons in 1893, chiefly owing to decreased demand for the United States, England, and Holland. The values fell uninterruptedly from 9,000 marks per 100 kilos. to 2,800 marks in 1892 and 1894.

The export values of *other alkaloids* enjoyed a more rapid increase than that of any other chemical industry, notwithstanding a decrease in the average values from 11,000 marks per 100 kilos. to 9,000 marks in 1893. The imports and their average value suffer considerable variations in the individual years, due to variations in a cheap Russian alkaloid (900 marks per 100 kilos.) and to the high price of cocaine (55,000 marks per 100 kilos.).

The imports (chiefly from England and France) and exports of *scented and shaped soaps* show a gradual increase, the latter reaching a maximum of 1,612 tons in 1893. The average values per 100 kilos. are 200 marks for imports, 150 marks for exports.

Among *perfumes* the scented waters occupy the most important position, increasing in value from 3·8 million marks to 5·63 million marks in 1893; the imports are valued at 1,000 marks up to 1889 and 950 marks since then; the exports at 500 marks per 100 kilos.

In *other perfumes* the important position attained by German West Africa has to be noticed (72 tons out of 288 tons in 1893). The import values are 500 marks, the export values 400 marks per 100 kilos.

## II. C.—RESIN OILS, LACQUERS, AND GLUE.

	Imports.		Exports.	
	Tons.	Thousand Marks.	Tons.	Thousand Marks.
Turpentine oil.....	9,816 up to 15,823	4,908 up to 7,524	1,110 up to 1,658	540 up to 895
Lacquers and varnishes.....	573 „ 678	1,431 „ 1,695	559 „ 750	1,050 „ 1,462
Glue.....	1,681 „ 2,085	354 „ 1,299	3,060 „ 4,042	2,976 „ 3,840
Dextrine and.....	129 „ 265	49 „ 119	4,361 „ 9,453	1,211 „ 2,930
Gelatine.....	56 „ 114	112 „ 571	389 „ 502	1,134 „ 1,277
Other materials.....	367 „ 446	430 „ 792	1,275 „ 1,849	728 „ 1,116
Total.....	12,879 „ 19,135	8,654 „ 11,006	11,611 „ 16,904	8,512 „ 16,123

The imports of *turpentine oil* are on a steady increase, three-fifths of the total amount coming direct from the United States and a considerable amount from Russian Poland. The exports are directed chiefly to Austria and Switzerland. The import values amounted to 50 marks in 1885, 58 marks in 1888, and 437 marks in 1893. The export values between the years 1887 and 1892 were 7—12 marks below the former.

One half of the imports of *lacquers and varnishes* are derived from England; the remainder from Holland, the States, France, &c. Since 1891 the exports remain fairly stationary at 550—600 tons, divided among a number of countries. The imports are valued at between 220—250 marks per 100 kilos., the exports at 165—290 marks.

*Glue* lost the Austrian and Dutch markets, but found compensation in England, the States, and English North America; the prices, however, receded from 100 marks per

100 kilos. to 70 marks in 1893. The imports are valued at 25 marks less (1893: 15 marks), and reached a maximum in 1890, 1,734 tons in 1892, and 1,958 tons in 1893.

Owing to the McKinley tariff and the high price of potatoes the exports of *dextrine* and *gelatine*, which rose from 4,657 tons to 9,455 tons in 1890, rapidly fell back to 4,361 tons in 1892, but recovered in 1893 to 7,366 tons. The prices varied in accordance, rising from 24 and 32 marks per 100 kilos. (1885—90), to 35 and 37 marks (1891 and 1892), and receding in 1893 to 25 marks.

The exports of *gelatine* lost ground in Holland, Belgium, and Russia, but this was more than compensated by the increased demand for England and the States. There is a simultaneous decrease of imports to 60—75 tons. The average values receded from 310 marks to 220 marks for exports, and from 290 marks to 200 marks per 100 kilos. for imports.

## H. D.—EXPLOSIVES.—MATCHES.

	Imports.		Exports.	
	Tons.	Thousand Marks.	Tons.	Thousand Marks.
Gunpowder .....	284 up to 1,002	68 up to 1,875	2,772 up to 6,431	4,127 up to 10,267
Explosives.....	1 " 600	16 " 950	1,457 " 2,578	2,315 " 4,125
Artillery.....	2 " 1,593	61 " 3,184	582 " 2,374	1,959 " 5,461
Matches .....	167 " 475	109 " 285	1,532 " 2,592	767 " 1,385
Other materials.....	157 " 225	246 " 310	345 " 567	433 " 707
Total .....	655 " 2,831	722 " 4,723	7,689 " 11,944	12,844 " 18,750

When deducting imports due to exceptional circumstances, the total import value of this sub-division fluctuates between 604,000 and 1,062,000 marks.

The chief consumers of German *gunpowder* and *blasting powder* are to be found in the West of Africa. The following are the turning points of the export trade:—

	1885.	1887.	1890.	1892.	1893.
Africa.....Tons	1,089	649	2,050	1,559	1,611
England..... "	1,658	816	554	70	1,016
Others..... "	1,531	1,307	1,707	1,533	
Total..... "	4,278	2,772	4,311	3,162	2,627

Other countries concerned are chiefly China, Bulgaria, and Brazil. The Russian, Dutch, Australian, and Japanese demands have, more or less, ceased. The values receded from 240 marks to 140 marks per 100 kilos.

The exports of *explosives* reached a maximum in 1890; they amounted in 1893 to 1,723 tons. The Transvaal

market is now in French hands, the Cape Colony in English hands. Notwithstanding conventions and trusts, the average values show a decrease from 250 marks per 100 kilos, in 1885 to 160 marks in 1889, and remain now stationary.

The exports of *artillery* were greatly influenced by Government orders. Chinese orders brought them up to 923 tons in 1885; Turkish orders, since 1889, and Chinese in 1892, up to 2,374 tons; Brazilian, Argentine, and Spanish orders up to 3,683 tons. The values were: from 1885 to 1889, 330—340 marks per 100 kilos.; 1890, 255 marks; 1891, 245 marks; 1892, 230 marks; 1893, 275 marks.

The imports of *matches* from Sweden and Austria are on the decrease. The exports amount to one-fourth of the Scandinavian, and have been greatly hampered in the East by the Japanese competition, and in Austria by the high protective duties which came in force in 1888. New markets were opened up in Belgium, Holland, Central America, Hayti, and Brazil. The decrease was most marked in 1888 and 1889, with 1,712 and 1,532 tons respectively. The average values for exports are, per 100 kilos, 55 marks for 1885 and 1886, and since then 50 marks; for imports they are 10 marks higher.

## H. E.—PITCH, TAR, AND TAR DISTILLATES.

	Imports.		Exports.	
	Tons.	Thousand Marks.	Tons.	Thousand Marks.
Pitch .....	2,313 up to 18,113	324 up to 2,536	7,999 up to 14,980	1,280 up to 2,357
Tar.....	29,392 " 36,890	1,617 " 2,868	9,015 " 17,448	496 " 1,221
Light tar oils.....	5,683 " 7,618	2,536 " 6,501	224 " 916	94 " 779
Anthracene .....	4,252 " 6,699	2,224 " 5,359	0 " 25	0 " 12
Carbolic acid .....	698 " 3,530	798 " 5,351	662 " 3,860	777 " 3,560
Wood spirit.....	490 " 937	490 " 1,124	477 " 817	668 " 1,143
Aniline oil .....	276 " 470	413 " 836	1,680 " 4,660	2,548 " 8,366
Other materials.....	2,306 " 5,237	332 " 786	1,213 " 3,445	198 " 524
Total .....	47,893 " 74,434	9,356 " 21,364	25,321 " 6,584	7,240 " 15,600

The commerce in *pitch* is characterised by two phenomena. On the one hand the imports, amounting to not more than 3,500 tons up to 1887, show suddenly a considerable increase, chiefly from England and Holland, thus:—

	1888.	1889.	1890.	1891.	1892.	1893.
Total imports .. Tons	8,319	12,111	18,113	13,819	11,506	27,769
English and Dutch imports.	6,592	10,323	14,695	11,310	9,649	25,02

The increase is most likely due to the utilisation of *pitch* for briquette making. On the other hand, the exports to France show most erratic variations since 1880:—

	1880.	1883.	1885.	1892.	1893.
Exports to France.. Tons	4,437	12,236	1,411	8,323	3,385
Exports to other countries.	6,082	12,108	6,588	6,651	5,793
	10,519	24,434	7,999	14,974	9,178

The exports of *tar* moved from the years 1886-92 between 9,000 and 12,000 tons, increasing to 14,500 tons in 1893, chiefly on Russian orders. The imports rose in 1893 to 39,722 tons.

Pitch was valued since 1885 at 14 marks per 100 kilos, for imports and at 16 marks for exports; tar at 8 marks for imports and 7 marks for exports in 1885, 6·5 marks for both in 1886, 5·5-5·3 marks up to 1892, and as low as 4·5 marks in 1893.

The demand for *light coal-tar oils* of English origin is undoubtedly on the increase, notwithstanding the increased home production in the manufacture of coke. The average values for imports and exports increased gradually from 40 marks in 1885 to 85 marks in 1890-92, with a reduction in 1893 to 55 marks for imports and 45 marks for exports.

The imports of *anthracene*, chiefly from England, reached a maximum in 1891 and suffered a reduction to 5,523 tons in 1893. The average values per 100 kilos, increased gradually from 50 marks in 1886-87 to 80 marks in 1890-93.

*Carbolic acid* was subject to great variations owing to its use for the manufacture of picric acid, which in its turn is required for explosives, and furthermore owing to the prevalence of cholera in 1892. The imports, chiefly from England, fluctuated between 700-800 tons in 1885 and

1887, 1,192 tons in 1888, 2,432 tons in 1889, 1,543 tons in 1891, 3,530 tons in 1892, and 2,572 tons in 1893. The exports kept from the years 1885 to 1891 within 660 and 1,380 tons, increasing in 1892 to 3,860 tons, chiefly on Russian and Austrian account, and falling to 1,820 tons in 1893. The import values per 100 kilos, were 110 marks in 1885, 220 marks in 1889, 115 marks in 1891, 130 marks in 1892, and 75 marks in 1893. The export values were 160 marks in 1885, 180 marks in 1889, 80 marks in 1891, 100 marks in 1892, and 55 marks in 1893.

The imports of *wood spirit* rose from 772 tons in 1892 to 1,581 tons in 1893, chiefly owing to its use for denaturing alcohol. The chief importer is Austria. The average values for imports and exports amounted to 140 marks in 1885, 100 marks in 1886; in the subsequent years 100-130 marks for imports and 15-20 marks more for exports.

The exports of "*aniline oil*, aniline salts, and other not enumerated coal-tar substances," are continually on the increase: for 1893, however, a fall has to be recorded to 4,996 tons, chiefly due to Russia and the States. The average import and export values varied between 150 and 200 marks from 1885-1891, receding to 140 marks in 1892 and 120 marks in 1893.

The home consumption of *indigo* must be characterised as most erratic; thus, when taking the difference between imports and exports, the home consumption for 1892 amounts to 1,124 tons, for 1893 to 681 tons. The direct imports from the East Indies amount to one-third of the total imports. The average values were 1,300 marks per 100 kilos, in 1885, falling uninterruptedly to 950 marks in 1890, and rising to 1,150 marks in 1893.

The chief consumer for *dye-wood extracts* is Austria, with 30 per cent., and in 1893 with 37 per cent. of the total exports. The values are pretty constant at 75 to 84 marks for imports and 80-89 marks per 100 kilos, for exports.

*Catechu* is obtained in increasing measure direct from the East Indies. The variations in the exports are due to the fluctuating Russian demand. The average values up to 1890 were between 49 and 57 marks per 100 kilos, falling to 40 marks in 1893.

*Coal-tar colours* constitute the leading article of export of the German chemical industry, alizarine and aniline dyes alone amounting to 20-26 per cent. of the total.

*Aniline and other coal-tar colours* (exclusive of alizarine and picric acid) show a most remarkable increase of exports, from 2,141 tons in 1880 to 11,560 tons in 1893. On the other hand, the average values decreased from 1,450 marks per 100 kilos, in 1880 to 460 marks in 1893. The chief consumers are the Continent, England, the United States, South and East Asia. The imports, chiefly from Switzerland, are on the increase since 1885.

*Alizarine* had its own vicissitudes, partly owing to the lapse of Gräbe and Liebermann's English patents. The exports to the various countries are shown in the table on next page.

The average values were 350 marks per 100 kilos, in 1880, 222 marks in 1885, falling after the dissolution of the German alizarine syndicate in 1886 to 175 marks, in 1892 to 155 marks, and in 1893 to 145 marks.

The great demand for *picric acid* in 1889 (for explosives) considerably increased the imports and the values; the latter amounted to 235 marks per 100 kilos, in 1885, 350 marks in 1889, and 170 marks in 1893.

*White lead* and *zinc white* are kept separate since 1888. The former is exported chiefly to England and lately to English North America, the total amounting to 11,700—13,700 tons; the imports, chiefly Dutch, fell from 1,100 tons to 700 tons (1893: 932 tons). The exports of zinc white are increasing from about 8,500 tons in 1889 to 12,300 tons in 1893, whilst the imports are stationary at 2,600—3,300 tons.

	1880.	1885.	1889.	1892.	1893.
England .....	3,716	1,910	3,164	2,224	2,727
United States.....	589	877	1,291	1,877	1,234
English East Indies ..	..	..	877	1,585	1,911
France.....	129	139	291	515	228
Other countries ....	1,454	1,328	2,170	1,976	1,966
Total ....	5,888	4,284	7,793	7,677	8,036

*Minium* was in request up to 1887, but since then the exports move between 5,100 and 6,000 tons.

The exports of *ultramarine* are decreasing, and amount to one-half to two-thirds of the total German production. The imports share a similar fate. The import values are estimated at 69 m. per 100 kilos. from 1887 to 1893, the export values to 56—58 m.

*Cinnabar* is consumed chiefly in England, Russia, and Austria. *Berlin blue* in England, Belgium, South-east Asia, and the States. The imports of Berlin blue are on the increase, chiefly on Dutch and Belgian account, but the stuff turns out to be of French origin. Remarkable is the simultaneous fall in the import values from 185 m. per 100 kilos. in 1891 to 80 m. in 1893, whilst the export values for the same period move between 185 and 220 m.

*Gold preparations* are valued at 46,000 m. per 100 kilos. England takes about one-half of the exports.

The exports of *paints and pigments* increased from 1,021 tons in 1888 to 1,354 tons in 1893, chiefly to England, the States, Russia, and South America. The average values are 120 m. per 100 kilos. for exports, 105 m. for imports.

The exports of *black and coloured lead pencils* increased to 1,090 tons in 1893; the destination of one-fourth of this quantity is England. The increase in the imports is due to a reduction in the duty on graphite in compressed tablets, according to the Austrian commercial treaty of 1891. The average import values amounted to 270—300 marks per 100 kilos. up to 1891, and 160 marks in 1892. The export values were 350 marks up to 1889, and receded lately to 300 marks.

In consequence of a change of classification the imports of "dyestuffs, tanning materials, and pigments not enumerated" record a considerable increase, with a corresponding decrease of the values from 90 marks to 80 marks. The exports reached a maximum in 1891 and receded to 4,523 tons in 1893, with an average value of 200 marks per 100 kilos.

On the whole the above is to Tentons a very satisfactory picture of the development of the German chemical industry. The exports of many important products indicate phenomenal progress, and in many instances foreign competition is successfully repelled at home. But in some cases new successes are achieved by foreign goods.—H. A.

#### PHOTOGRAPHIC EXHIBITION AT THE IMPERIAL INSTITUTE.

The Executive Council of the Imperial Institute announce that a special exhibition of photography in its applications to the arts, sciences, and industries will be held at the Imperial Institute during the summer season of 1895. An influential committee of advice has been formed, and sub-committees have been appointed in connection with the seven sections of the exhibition, viz.:—

1. The history of photography, including illustrations of early processes, the progressive development of processes,

the early processes of photomechanical work and modern photographic literature. 2. Artistic photography, with illustrations of the present condition of photographic art in the various colonies and in India. 3. Photography as an industry, demonstrating the apparatus used in photography and the special processes connected with the preparation of lenses, the production of brass fittings, cameras, &c., shown in actual operation; the preparation of dry plates, coating of sensitive media, printing processes also shown in actual operation; reproduction of pictures, and the production of portraits by daylight and artificial light. 4. Photography in its application to industries, such as reproductions having photography as their basis. 5. Applications of photography to the sciences, including orthochromatics, optics, stereoscopy, photomicrography, spectroscopy, metrology and magnetism, astronomy, automatic recording apparatus, &c. 6. Applications of photography to educational purposes. 7. Miscellaneous applications of photography.

Notification of the exhibition will shortly be transmitted to the principal firms engaged in the manufacture of apparatus connected with photography in the United Kingdom. The Governor-General of India, the Governor-General of the Dominion of Canada, and the Governors of the various colonies have, by a recent mail, been requested to invite Indian and Colonial manufacturers to exhibit.—*Chemist and Druggist*.

#### BUYING TURPENTINE BY WEIGHT.

In Canada a system is coming into use of buying turpentine by weight, owing to the losses suffered by retailers through the exudation of the liquid and other causes. It is found that a barrel, supposed to contain 50 gallons, never contains more than 49. The rule for ascertaining by weight the contents of a barrel is, after deducting the tare of barrel from the gross weight, to divide the product by  $8\frac{2}{3}$ , the number of pounds to the imperial gallon, the remainder representing the number of gallons contained therein. Thus—

450 lbs. gross.
75 lbs. tare.
—
$8\frac{2}{3}$ 350
—
41 $\frac{1}{3}$ gallons.

Manifestly the only proper way, the only just way, to buy turpentine is by weight.—*Ironmonger*.

#### INDIA AS A FIELD FOR INDUSTRIAL ENTERPRISE.

The numbers employed in the trades of India are as follows:—There are nearly 2,000,000 oil pressers—showing what an opening there is for a cheap and useful oil mill; on the other hand, of gas and candle makers there are only 1,233—while the use of kerosene oil is spreading enormously—another indication of material progress. There are also:—

	Nos.
Arms and ammunition, blasting powder, fireworks, swords, bows, and arrows.	42,365
Brass and copper .....	105,610
Brick and lime burners, besides those included among potters.	410,142
Earthenware and stoneware, potters, &c. ....	2,346,204
Glass and china .....	11,419
Gums, dyes, and drugs. ....	391,575
Iron and steel makers and sellers .....	1,572,911
Leather tanners, mostly villagers .....	3,285,397
Paper, exclusive of prison labour .....	78,153

AMMUNITION, &c.—The very roughest kind of gunpowder is manufactured all over the country and used for blasting and for fireworks. The necessary ingredients are found everywhere, and improved methods of manufacture should be introduced. That they may be taught the trade is proved by the success of the Government establishment for the manufacture of service powder and cordite.

**EARTHENWARE, &c.**—There is no reason in the world why the skilled potters of Hindustan should not be taught the higher branches of ceramic art. Even such common articles as gallipots are imported.

**LEATHER, &c.**—The Cawnpore factories, where leather goods of all kinds are manufactured, could hold their own anywhere; it seems incredible under these circumstances that any hides should be exported, or leather goods imported, not to mention the horns and bones, which should all be kept in the country for the country's good.

**MASONS, &c.**—Of these only 17,678 are returned as builders. Amongst the stonecutters are reckoned the carvers in steatite or soap stone, also called French chalk. There are large quantities of this stone to be found at the marble rocks near Jabulpore, at Mora in Jaipur, near Tehri, and Orchha in Bundelkand, and in the Kurnal district in Madras, where it is called *bulpum*. These places are easy of access, and the men who have worked in it for generations might be trusted to select the right kind of stone for gas-burners, fire-proof paint, lubricants, and marking-chalk for tailors. German steatite costs quite three times as much as the Indian stone would come to landed in England. Some 50 specimens were sent home some years ago, but nothing came of it.

**Music, &c.**—The musical instrument *par excellence* throughout India is the tun-tum or hand-drum. Square acres of parchment, made of goat or sheep skin, are used for the heads; this parchment should be prepared by machinery.

**PAPERMAKERS, &c.**—The number given is exclusive of prison labour, which turns out a rough article made by hand, much affected by the natives for writing on with their woden styles. The same kind of paper is also made elsewhere; but paper mills are being erected, as will be stated further on. The whole of the 290 tons of paper used in the last Indian census was made near Calcutta. In Gwalior there are also mills, which use the special quality of grass employed for tough paper. Poona and Lucknow have their paper mills too. There is also a project on foot for using bamboos as pulp in Burma. Tenders should be asked for in India by the British Government for blue books and other publications, especially as they claim that they go to the open market for the enormous quantity of paper required.

**TIN, &c.**—Kerosene oil tins are now converted into lamps, water cans, and plates for roofing. But besides the kerosene tins there is an enormous amount of tin which now finds its way into the scrap heap—the tin lining of cases, the empty provision tins, &c. If a process of removing the tin could be introduced, the material is all there ready to hand.

**TOOLS, &c.**—Sugarcane presses are a success; Swedish ploughs are obtaining a footing; but a fortune awaits the man who successfully introduces an oil press or a hand loom that can be manufactured in the country and be repaired by village artisans. Some very fair cutlery is turned out in some parts.

**FUEL.**—The fuel consumed on the railways was, in tons:—

Coal, English .....	178,656	Indian .....	919,943	Coke .....	1,957	Patent fuel.....	6,135	Wood .....	358,756
As compared with previous year...decrease	25,711	Increase .....	153,801	Decrease .....	1,541	Increase .....	1,996	Increase .....	55,916
Percentage .....	12.58	" .....	6.21	" .....	48.22	" .....	48.22	" .....	18.46

As compared with previous years the total consumption of coal increased 2.62 per cent. The consumption per 1,000 tons gross miles varies from 127.13 lbs. on the Bombay, Baroda, and Central India, to 286.82 lbs. on the South Indian; and the average cost of fuel per ton, from Rs. 1.86 on the East Indian, which uses Indian coal exclusively from its own collieries, to Rs. 4.89 on the North-Western, where the average lead for the coal varies from 140 miles for the very indifferent coal found on the line, to 255 miles for Bengal coal, and where large quantities of wood fuel are used, amounting to 30 per cent. of the whole. This wood has an average lead of only 50 miles, but the supply is gradually diminishing.

There was actually less coal got in India in 1893 than in 1892, as the following figures will show, the decrease being entirely due to restricted output in Bengal. The total output in 1880 was 1,019,793 tons.

coal resources of the country, and, if the colliery labour is interfered with, another obstacle will be put in the way of progress.

Most of the imported coal is English, but some has been sent from Australia and a small quantity from Japan. Briquettes are not manufactured or imported in any large quantity, but there is a good market for them, both for machinery and for domestic use.

With regard to petroleum, only the figures for 1892 are available, and are as under:—

—	Assam.	Baluchistan.	Burma.	Punjab.	Total.
	Gallons.	Gallons.	Gallons.	Gallons.	Gallons.
1891	23,000	138,000	5,793,000	2,000	6,136,000
1892	22,000	3,000	8,098,000	2,000	8,725,000

The Yenangyaung field in Upper Burma has been worked for eighteen years by the Burma Oil Company, which has a refinery at Rangoon, and a sufficiency of machinery and skilled workmen; the increase in the Burmese figures is almost entirely due to their operations. The Assam oil field is valuable, and when the railway reaches the tract an enormous increase in the yield may be expected. Locomotives should be so designed as to use either coal or crude oil, or a mixture of both. The slack coal in the Punjab and Baluchistan, which at present breaks the hearts of the engine drivers, should be made into briquettes. Meanwhile the imports of petroleum are also increasing enormously, and will continue to do so as tank steamers and tank waggons increase. Already the earth oil is displacing vegetable oil in even the remotest villages in the land; but a cheap safe lamp is wanted and wick manufactories should spring up everywhere.

Total.....	13,883,838	58,069,000	67,096,000

Iron ore of surpassing richness is found in the Central Provinces in Madras and in other parts, but is not worked to any large extent, except at Barrakur, in Bengal, about 150 miles from Calcutta, near the East Indian Railway. Here are found coal, iron, and lime close to the works, and yet it has taken 20 years to make them a success. The company turned out last year 10,017 tons of pig iron and 3,970 of castings, and sold 12,917 tons of pig and 4,253 of castings; this being the first year in which a market has been found for all the output of the year. "The capital expenditure of the company up to September 1892, was Rs. 185,000. The total profit on the working of the year in India came to 10½ per cent. on the total capital, against 5 per cent. in the preceding year."

Paper, other than hangings.....	175,905	"
Spirits.....	179,487	Risen

Note.—"Risen" and "Fallen" indicate that the figures have changed from the year before: "Rising" and "Falling," that the change has been going on for some time.

The export trade to the United Kingdom does not keep pace with the increasing export trade as a whole; and the direct shipments to the continent of Europe, especially to Belgium and Germany, are constantly increasing.

## Indian Production and Consumption.

CHEMICALS.—Increasing largely. There is a good field open for local manufacturers of aniline and alizarine dyes, the imports of which have doubled in the last five years. Out of 94,782,000 ounces landed last year, 84,318,000 came from the Continent. They are replacing the indigenous dyes, and are said to be preferable to them for common use.

COPPER.—Imports depend on prices and on good harvests, when more copper utensils are made. If the cost of these

could be cheapened the sale would be enormously increased. Belgium is sending yellow sheathing in increasing quantities.

DYES (see Chemicals also), 1890-9.—The normal area under cultivation is about 1,100,000 acres; 50 per cent. in Lower Bengal, and about half and half of the remainder in the North-West Provinces and Madras.

GLASS.—India possesses only one glass factory, and this is in Calcutta. There are a few smaller glass factories, but when they do not use broken imported glass, they turn out goods of an inferior quality. Most of the broken glass that reaches the ports of India is sent to China, where it is worked up by the Chinese glass-workers. Good glass-making materials are to be found in India, and a factory for the manufacture of soda-water bottles alone would find occupation for a large number of operatives. Window-glass is now largely used throughout India where only shutters were used heretofore. It is obtained principally from Belgium, but English soda-water bottles, either from the superior material used in their manufacture, or on account of more careful testing, are found to be better than those of other countries.

PAPER.—Nine mills, of which four are in Bombay, turned out 26,834,692 lbs. of paper in 1891, an increase of 118 per cent. since 1885; ten years ago only 7½ million lbs. were made. The quality of the paper has improved of late years, and there is a large and increasing sale for it. Government professes to encourage local enterprise in every way, and yet they do not get their 127½ million railway tickets in India. Were they to do so, it would keep one mill going for six months. The materials used are: rags, babui and moonj grasses, rice straw, jute and hemp cuttings, old jute bags and cloth.

SALT.—The imports into Bengal and Burma are steadily declining, while the local consumption is increasing; it was 31,355,910 maunds in 1888-89, and 35,051,391 maunds in 1892-93. This is almost entirely due to the extension of railways, as the price of salt is mainly affected by the cost of transport. An increase of consumption is also an indication of greater prosperity. This price of Liverpool salt declined from Rs. 96 per 100 maunds in 1883-84, to Rs. 61·8 in 1892-93, but is rising again.

Imports from	1888-89.	1892-93.	Remarks.

Aden (lowest) ..	17,397	37,282	(Highest.)
Other countries ..	16,484	8,421	Lowest, 4,481 in 1891-92.
Total.....	398,810	359,042	

The following manufactures could also be produced in India, the raw materials and skilled labour being available:—Explosives, earthenware and porcelain, fireworks, glass, leather goods, matches, oil- and floor-cloth, paints and painter's materials, paper and pasteboard, and soap.

## Indian Exports for 1892-93.

Articles.	Rs.	Remarks.
Dyes other than indigo.....	802,013	Rising.
Hides and skins.....	5,591,934	"
Indigo.....	4,141,179	"
Lac.....	784,959	Fluctuates.
Oils.....	595,568	Rising.
Opium.....	9,253,013	Falling.
Sugar.....	597,014	Fluctuates.

*Indian Re-exports in 1892-93.*

Articles.	Rx.	Remarks.
Cum. ds. ....	76,682	Rising.
Copper .....	133,338	"
Glass .....	43,175	"
Gums and resins .....	67,208	Falling.
Sugar (refined) .....	328,980	Rising.

**EARTHNUTS.**—About 40 per cent. of the whole trade is exported from the French Indian ports, being mostly grown in the neighbouring British territory, and from Bombay and Madras. This nut is also called the ground or pea-nut, being *Arachis hypogea*. An average crop yields about 50 bushels per acre. In Europe it is used as a substitute for salad oil, in the manufacture of soap and of lubricants; also as lamp oil and for dressing cloth, and as a constituent of margarine; the consumption being 100,000 tons a year. Formerly the oil was prepared in India, but now the nuts are chiefly sent to Barcelona, Marseilles, and Genoa. It is eaten in India and also largely in the United States, where, however, the Indian product does not find favour for that purpose. The amount exported in 1892-93 was 1,525,000 cwt., having been practically stationary during the last three years. However, the cultivation is extending in Madras. It is extensively used in Marseilles, where the husked nut, as received from India, is ground for soap-making by rather rude machinery. The most modern cotton-seed mills would be most suitable for extracting the oil, with a little additional care, due to the difference in value of the raw product. A steam oil-mill was started in Pondicherry in 1890-92, but from various causes was not a success. There is no reason why this industry should not be successful in India, especially as the by-products are of distinct value. Forty-eight pounds of husked nuts are sufficient wherewith to sow an acre. In the Bombay Presidency a good crop usually yields about 4,800 lbs. of unhusked nuts per acre; the average crop on good land being about 3,500 lbs. The yield of oil in Bombay is often as much as 50 per cent. of the weight of milled seeds; in Madras it is 43 per cent., and in Pondicherry 38 per cent. By cold pressing the quality of the oil is improved, by heat the quantity. The shelled nuts are sent to Europe, the pods to Burmah and the Straits Settlements, oil to these places and Mauritius, and oil-cake to London, Ceylon, and the East. With ground nut-oil, ghee and pure gingelly oil is adulterated. In Southern India the exportation of these nuts is most extensive, and nine-tenths of it is monopolised by the natives. The following figures for 1891-92 will show the proportion raised in each district and the destination of the exported nut.

From	Cwt.	To	Cwt.
Bengal.....	84	United Kingdom....	45,069
Bombay .....	1,041,987	Belgium .....	98,271
Sand .....	138	France.....	1,185,358
Madras .....	187,668	Germany .....	8,974
Burma.....	63	Italy.....	74,845
		Egypt.....	93,097
		Others .....	5,547

**CHEMICALS.**—The exportation of cinchona bark was 3,074,000 lbs. in 1888-89, 2,643,000 lbs. in 1891-92, and 2,814,000 lbs. in 1892-93, besides what was consumed locally. There are large Government plantations in the Darjeeling district, containing nearly  $4\frac{1}{2}$  million cinchona trees, the harvest of the year being 304,000. In similar Government plantations in the Nilgiri Hills the harvest was 119,000 lbs.

**COCONUT PALMS.**—The export of the products of these amounted to Rx. 486,688 from 1891 to 1893. Out of the fibre, or *coir*, is made matting, cordage, rugs, and brooms; of the *oil*, candles and soap are manufactured; of the *oilcake*, manure and food; and of the *toddy*, sugar and spirits. The local consumption of these articles is enormous.

**HIDES.**—There is an increased demand for tanning purposes in India, and also for goat-skins, of which the United States take three-quarters. Gloves and parchment should be manufactured wholesale in India.

**Tanned Hides and Skins** have risen since 1889-90 from 260,716 cwt. and Rx. 2,521,008 to 298,930 cwt. and Rx. 2,956,439. The trade is now established on a sound basis, and should increase enormously in the near future. In Japan, for instance, the natives are producing quantities of fine leather for travelling bags, &c.

**MANURES.**—17,584 tons of bones were exported, which should have been ground and used in the country; also 1,032 tons of other manures, which should also have been used locally.

**OILS.**—If the wealth of oil-producing materials be taken into account, it is passing strange that so little oil is exported. "Oil has been expressed for many centuries by the 'ghanee,' a mortar having a revolving pestle driven by hand or bullock power. The residual cake contains a large quantity of oil, and is fed to the cattle. This mill is in general use, excepting where Europeans have a hand in the production—European machinery, of course, giving better results. Until six or seven years ago, vegetable oils were almost exclusively used for every kind of lubrication in India." A similar mill to that introduced for sugar (which see) would be equally successful.

**OPIMUM.**—75,384 chests were made in 1892-93. The following figures tend to show that, where the opium shops are numerous, there the liquor shops are few, and *vice versa*.

Number of Retail Shops Licensed in 1892-93 for the Sale of	Bengal.	N.W.P.	Punjab.	Burma.	C.P.
Spirits .....	20,887	11,437	1,747	1,413	7,589
Opium and other narcotics.	4,670	4,912	3,401	34	2,180

Number of Retail Shops Licensed in 1892-93 for the Sale of	Assam.	Madras.	Bombay.	Berar.	All India.
Spirits .....	326	31,422	5,068	2,114	82,063
Opium and other narcotics.	1,138	1,276	2,415	962	20,988

**SEEDS.**—*Castor.*—The seeds are exported in increasing numbers for manure cakes, and for inferior qualities of lused cake. It is not recommended for cattle, being a purgative. There were 989,000 cwt. exported in 1892-93, and the quantities are increasing. The oil is used in India as an illuminant and a medicine, and is exported to the United Kingdom and Australia for lubricants.

*Linseed.*—A marketable article has been produced, as an experiment, in India of this fibre. There are 4,000,000 acres under cultivation, producing 2 cwt. an acre. The maximum area is 5,000,000 acres. The seed is used as food to a limited extent; the quantity crushed for oil is still less, such demand as exists being met by importation. Eight million cwt. of the seed are exported now. The seed yields 30 to 35 per cent. of oil, which is used in the manufacture of paint, floorcloth, oil-varnish, and soft soap—all of which should be made in the exporting country. Pure linseed is unknown; the oilcake is of great importance as a cattle food, for which the Indian seed, being richer than the Russian, is preferred.

**Poppy.**—The seed is used as food in India, and the oil for cooking and lighting. Belgium and France take the bulk of the exports, using the oil for soap, for adulterating olive oil, and for painters' colours. The amount exported in 1892-93 was 502,000 cwt., and is decreasing.

**SODA WATER.**—This is made everywhere; three years ago there were 72 factories; the carbonic acid is employed in the manufacture of spurious sparkling wines. As most of the water used is anything but nice, the taste for this product is quite an acquired one. In Karachi, before the Mulleer water was brought in, it was made of brackish water; there is, therefore, not much likelihood of an export trade springing up.

**SUGAR.**—The export trade, which is carried on mostly from Madras, is struggling for existence—although it should be thriving, if the cultivation of cane were encouraged. At present the production of the country is not sufficient for local consumption; the quantity imported to supplement local supplies was more than double the quantity exported—viz., 836,234 cwt., in 1892-93.—*The Indian Engineer.*

### BOARD OF TRADE RETURNS.

## Monthly Patent List.

\* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

#### APPLICATIONS.

19,529. G. C. Douglas.—From W. Don and T. Watson, India. Improvements in non-conducting composition for retarding the flow of heat from, or to, boilers, cylinders, refrigerators, and the like. October 15.

19,691. J. Lyle. Improvements in retorts for heating, drying, or destructive distillation. October 16.

19,753. T. Illingworth. Improvements in apparatus for steaming textile fabrics, also applicable for drying fabrics. Complete Specification. October 17.

19,832. T. Cudlipp. Improved hydro-extractor. October 18.

20,061. J. Mitchell. Improvements in or relating to fastening devices for the doors of gas retorts. October 20.

20,175. O. Perrier. Improvements in processes and apparatus for distillation. Complete Specification. October 22.

20,202. J. Entwisle.—From W. L. Wallis, United States. An improvement in gas purifiers for furnaces. Complete Specification. October 23.

20,480. J. J. Meldrum, T. F. Meldrum, and J. W. Meldrum. Improvements in or connected with the treatment of liquids by gases. October 26.

20,874. A. Bloch. Improvements in apparatus for mixing liquids and gases. October 31.

21,298. F. W. Kent. Improvements in and connected with valves for hot or cold water, steam, or other liquids or gases, and improved methods of operating the same. November 6.

21,326. W. P. Thompson.—From J. Furbringer, Austria. Improvements in muffle furnaces. Complete Specification. November 6.

21,372. B. Abeil. Improvements in evaporating apparatus. November 6.

21,527. F. W. Berk. An improved apparatus for cooling acids or other fluids. November 8.

21,615. J. B. Lee. Improvements relating to the construction of thermometers. November 9.

21,631. E. Orval. Improvements in drying kilns. Filed November 9. Date applied for 9 May 1894, being date of application in Belgium.

21,633. H. H. Lake.—From H. See, United States. Improvements in evaporating apparatus. Complete Specification. November 9.

21,778. I. S. McDougall. Improvements in evaporating-pans for the concentration of sulphuric acid and other liquids. Complete Specification. November 12.

21,946. W. Thomson and P. J. Worsley. Improvements in and connected with furnaces for treating chemicals, ores, or the like. November 13.

22,262. J. Benson. Improvements in apparatus for ascertaining the amount of acidity in liquids. November 17.

#### COMPLETE SPECIFICATIONS ACCEPTED.\*

1893.

21,000. P. D. de la Grée. Improvements in and relating to evaporating apparatus. November 7.

21,761. The Manchester Oxygen (Brin's Patent) Co., Ltd., and W. M. Jackson. Improvements in means for utilising the pressure in cylinders or reservoirs containing compressed gases, in the application and use of such gases. October 31.

1894.

24. J. B. Hilliard. Preventing gases from intermingling while passing through liquids. November 7.

358. J. B. Allott. Improvements in apparatus for drying or evaporating viscous semi-solid or other materials at low temperatures. November 21.

1098. H. H. Lake.—From the Actien Gesellschaft für Kohlensäure-Industrie. An improved cap for cylinders or receptacles for containing liquid or gas under pressure. November 21.

9049. E. A. Fehling and A. Steinbart. Improvements in and relating to processes and apparatus for analysing gases and gaseous mixtures. November 14.

17,289. H. E. Newton.—From E. Hart. See Class VII.

17,314. J. S. Detwiler. Improvements in apparatus for treating powdered materials. November 7.

17,315. J. S. Detwiler. Improvements in apparatus for blending powdered materials. November 7.

18,214. H. H. Lake.—From R. Schicht. An improved method of and apparatus for drying substances which are viscous or semi-fluid in the hot state. October 31.

19,169. G. L. F. Edeline. An improved composition for the prevention of incrustation in boilers. November 14.

19,753. T. Illingworth. Improvements in apparatus for steaming textile fabrics. November 21.

### II.—FUEL, GAS, AND LIGHT.

#### APPLICATIONS.

19,689. W. G. Smith. Improvements in the manufacture of night-lights. October 16.

19,692. J. Lyle. Improvements in the manufacture of solid petroleum fuels. October 16.

19,693. J. Lyle. Improvements in the manufacture of asphaltic compounds. October 16.

19,815. H. Tempest. Improvements in the manufacture of fuel-blocks or briquettes. October 18.

20,066. W. E. Price. Improvements in apparatus for carburetting coal gas or other gaseous fluid. October 20.

20,178. R. Schewe and F. Messedat. A composition for improving petroleum and method of producing such composition. October 22.

20,253. P. C. Tennant and J. E. Hall. Improvements in and relating to apparatus for regulating or controlling the supply of fluids, chiefly designed for use in connection with apparatus for carburetting or enriching gas. October 23.

20,375. F. K. Byerley. Improvements in the manufacture of asphalt and the like from petroleum and in apparatus therefor. October 24.

20,414. R. Fegan. Improvements in the manufacture of briquettes for fuel. October 25.

20,502. W. Sander.—From C. F. Winkelmann, Germany. New or improved fire-lighter. October 26.

20,609. W. B. Fitch. Improvements in candles. October 27.

20,941. W. Ritchie. Improvements in or relating to gas-carburetting apparatus. November 1.

20,998. J. Morrison and T. Booth. An improved apparatus for producing and saving gas. November 2.

21,051. J. Ruscoe. Improvements in apparatus for charging gas retorts. November 2.

21,018. S. W. Borchers. A novel or improved process and means for obtaining electrical energy from fuel gases. Complete specification. November 3.

21,222. T. L. Willson. Improvements in the manufacture, distribution, and use of gas for illumination, heating, and other purposes, and in apparatus therefor. November 5.

21,441. R. Denormandie and H. Hennebute. Improvements in the manufacture of petroleum briquettes or blocks. November 7.

21,655. E. J. Duff. Improvements in gas producers. November 10.

21,658. J. J. Atkins. See Class XVII.

22,034. H. Schon. Improvements in apparatus for the manufacture of coke. November 14.

22,036. W. H. Biggs and R. R. Greenhow. Improvements in the manufacture of artificial fuel. November 14.

22,170. A. E. Tavernier and W. L. Maleolmson. A new household briquette fuel. November 16.

22,184. C. W. Pinkney. Improvements in or connected with apparatus for the manufacture of gas from liquid hydrocarbons. Complete specification. November 16.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

21,926. F. E. Baron and C. C. Fry. Improvements in liquid fuel, and in means or apparatus employed in the manufacture thereof. October 24.

22,169. F. McNamee. Improved fuel for domestic and steam purposes. November 21.

22,378. E. de Pass.—From L. J. Baptiste. Improvements in machines for the manufacture of candles. October 31.

24,422. E. E. Dulier. An improvement in apparatus for destroying smoke. October 24.

24,856. J. Young. Improvements in obtaining cyanides and ammonia direct from the air or other gases containing nitrogen. November 7.

24,955. B. J. B. Mills.—From La Compagnie Internationale pour l'Exploitation des procédés A. Seigle. See Class XII.

1894.

4283. O. Imray.—From La Société Anonyme des Moteurs Thermique Gardie. Process for the manufacture of combustible gas. November 14.

12,888. J. C. Fell.—From M. M. Armstrong. Improvements in the method of burning fuel to obtain complete and smokeless combustion and in the furnaces used therefor. September 26.

16,395. W. F. Browne. Improvements in the manufacture of gas and in apparatus therefor, and in the utilisation of the waste heat produced therein for the generation of steam. November 14.

17,484. E. Kirbis. Method of manufacturing artificial fuel. November 7.

17,679. F. Bremme. Improved mode of treatment and apparatus for the carburisation of gases. November 14.

19,127. J. T. Donovan and H. L. Gardner. A new and improved process for the production of ozone. November 14.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

#### COMPLETE SPECIFICATION ACCEPTED.

1894.

736. J. H. W. Stringfellow. Improvements in the treatment of tar and in obtaining useful products therefrom. November 21.

### IV.—COLOURING MATTERS AND DYES.

#### APPLICATIONS.

19,712. G. W. Johnson.—From The Chemische Fabrik, late Goldenberg, Geromont, and Co., Germany. A process for obtaining lactyl compounds derived from methyl aniline, ethyl-aniline, *p*-anisidine, and *p*-phenetidine. October 16.

19,885. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation, Germany. Manufacture of colouring matters of the induline series. October 18.

19,970. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation, Germany. Manufacture of direct dyeing colouring matter. October 19.

19,971. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation, Germany. Manufacture of direct-dyeing colouring matter. October 19.

19,972. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation, Germany. Manufacture of direct-dyeing colouring matter. October 19.

20,086. A. Levinstein. Improvements relating to the manufacture of cellulose from the waste produced in the extraction of tanning and dyeing materials. October 20.

21,227. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning, Germany. Manufacture of stable diazo-compounds in concentrated liquid or solid form. November 5.

21,786. A. G. Green and R. Jansen. Production of dehydrothioniline sulphonic acid and of colouring matters therefrom. November 12.

21,787. A. G. Green and R. Jansen. Production of a new basic yellow colouring matter. November 12.

21,788. A. G. Green and R. Jansen. Improvements in the manufacture of red direct cotton colouring matters. November 12.

22,174. H. S. Wilkinson. Improved dyewood extractor. November 16.

22,273. S. Pitt.—From L. Cassella and Co., Germany. The production of mixed disazo dyestuffs from delta-amidonaphthol. November 17.

22,276. W. W. Horn.—From W. Maybury, United States. Improvements in and relating to thickeners or vehicles for colours, mordants, and the like. November 17.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

20,605. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik. The manufacture and production of new compounds suited for use in the preparation of diazo-compounds and their application in the production of dyes. October 31.

24,365. P. R. J. Willis.—From W. J. Matheson. Improved process for making solid and friable colouring matters from logwood extract and other dyewood extracts. October 24.

24,543. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik. The manufacture of colouring matters and of intermediate products related to the rhodamine series. October 24.

24,714. S. Pitt.—From L. Cassella and Co. The production of azo-dyestuffs derived from  $\alpha_1 \alpha_1$  azimidonaphthalene. October 31.

24,715. S. Pitt.—From L. Cassella and Co. The production of dyestuffs from di-azo safranines and amidonaphthols. October 31.

24,870. C. Dreyfus. The manufacture and production of new colouring matters. October 31.

25,074. H. E. Newton.—From the Farbenfabriken vormals F. Bayer and Co. The manufacture or production of sulpho acids of the naphthalene series derived from naphthalene  $\beta_1 \beta_2$  disulpho acid or naphthalene  $\beta_2 \beta_3$  disulpho acid. November 7.

25,071A. H. E. Newton. — From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of  $\beta_1 \beta_1$  dihydroxy-naphthalene  $\beta_1 \beta_1$  disulphonic acid. November 7.

1894.

406. O. Imray. — From The Farbwerke vormals Meister, Lucius, and Brünig. Improvements in the production of sulphurous aromatic bases and of their sulphonic acids. November 14.

515. J. V. Johnson. — From Kalle and Co. Improvements in and relating to the manufacture of azo dyestuffs. November 14.

973. H. E. Newton. — From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of anthraquinone derivatives. November 21.

974. H. E. Newton. — From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of colouring matters derived from anthraquinone. November 21.

975. H. E. Newton. — From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of hydroxyanthraquinones. November 21.

1062. H. E. Newton. — From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of dyestuffs. November 21.

1063. H. E. Newton. — From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of  $\beta_1$ -naphthol,  $\alpha_1 \beta_1$ -disulpho acid, and  $\beta_1$ -naphthylamine,  $\alpha_1 \beta_1$ -disulpho acid. November 21.

## V.—TEXTILES, COTTON, WOOL, SILK, Etc.

### APPLICATIONS.

19,722. T. Illingworth. Improvements in the process or method of rendering certain woollen and worsted fabrics unspottable, unshrinkable, and impermeable. October 17.

20,033. J. L. Byrom and B. F. Byrom. Improvements in the manufacture of yarns made from wool and other fibre or fibres combined, and in apparatus employed therefor. October 20.

20,121. J. V. Johnson. — From L. F. Gros, France. Improvements in and relating to the manufacture of cotton thread. October 22.

20,122. J. V. Johnson. — From L. F. Gros, France. Improvements in the manufacture of printed woven fabrics. October 22.

20,133. R. M. Harvey. An improvement in the manufacture of inlaid floor-cloth. October 22.

20,341. G. C. Franklin. Improvements in broad silk pieces, and in the manufacture of the same. Complete Specification. October 24.

20,763. T. Burrows and D. E. Radclyffe. Improvements in machines for combing vegetable or animal fibres, such as ramie, flax, wool, or silk waste, and preparing same for spinning. October 30.

21,029. W. G. Thomsen. Improvements in the method of and apparatus for manufacturing inlaid linoleums and other floor-cloths. November 2.

21,519. T. H. Copley and D. Scott. Improvements in the treatment of waste from textile manufactures in order to recover fibres therefrom. November 8.

22,004. T. R. Hanmer. Improvements in finishing textile or woven fabrics. November 14.

### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

21,060. B. Barraclough. Improvements in certain textile fabrics. October 21.

21,976. W. L. Hays. — From E. Gochley. See Class XII.

21,998. Com. H. de Clavelonnet. Improvements in the manufacture of artificial silk. November 21.

1894.

1089. J. Smith and P. W. Nicolle. Improvements in the treatment of vegetable fibrous matters to obtain fibres therefrom. November 11.

17,625. A. Stephenson. Improvements in apparatus for scouring and washing wool and the like. October 24.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

### APPLICATIONS.

20,308. W. E. Kay and The Thornliebank Co., Ltd. Improvements in and relating to the printing and mangle-creasing of cotton fabrics. October 21.

21,119. T. Lye and W. T. Lye. Improvements in the bleaching or dyeing of "chip," "straw" and "chip plait," and "straw plait." November 3.

21,120. T. Lye and W. T. Lye. Improvements in the printing or colouring of "chip" and "straw" in plait and otherwise, and in means or apparatus employed therein. November 3.

21,287. J. A. O'Loughlin. Improvements in and connected with the production of patterns on indigo-dyed cotton fabrics. November 6.

21,324. F. Scott and R. J. Flintoff. Improvements in the printing of aniline black. November 6.

21,481. W. L. Hiffe, J. J. H. Sturmer, and J. Ward. New or improved method of and means for printing colours and the like on textile fabrics. November 8.

22,221. J. Clapham, W. W. L. Lishman, and M. Jefferson. Improvements in machinery for dyeing and bleaching yarns and fabrics. November 17.

### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

15,829. O. Imray. — From F. Erbau and L. Specht. Process for dyeing textile material in cops or spools with alizarine and other mordant dyes. October 24.

23,750. M. Williams. Improvements in or appertaining to the bleaching of fibrous or textile materials. November 14.

1894.

98. A. H. Leggif. Improvements in machines or apparatus for applying bronze or other powders to the surface of paper, cardboard, cloth, and such like. November 7.

6887. C. F. Cross and E. J. Bevan. — From C. Bealle. A process for marking indelibly on paper, fabrics, and like receptive material. November 7.

19,226. W. H. Thorpe. Improvements in machinery for mordanting, dyeing, washing, and scouring hanks of yarn. November 14.

19,235. T. Ingham. Improvements in dyeing mixed woven or knitted fabrics. November 14.

## VII.—ACIDS, ALKALIS, AND SALTS.

## APPLICATIONS.

19,584. V. L. Eley.—From The United States Smokeless Powder Co., United States. Preparation of ammonium chromates. Complete Specification. October 16.

19,768. J. E. Riley. Improvements in the process of manufacturing or recovering cyanogen compounds. October 17.

19,769. J. E. Riley. Improvements in the manufacture of sulphuric acid. October 17.

19,770. J. E. Riley. Improvements in the production or manufacture of ammonia. October 17.

19,876. J. Armstrong. Improvements in concentrating and storing acids, alkalis, and other chemicals, and furnaces and apparatus therefor. October 18.

20,168. W. L. Wise.—From Deutsche Solvay-Werke Actien-Gesellschaft, Germany. Improvements in the manufacture or production of chromates. October 22.

20,169. W. L. Wise.—From Deutsche Solvay-Werke Actien-Gesellschaft, Germany. Improvements in the manufacture or production of manganates and stannates. October 22.

20,622. P. Bateson and F. K. Muspratt. Improvements in the manufacture of carbonate of soda. October 27.

20,961. M. Guthrie. Improvements in or relating to the decomposition of alkaline chlorides. November 1.

21,147. J. Y. Johnson.—From N. Basset and W. de Baranoff, France. Improvements in the treatment of alkaline salts or the salts of alkaline earths. November 7.

21,529. E. Andreoli. Production of vinegar by means of ozone. Complete Specification. Filed November 8. Date applied for 20 July 1894, being date of application in Belgium.

21,557. A. Walker. A new process for the purification and utilisation of the chemical by-product known as sulphate of lime sludge. November 9.

21,732. H. Y. Castner. Improvements in the manufacture of alkali cyanides. November 10.

21,774. M. N. d'Andria. Improvements in and connected with the production of caustic soda, caustic potash, and barium and strontium hydroxides. November 12.

21,778. I. S. McDougall. See Class I.

21,945. W. Thomson and B. J. Worsley. Improvements in apparatus for use in the decomposition of common salt, in the production of sulphate of soda, or for analogous purposes. November 13.

21,962. W. Wyld and J. H. Cox. A new or improved method of manufacturing persulphate of iron or ferric sulphate. November 14.

21,963. W. Wyld and J. H. Cox. A new or improved method of manufacturing ferric sulphate. November 14.

22,028. L. Gautreau, E. Charbonnier, and E. Serrant. Process of manufacture and employment of humic acid and its compounds. November 14.

22,297. H. H. Lake.—From C. Piejer and C. Fellner, Germany. Improvements in and relating to the manufacture of ammonia and by-products. November 16.

22,251. J. J. Cresfield and G. S. Johnson. New or improved crystalline salts containing soluble compound silicates and method of manufacturing the same. November 17.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

23,889. G. Jarman. Improvements in or appertaining to apparatus for drying bicarbonate of soda. November 21.

23,890. G. Jarman. Improvements in the manufacture of refined bicarbonate of soda. November 21.

24,175. E. J. Hunt. Improvements in treating the residual products of certain manufactures, and in treating certain metallic ores for the manufacture of chlorine. November 14.

24,856. J. Young. See Class II.

25,024. H. Gaskell, jun., V. C. Driffield, A. Carey, and F. W. Wright. Improvements in and connected with the manufacture of bleaching powder. October 31.

25,024. H. Gaskell, jun., and A. Carey. Improvements in or relating to the manufacture of chlorine. October 31.

1894.

60. J. Werlein. An improved method or process of hardening aluminous materials and the product obtained thereby. November 7.

11,905. E. Driesel and J. Lenhoff. Process for the manufacture of neutral sodium carbonate, neutral sodium sulphite, and sodium borates from sodium chloride. November 21.

17,289. H. E. Newton.—From E. Hart. Improved apparatus for the condensation of nitric acid and other vapours. October 24.

17,556. J. Ascongh. Improvements in the manufacture of sodium bichlorate or borax. October 24.

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

## APPLICATIONS.

20,050. J. W. S. Holt and S. Hargreaves. Improvements in or relating to the manufacture of crucibles, fire-clay, refractory, and non-conducting bricks and blocks, furnace linings, or the like. October 20.

20,113. H. Cartledge. Improved construction of potters' kilns. October 22.

20,138. E. A. Shaw. Improvements in the manufacture of pottery or like ware. October 22.

20,156. E. W. Crebbin. Improvements in crucibles, "firebrick" articles, and fireproof or refractory composition for lining furnaces and the like. October 22.

20,287. J. Slater and A. Doulton. Improved methods of preparing "transfers" for use in decorating ceramic-ware. October 24.

20,557. W. G. Moore. See Class X.

20,964. F. von Hardtmuth. Improvements in presses for the production of tiles and other ceramic ware. Complete Specification. November 1.

21,091. T. H. Stubbs. Improved method or methods of decorating tiles or the like. Complete Specification. November 3.

21,191. J. Adams and J. Sherwin. An improved method of stamping undercut dovetailing notches or indentations on or in the backs of encaustic and other tiles and other ceramic productions. November 5.

22,008. C. D. d'Enghien, A. D. d'Enghien, and S. D. d'Enghien. Improvements in kilns or ovens for firing terracotta and other like materials. Complete Specification. November 14.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

23,505. R. Y. Foley and F. L. Carslake. Improvements in or relating to the manufacture of clay goods. November 14.

23,753. A. Maw, G. H. Maw, and B. Stuart. An apparatus for applying glazes or enamels to tiles or other like goods. November 14.

24,283. J. E. G. Meran. Improvements relating to the manufacture of pottery. October 31.

24,682. The Worcester Royal Porcelain Co., Lim. E. P. Evans, A. Rushton, and H. Hawker. Improvements in the manufacture of pottery or earthenware. October 24.

1894.

878. E. Bohm. Improvements in the manufacture of enamelled glass letters and other devices. October 24.

17,366. Craven, Dunnill, and Co., Lim., and T. Pitt. Improvements in apparatus for the manufacture of tiles. October 24.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

### APPLICATIONS.

19,580. C. Williams. The manufacture of improved fireproof and weather-proof materials or products. October 15.

19,647. W. Owen. Improvements in or relating to the manufacture of artificial stone. October 16.

19,737. J. Wheeler. An improved material for roofing, weathering, and decorative purposes. October 17.

19,829. J. Tulloch. Improvements in tubular bricks or blocks and wall linings for fireproof buildings. October 18.

19,847. N. Davies.—From G. Frederick and S. P. Davies, Australia. An improved composition for use on streets, roads, pavements, and the like, and on the surfaces of wood and metal. October 18.

20,650. L. Kupper. Improvements in gypseous walls. Complete Specification. October 29.

20,848. E. Wilder and H. Holt. Improvements in the process of manufacturing and calcining Portland cement and in the calcining of similar material. October 31.

20,869. G. F. Bowman. Improvements in or relating to fireproof doors, screens, and partitions for buildings and other structures. October 31.

21,173. J. Sheppard and F. Dashwood. Improved fire- and heat-resisting and ventilating floors, ceilings, and other structures. November 5.

21,525. T. H. Lewis. An improved paving and flooring block. November 8.

21,586. M. Williams. Improvement in the manufacture of asphalt blocks and slabs for paving and other purposes. November 9.

21,734. E. Weekwarth and M. Hoeft. Improvements in and relating to the manufacture of cements for making mortars suitable for the production of artificial stone. November 10.

21,735. E. Weekwarth and M. Hoeft. Improvements in and relating to the manufacture of lime mixtures and cements, or mortars suitable for use in the production of artificial stone. November 10.

22,001. W. Youten. Improvements in fireproof construction. November 14.

### COMPLETE SPECIFICATIONS ACCEPTED.

1894.

2247. D. Belloe and E. Benard. Improved process for transforming roasted cements into powder, and in apparatus therefor. October 24.

10,585. C. Geige. A new or improved method or process for the manufacture of artificial wood. November 14.

12,350. W. Bruch. Improvements in the utilisation of precipitated sewage matters (for the manufacture of cement). October 24.

17,049. J. H. Amies and J. L. Robertson. Improvements in pavements. October 24.

17,221. J. R. Ben. Improvements in or relating to fireproof chimneys. October 4.

19,184. C. A. Repl and L. P. S. Wright. Improvements in and relating to fireproof floors and ceilings. November 14.

## X.—METALLURGY, MINING, &c.

### APPLICATIONS.

19,797. The Cowper-Coles Galvanising Syndicate, Lim., and S. O. Cowper-Coles. Improvements in or connected with the manufacture or production of zinc coated wire and other zinc-coated metallic articles. October 17.

20,067. F. Stubbs. A method of carburetting the surfaces of armour plates. October 20.

20,071. L. Bangert. Process for coating metals with tin. October 20.

20,247. D. W. Sugg. An improved metallic alloy. Complete Specification. October 23.

20,365. W. S. Rawson and R. Heathfield. A process for recovery of zinc from scrap galvanised iron and from hard spelter and other zinc alloys. October 24.

20,422. W. P. Thompson.—From F. Bertrand and O. Thiel, Austria. Improvements in the manufacture of steel, steady iron, or homogeneous metal. October 25.

20,557. W. G. Moore. Improvements in furnaces for heating and annealing steel, iron, brass, castings, glass, earthenware, and the like. October 27.

20,615. J. C. Fell.—From F. A. Gooch and L. Waldo, United States. Improvements in processes for reducing aluminium. Complete Specification. October 27.

20,616. J. C. Fell.—From F. A. Gooch and L. Waldo, United States. Improvements in processes for reducing aluminium. Complete Specification. October 27.

20,636. A. Ryrie. Improvements for the protection from corrosion and preservation of iron, steel, and other metallic surfaces. October 29.

20,814. C. F. Claus, C. Goepner, and C. Wichmann. Improvements in the treatment of argentiferous and auriferous complex sulphuretted ores. October 29.

20,815. E. A. L. Langlois and P. F. de Susini. A metallic composition or alloy. October 30.

20,872. P. de Wilde. A method for the extraction of gold. Complete Specification. October 31.

20,955. A. E. Morgans. Improvements in the extraction of precious metals from their ores. November 1.

21,025. H. R. Angel. A process for extracting gold from antimony ore. November 2.

21,069. P. Rogers and J. Player. Improvements in machinery or apparatus for coating metal plates or sheets with tin, lead, or other metals or alloys. November 2.

21,213. P. Huth. Improvements in casting metals. November 5.

21,245. R. Fegan. Improvements in the smelting of ores. November 5.

21,520. A. H. Smith. Improvements in armour-plates. November 12.

22,023. H. Moissan. Improvements in the manufacture of alloys. November 14.

22,051. J. C. Quinn and R. McDougall. Improvements in the extraction of gold and other precious metals from their ores. November 15.

22,066. T. Hampton. Improvements in and relating to the manufacture of compound armour plates. November 15.

22,195. The Cowper-Coles Galvanising Syndicate, Lim., and S. O. Cowper-Coles. Improvements in and apparatus for applying zinc or other metallic coatings to iron, steel, or other surfaces. November 16.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

20,480. W. J. Clapp and S. D. Williams. Improvements in the manufacture and purification of iron and in means or apparatus employed therein. November 7.

21,530. H. F. Taylor. Improvements in apparatus for coating with tin, lead, or other metals or alloy with same. November 14.

21,823. G. Kynech and Co., Lim., and D. Clerk. Improvements in the manufacture of steel shells. October 24.

23,770. E. G. N. North. Process for the elimination and recovery of arsenic from copper precipitates. October 24.

23,930. R. Pearson. A new or improved process and means for treating quartz containing gold, silver, and other metals. November 21.

24,230. C. J. L. Leffler. The manufacture of ferro boron. November 7.

24,231. C. J. L. Leffler. Improvements in the manufacture of steel. October 24.

1894.

3956. W. F. Reid. A new or improved process and material for the production of articles of metal. November 14.

4533. T. Hampton. Improved method of and moulds for casting compounds, ingots for armour plates, and other plates. November 7.

8586. C. M. Allen. Processes of and converters for smelting and refining ores. November 7.

18,919. B. Talbot. Improvements in the manufacture of steel. November 14.

### XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

#### APPLICATIONS.

19,702. G. E. Heyl. Improvements in accumulators. October 16.

19,868. W. A. Thoms and W. H. Burgam. An improvement in electro deposition of an alloy of zinc and cadmium. October 18.

20,059. P. Scheidt and J. W. Tideman. Casting by means of electric current. October 20.

20,127. M. M. Bair. Improved porous pot for primary batteries. October 22.

20,359. C. Kellner. Improvements in electrolytic apparatus for decomposing metallic salts. October 23.

20,354. P. Marino. Improvements in and connected with the electro-deposition of aluminium and aluminium alloys. Filed October 24. Date applied for May 31, 1894, being date of application in France.

21,080. C. Langier. Improvements in secondary batteries. November 2.

21,323. W. P. Thompson.—From C. L. Coffin, United States. Improvements in apparatus for welding electrically. Complete Specification. November 6.

21,330. G. Hübner. Improvements in galvanic batteries. Complete Specification. November 6.

21,555. L. A. Timmés. Improvements in secondary batteries. November 9.

21,822. J. C. Mewburn.—From F. Horaig and W. Borchers, Germany. A vessel for the electrolytic separation and alloying of metals in the molten state. November 12.

21,838. W. Rein. New or improved process for electrolyzing chemical combinations and winning the products of decomposition formed by the electrolysis. Complete Specification. November 12.

21,845. R. Myers. Improvements in dry batteries. November 12.

22,070. J. Hargreaves and T. Bird. An improved process and apparatus for the electrolytic decomposition of metallic salts, and for treating products therefrom. November 13.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

21,120. W. H. Longsdorf.—From G. Hewett. Improvements in primary batteries. November 14.

21,631. W. H. Caldwell. Improvements in electrolytic apparatus. November 7.

21,276. H. Guthrie. Improvements in apparatus for electrolytic purposes. October 24.

24,353. C. K. Mills.—From C. J. Barbier. A new or improved preparation of active material for electric accumulators. October 24.

21,389. A. Lehmann. Improvements in electrode plates for secondary batteries. October 24.

24,442. C. K. Mills.—From C. J. Barbier. A new or improved electrical accumulator plate. October 24.

1894.

646. W. Walker, jun., F. R. Wilkins, and J. Lones. Improvements in primary voltaic batteries. November 7.

9975. W. P. Thompson.—From C. L. Coffin. Improvements in the method of and apparatus for heating, welding, or working metals by electricity. October 31.

13,499. A. Sinding-Larsen. Improvements in process and apparatus for electrolytical decomposition of alkali salts. October 31.

18,288. C. Rordon. Improvements in secondary or storage batteries. October 31.

### XII.—FATS, OILS, AND SOAP MANUFACTURE.

#### APPLICATIONS.

19,968. H. Whitbread. An improved sapaceous compound. October 19.

20,158. M. Perls. Improvements in materials for and in the manufacture of soft soap. October 22.

20,974. H. A. Leverett. See Class XVII.

21,131. A. L. G. Dehne. Process for the separation of oils and fats from water. November 3.

22,205. J. Wigglesworth and C. H. Simpson. An improved soap tablet. November 16.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

21,976. W. E. Heys.—From E. Godehanx. Improvements in compounds for oiling and similarly treating wool. November 21.

24,955. B. J. B. Mills.—From La Compagnie Internationale pour l'Exploitation des procédés A. Seigle. Improvements in the composition of oils for feeding vapour-burning lamps. October 31.

25,001. H. W. Taylor. An improved soap. November 7.

1894.

1088. A. Warwick, J. Smith, and P. W. Nicolle. Improvements in the manufacture of soap and washing compounds. November 21.

### XIII.—PAINTS, PIGMENTS, VARNISHES, RESINS, INDIA-RUBBER, Etc.

#### APPLICATIONS.

19,535. T. Coppock, jun. Improved varnish applicable to mixing with the bronze powder colours, and for decorative painting purposes. October 15.

19,858. A. J. Boulton. — From G. Philippe, Belgium. Impermeable paint for mirrors. Complete Specification. October 18.

20,023. J. Round. An improved adhesive composition for use upon india-rubber surfaces. October 20.

20,250. J. Armstrong. Improvements in the manufacture of paint varnish and the like. October 23.

20,373. J. P. Lacy and A. J. Ash. Improvements in the production of zinc compounds for use as pigments and for other purposes. October 24.

22,020. A. Tolhurst. A new or improved composition for the preservation of iron, steel, wood, and stone from rust, corrosion, and scaling, and for preventing the fouling of ships' bottoms. November 14.

22,100. A. J. Boulton. — From G. Philippe, Belgium. Improvements in or relating to damp-proof paints or the like. November 15.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

22,730. A. Buecher. Improvements relating to rust-preventive paints. November 21.

1894.

958. J. Hickisson. Improvements in marking-ink pencils. November 21.

5440. E. Herisse. An elastic composition for moulds. October 24.

9883. L. L. B. Meyer. New or improved manufacture of varnish or of a substance for use in making varnish. October 24.

17,630. K. Ammann. Improvements in washing blue. October 24.

17,662. R. Hingston and J. P. Wernegreen. An improved anti-fouling composition for the prevention of marine growth in or on wood or iron. October 24.

### XIV.—TANNING, LEATHER, GLUE, AND SIZE.

#### APPLICATIONS.

21,550. J. Y. Johnson. — From F. Kornacher and Diesel and Weise and Co., Germany. Improvements in tanning. November 8.

22,260. R. H. Evans. Improvements in the manufacture of size. November 17.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1894.

12,941. P. C. Hewitt. Improvements in glue making machinery. October 31.

13,195. T. H. L. Bake and H. A. Leverett. Improvements in tanning skins and hides. November 21.

### XV.—AGRICULTURE AND MANURES, Etc.

#### APPLICATIONS.

20,971. C. H. Thompson. The manufacture of improved fertilised and fertilising materials for promoting the growth of plants. Complete Specification. November 1.

21,658. J. J. Adkins. Treating brewers' spent hops, wet and dry, for the production of manure and fuel. Complete Specification. November 10.

#### COMPLETE SPECIFICATION ACCEPTED.

1893.

21,931. J. T. Dinsdale. Improvements in the treatment of sewage sludge to obtain a useful manurial product therefrom. November 14.

### XVI.—SUGARS, STARCHES, GUMS, Etc.

#### APPLICATIONS.

20,534. A. Young. Improvements in apparatus for the dissolving of saccharum. October 26.

21,344. S. Briggs. — From H. Vynsteke, Belgium. Improved means and apparatus for treating cereals and amylaceous substances. November 6.

21,708. C. H. Meyer. See Class XVII.

21,837. T. Moore, J. A. Sanders, and W. H. Percy. Improvements in apparatus for boiling sugar and the like. November 12.

22,115. A. Harrison. Improvements in preparing starch for laundry purposes. November 15.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

20,397. C. Steffen. Process for purifying and decolorising saccharine juices and sugar solutions. October 31.

1894.

1146. C. H. Meyer. Improvements in the manufacture from starch or starchy substances of a material suitable for use in brewing and for other purposes. November 21.

14,842. H. H. Leigh. — From G. Cambray. Improved process for the treatment of the juice of sugar-canes. October 31.

### XVII.—BREWING, WINES, SPIRITS, Etc.

#### APPLICATIONS.

19,662. T. R. Timby. Mechanism for ageing liquors. Complete Specification. October 16.

20,022. J. Y. Johnson. — From E. L. Doyen, France. Improvements in the manufacture of sparkling wines, cider, and other effervescent beverages. October 20.

20,987. F. N. Mackay. Improvements in apparatus for cooling wort. October 20.

20,796. P. Kröpf and A. Gruell. An improved method of manufacturing beer. Complete Specification. October 30.

20,974. H. A. Leverett. Improvements in the maturing of alcoholic liquors, vegetable oils, tobacco, and other substances, and in apparatus connected therewith, partly applicable to other purposes. November 1.

20,988. J. T. Poplawsky. Apparatus for cooling beer. Complete Specification. November 1.

21,033. E. Larsen. Improvements in pneumatic malting and apparatus used for same. November 2.

21,658. J. J. Adkins. Treating brewers' spent hops, wet and dry, for the production of manure and fuel. Complete Specification. November 10.

21,708. C. H. Meyer. An improved method of manufacturing from starch or starchy substances a material suitable for use in brewing and for other purposes. November 10.

22,270. P. L. F. E. Vignier. Improvements in and relating to distilling apparatus, chiefly designed for the manufacture of pure grape spirit and of whiskies free from fusel oil. Complete Specification. November 17.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1894.

1146. C. H. Meyer. See Class XVI.

17,277. J. Takamine. Improvements in and in the production of diastatic and alcoholic ferments, and the utilisation of the by-products. November 21.

### XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

#### APPLICATIONS.

##### A.—Chemistry of Foods.

19,987. J. Escuyer. An improved alimentary product and process of manufacturing the same. October 19.

20,319. J. A. Wilson. Improvements in methods of treating meat and like foodstuffs in the raw condition, in order to arrest or retard decay. October 21.

20,428. F. Gaillaume and E. Goltstein. Improvements in and apparatus for sterilising milk. October 25.

20,185. W. F. MacLaren. Improvements in and relating to condensed milk products. October 26.

21,224. W. Schwartz. Improved manufacture of cattle food. November 5.

21,710. C. F. Hope. Improvements in the manufacture of cheese. November 10.

22,018. J. H. Theberath and A. de Kunwald. Improvements in the manufacture of margarine and in apparatus therefor. November 14.

22,103. G. Bergman. Improvements in the method of producing fish meal from fish-offal, fresh fish, or other sea animals. November 15.

##### B.—Sanitary Chemistry

20,447. W. Michalik. A process for the combustion of soot. Complete Specification. October 25.

20,744. E. W. Ives. An improved system and apparatus for purifying sewage or other foul or waste waters. Complete Specification. October 30.

20,790. C. D. Abel.—From A. Schlumberger, France. Improved compounds for filtering and purifying liquids. October 30.

21,635. W. E. Adeney and W. K. Parry. Improvements relating to the precipitation of sewage and waste liquids, and the utilisation of the products. November 9.

21,921. W. Smethurst and J. Van der Crab. Improvements in the process of and apparatus for destroying town and other refuse. November 13.

##### C.—Disinfectants.

20,556. C. Gates. Improvements in and relating to disinfecting compounds. October 27.

20,852. E. Burton. An improved disinfectant compound. October 31.

#### COMPLETE SPECIFICATIONS ACCEPTED.

##### A.—Chemistry of Foods.

1893.

23,266. E. Krog. Malted provender for horses, cattle, and sheep. November 14.

1894.

10,106. A. Berstein. Improvements in the production of a peptonised beverage from milk. November 21.

18,143. W. Paasch. Improvements in pasteurising apparatus for milk, cream, or the like. November 7.

19,309. T. T. Chard. A new and improved phosphate food for horses. November 21.

##### B.—Sanitary Chemistry.

1893.

21,082. C. Raleigh. Improvements in separating solid from liquid matter more especially relating to the treatment of slimes, finely-divided ore, precipitates, and sewage. November 14.

21,931. T. J. Dinsdale. See Class XV.

25,040. H. B. Sharp and J. B. Petrie. Improvements in the preparation of compositions adapted for use in the treatment of sewage and foul waters. November 7.

1894.

17,62. C. Salzberger. Improvements in or relating to the disinfection or purification of water. November 21.

##### C.—Disinfectants.

1894.

1415. I. Levinstein. Improvements in and connected with iron compounds for use in precipitating sewage, purifying waste liquors, colouring, and the like purposes. October 31.

### XIX.—PAPER, PASTEBOARD, Etc.

#### APPLICATIONS.

20,051. W. P. Thompson.—From M. C. Stone, United States. Improvements in or relating to the treatment of paper or other tubes. Complete Specification. October 20.

20,221. Henderson, Craig, and Co., Lim., and E. Rutley. Improved means for watermarking paper. October 23.

20,358. H. H. Lake.—From Arndt and Trost, Germany. Improvements relating to the manufacture of photographic printing paper. October 24.

21,520. T. H. Cobley and D. Scott. Treatment of waste fibrous matter for the production of material suitable as a substitute for mill-board, papier-maché, and the like. November 8.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

21,503. J. Y. Johnson.—From P. Sohege. Improvements in the manufacture of cellulose pulp. October 21.

21,669. J. Craig. Improvements in machinery or apparatus for manufacturing paper. October 31.

### XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

#### APPLICATIONS.

19,869. J. E. T. Woods and W. J. Birnie. Improvements in the manufacture of camphor substitutes. October 18.

20,521. C. D. Abel.—From The Fabriques de Produits Chimiques de Thann et Mulhouse, Germany. Improvements in the manufacture of artificial musk. October 26.

21,730. B. Willeox.—From M. Otto and A. Verli, France. Improvements in the manufacture and production of perfumes. November 10.

21,815. A. B. F. Wegemund. Process for the manufacture of a parasite tincture. Complete Specification. November 12.

22,028. L. Gautreau, E. Charbonnier, and E. Serrant. See Class VII.

22,190. O. Inray.—From The Farbwerke vormals Meister, Lucius, and Brüning, Germany. Manufacture of casein compounds. November 16.

22,191. O. Inray.—From The Farbwerke vormals Meister, Lucius, and Brüning, Germany. Manufacture of a new solid silver compound. November 16.

22,251. J. J. Crosfield and G. S. Johnson. See Class VII.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

24,177. S. Pitt.—From the Chemische Fabrik auf Actien vormals E. Schering. Improvements in the manufacture of aromatic sulphuryl derivatives of protocatechuic aldehyde and their conversion into vanillin. October 24.

24,178. S. Pitt.—From The Chemische Fabrik auf Actien vormals E. Schering. Improvements in the manufacture of vanillin. October 24.

24,179. S. Pitt.—From The Chemische Fabrik auf Actien vormals E. Schering. The preparation of a crystalline polymeric base suitable for medicinal use from amido-acetic aldehyde. October 24.

1894.

18,509. M. Otto and A. Verley. Manufacture of ethers of the alcohols contained in natural essences and of their corresponding alcohols. November 7.

### XXI.—PHOTOGRAPHIC PROCESSES AND MATERIALS.

#### APPLICATIONS.

20,358. H. H. Lake.—From Arndt and Frost, Germany. See Class XIV.

22,013. C. E. Hearson. Improvements in apparatus for imparting a predetermined temperature to liquids for use in developing photographic plates and for other purposes. November 11.

22,189. F. Davis. An improved developing film or plate holder. November 16.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

21,663. J. Packham. Improvements in producing photographic prints. October 31.

25,002. M. Andresen. Improvements relating to the development of photographic pictures. October 31.

1894.

1109. T. Maloni. Improvements in and connected with lighting apparatus for taking photographs at night or in dull weather. November 7.

### XXII.—EXPLOSIVES, MATCHES, ETC.

#### APPLICATIONS.

19,684. V. I. Efeny.—From the United States Smokeless Powder Co., United States. See Class VI.

20,281. R. Thieme. An improved process for producing nitropentaerythrite and a smokeless explosive therewith. Complete Specification. October 23.

20,593. G. Schinko.—From A. Thümann, Austria. Improvements in or relating to "lucifer" matches and the like. October 27.

20,786. E. B. Beeches and J. P. Wright. Improvements in and relating to machines for making matches. Complete Specification. October 30.

21,331. R. C. Schupphaus. Improvements in pyroxylin compounds and in the processes for manufacturing the same. Complete Specification. November 6.

21,729. J. W. Swan. Improvements in and apparatus for the manufacture of nitro-cellulose or gun-cotton. November 10.

22,019. F. Greening, jun. Improvements in and connected with the manufacture of nitro-cellulose or pyroxylin compounds. November 14.

22,192. Siemens Bros. and Co., Lim., and A. S. Schloemer. An electric exploder. Complete Specification. November 16.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

24,425. H. Boyd. A new explosive. November 7.

1894.

1074. M. von Forster. Improvements in or relating to the manufacture of smokeless powder. November 14.

18,682. H. Maxim. Improvements in fulminating compounds. November 7.

18,683. R. C. Schupphaus. Improvements in the process of nitrating cellulose. November 7.

19,098. A. G. Brookes.—From W. J. Smith. Improvements in exploders or fuses for projectiles. November 14.

19,299. G. Hübner. Improvements in smokeless explosives. November 21.

## XXIII.—ANALYTICAL CHEMISTRY.

## APPLICATION.

21,092. R. H. Wilkinson. Improved process for rapidly estimating water in butter, butter substitutes, lard, or other solid fats; also improved apparatus employed in such process. November 3.

---

## PATENT UNCLASSIFIABLE.

## APPLICATION.

21,913. C. D. Ekman and C. Christian. Improvements in the treatment of locust beans in order to obtain useful products therefrom. November 13.

---

OF THE

# Society of Chemical Industry.

## A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 12.—Vol. XIII.]

DECEMBER 31, 1894.

[Non-Members 30/- per annum; Members 21/- per Set of extra or back numbers; Single Copies (Members only) 2 6.]

### The Society of Chemical Industry.

#### Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S. ....	1881—1882.
Sir Frederick Abel, Bart., D.C.L., F.R.S. ....	1882—1883.
Walter Weldon, F.R.S. ....	1883—1884.
W. H. Perkin, Ph.D., F.R.S. ....	1884—1885.
E. K. Muspratt ....	1885—1886.
David Howard ....	1886—1887.
Prof. James Dewar, F.R.S. ....	1887—1888.
Ludwig Mond, F.R.S. ....	1888—1889.
Sir Lowthian Bell, Bart., F.R.S. ....	1889—1890.
E. Rider Cook ....	1890—1891.
Prof. J. Emerson Reynolds, M.D., D.Sc., F.R.S.	1891—1892.
Sir John Evans, K.C.B., F.R.S. ....	1892—1893.
E. C. C. Stanford ....	1893—1894.

### COUNCIL FOR YEAR ENDING JULY, 1895.

*President:* Prof. T. E. Thorpe, F.R.S.

#### *Vice-Presidents:*

Sir F. A. Abel, Bart., F.R.S.	Sir John Evans, K.C.B., F.R.S.
Horace T. Brown, F.R.S.	E. K. Muspratt.
H. Brunner.	Dr. W. H. Perkin, F.R.S.
John Calderwood.	John Spiller.
Chas. Dreyfus.	E. C. C. Stanford.
Dr. A. Dupré, F.R.S.	Prof. W. A. Tilden, F.R.S.

#### *Ordinary Members of Council:*

Frank Clowes, D.Sc.	Ivan Levinstein.
Thos. Fairley.	Manning Prentice.
C. A. Fawsitt.	G. N. Stoker.
Prof. G. G. Henderson, D.Sc.	Wm. Thorp, B.Sc.
David Howard.	T. Tyrer.
Prof. A. K. Huntington.	Frank Wilson.

With the Chairmen and Secretaries of Sections.

#### *Honorary Treasurer:*

E. Rider Cook, East London Soapworks, Bow, E.

#### *Honorary Foreign Secretary:*

Ludwig Mond, F.R.S.

#### *General Secretary:* Charles G. Cresswell.

*Offices:* Palace Chambers, 9, Bridge Street, Westminster, S.W.

#### *Editor:*

Watson Smith, 31, Upper Park Road, Haverstock Hill, N.W.

#### *Assisted by the following Staff of Abstractors:*

L. Archbutt, F. XII., XVIII. B.	D. A. Louis, ..... X.
D. Bendix, ..... III.	F. Machenhauer III., IV., VI.
Bertram Bleunt, { IX., XI., XII., XIII.	W. G. McMillan { X., XI., XIV., XXII.

### THE JOURNAL.

#### *Publication Committee:*

The President.

A. H. Allen.	F. Hurter, Ph.D.
G. H. Bailey, D.Sc., Ph.D.	C. Clarke Hutchinson.
Joseph Bernays, M.I.C.E.	Wm. Kellner, Ph.D.
Horace T. Brown, F.R.S.	J. Lewkowitzsch, Ph.D.
H. Brunner.	Ludwig Mond, F.R.S.
E. Rider Cook.	B. E. R. Newlands.
W. Y. Dent.	John Pattinson.
Chas. Dreyfus, Ph.D.	W. H. Perkin, Ph.D., F.R.S.
Sir John Evans, K.C.B., F.R.S.	H. R. Procter.
Percy Gilchrist, F.R.S.	Boverton Redwood.
John Heron.	Walter F. Reid.
D. B. Hewitt, M.D.	John Spiller.
David Howard.	Wm. Thorp.
Prof. J. J. Hummel.	Thomas Tyrer.
Prof. A. K. Huntington.	Lewis T. Wright.

### NOTICES.

Notice is hereby given that, in accordance with the alterations in Rule 27 sanctioned at the Annual General Meeting in Edinburgh, all new members elected after January 1st, 1895, and also those elected since the last Annual General Meeting, who do not pay subscription for 1894, will be required to pay an entrance fee of one guinea. In accordance with the same rule the Life Composition Fee will be 20*l.*, instead of 15*l.* as heretofore, after the 1st January 1895.

#### BANKERS' ORDERS.

For the convenience of Members, the Treasurer has arranged with the Bankers of the Society that they shall collect subscriptions from Bankers in town and country; and Members, who have not already done so, are invited to

fill up and sign the Banker's Order enclosed with the December 1893 number of the Journal, which should then be sent to the Honorary Treasurer, Mr. E. Rider Cook, East London Soap Works, Bow, E.

Authors of communications read before the Society, or any of its Local Sections, are requested to take notice that under Rule 41 of the bye-laws, the Society has the right of priority of publication for three months of all such papers. Infringement of this bye-law renders papers liable to be rejected by the Publication Committee, or ordered to be abstracted for the Journal, in which case no reprints can be furnished to the author.

Notice is hereby given, for the information of members and advertisers, that the advertisement columns of this Journal have been contracted for by Messrs. EYRE and SPOTTISWOODE, the Society's printers and publishers, to whom all communications respecting them should be addressed.

Notice is hereby given that the next List of Members will contain the professions or business occupations of the Members of the Society. Any Member who desires to confirm or alter his description as given before election should communicate with the General Secretary.

Members are reminded that the subscription of 25s. for 1895, payable on January 1st, should be sent in good time to the Treasurer, in order to ensure continuity in the receipt of the Society's Journal. Any changes of address to appear in the new List of Members now in course of preparation, should reach the General Secretary not later than January 15th, 1895.

#### LIST OF MEMBERS ELECTED 1st DECEMBER 1894.

Appleton, H. A. c/o Dr. Hess, Oil Works, Newlay, near Leeds, analytical chemist.

Ashworth, Arthur, Ferrihill Chemical Works, Bury, Lancashire, chemical manufacturer.

Cook, W. Martyn, 29, Highbury Hill, London, N., analytical chemist.

Emanuel, J. F., 36, West 91st Street, New York, U.S.A., varnish manufacturer.

Enquist, Jno., Richmond Hill, Long Island, N.Y., U.S.A., manager of chemical company.

Frank, Jerome W., 29, Broadway, New York, U.S.A., chemist.

Greaves, Wm., Powell Duffryn Collieries, Aberaman, Aberdare, chemical engineer.

Griffiths, Thos., The Cedars, Clapham Common, S.W., manufacturing chemist.

Healy, A. Augustus, 90, Gold Street, New York, U.S.A., tanner.

Heyl, J. Edward, 134, Fenchurch Street, E.C., chemical and electrical engineer.

Hutchison, Jno. F., 22, St. Enoch Square, Glasgow, chemical manufacturer.

Kerr, Jas., c/o Linlithgow Oil Company, Limited, Linlithgow, N.B., works chemist.

Laing, Wm., 224, Swan Arcade, Bradford, Yorks, oil merchant.

Lidgey, Cecil R., 43, Marmora Road, Honor Oak, S.E., analyst.

Machalski, F. J., 159, North Fifth Street, Brooklyn, N.Y., U.S.A., technical chemist.

Macmillan, Arch., Chemical Laboratory, 29, Chambers Street, Edinburgh, analytical chemist.

Pureell, M. F., 13, Victoria Street, Westminster, S.W., consulting chemical engineer.

*Meeting held Monday, December 3rd, 1894.*

MR. B. E. R. NEWLANDS IN THE CHAIR.

## ON THE RATIONAL STERILISATION OF ALIMENTARY LIQUIDS.

By E. W. KUHN, OF PARIS.

THE researches of those celebrated masters of the modern science of "Biological Chemistry," Lister, Pasteur, Hansen, and others who have worked in the same direction, have superabundantly proved that the chief modifications occurring in alimentary liquids are originated and caused by the action of micro-organisms,—yeasts, bacteria, and ferments, and that in some cases the pathogenic properties of waters used for drinking purposes must be ascribed to microbes. These researches, most of which have been made during the last 20 years, have shown that under certain circumstances it may be of extreme importance to destroy these organisms, and thus prevent the changes they set up in the liquids themselves and in the organs of those consuming them.

The chief methods adopted for carrying out this idea of destroying the micro-organisms can be classed under three leading categories:

1. Chemical or antiseptic methods.
2. Physical methods, other than the use of heat, *i.e.*, filtration, electricity, intense artificial cold.
3. The use of heat.

What reception has been accorded to these various methods in science and the industries?

The use of antiseptics has been persistently rejected by medical authorities, because the daily ingestion of any chemical substance with food must be regarded as entailing some risk to the health of the recipient. This method is therefore discarded on hygienic grounds.

Filtration, a method of great merit, although capable of rendering great service in some directions, cannot be applied with success to the sterilisation of alimentary liquids. Besides the difficulty of working and constantly superintending the filters, every system of filtration carried far enough to be efficacious bacteriologically has then the disadvantage of retaining and eliminating from the alimentary liquids, besides the organisms, a quantity of other substances finer than these. These being an essential part of the liquid, cannot be eliminated without completely modifying the liquids, and thus diminishing their value.

Thus if wine, milk, beer be filtered through Chamberland's porcelain filter, with a view to their sterilisation, they lose their colour, become decomposed, and assume in appearance having quite as great a resemblance to pure water as to the original liquid sought to be sterilised. This has been shown by a series of very exhaustive experiments made by Dr. Aubry at the Munich Institution for the scientific investigation of brewing.

The use of electricity and of alternating currents, which has been the subject of much investigation at the hands of Mr. de Meritens in France, has not realised the expectation formed in regard to it. These processes, although perhaps of value in certain directions, such as the rapid maturing of fermented liquids, offer no guarantee of homogeneous or efficacious action in the sterilisation of liquids.

As to intense artificial cold, Mr. Raoul Pictet has made some extremely curious experiments at Geneva, and found that microbes are not destroyed, even on being submitted to a temperature exceeding 200° C. below zero, whereby they are imprisoned in solidified atmospheric air, but on the contrary resume their functions as soon as they are restored to normal temperature.

There remains one other method, the intensely destructive effects of which renders it the most efficacious of them all, and that is, the use of heat.

Although up to the present the use of heat has been attended by very serious disadvantages, the necessity of applying some method or other is so general and urgent that this method has already found application to large quantities of milk and beer, which are heated in bottles by the process known as "pasteurisation." All the beer which is exported from Germany, Austria, Scandinavia, and the United States is thus pasteurised. Moreover, the heating of wine by the "appareils continus" is also resorted to to a certain extent, and similar apparatus are coming into use for the sterilisation of water.

But though the use of heat as a sterilising agent for liquids has already yielded enormous results, it must be recognised that its use hitherto has involved very serious disadvantages, which have arrested the development of its application. The methods hitherto devised have only aimed at utilising the useful effects of heat, without simultaneously suppressing the harmful effects. These harmful effects are the more serious because sterilisation by heat is of value chiefly in its application to the alimentary liquids, that is to say, to liquids in which the slightest alteration of their original condition would be so serious as to involve the rejection of any method causing it. The alterations which these liquids undergo are chiefly:

Alterations of flavour, which in the case of beer has been called the "pasteurisation" or caramel flavour; in the case of milk, the flavour of cooking or boiling; in the case of water subjected to this process, the insipid flavour of boiled water. Then comes the loss of gas, which is likewise one of the usual alterations. All these liquids, even water, are gaseous, and these gases play an important part in the taste and in the assimilating, stimulating, and digestive properties of the liquids, so that the loss of these gases modifies them considerably. Lastly, alterations in brilliancy, which nearly always occur when heat has been used by any of the processes hitherto applied. These are very serious in the case of beer, wine, and water, as are also the dissociation and coagulation which occur in milk. Further, if the pasteurisation of beer, wine, milk, &c. be effected in metal receptacles, they invariably become turbid, a fact which has hitherto been attributed to the use of heat.

I have been engaged in seeking to ascertain the causes of these various disadvantages, with a view to devising a system by which they might be overcome, and it is the result of my work in this direction which I have the pleasure of laying before you.

After lengthy research I have found the following to be essential to the solution of the problem:

1. Immediate action.
2. Equal distribution of calorific effect.
3. Absolutely air tight apparatus.
4. Complete reabsorption of the gases and vapours.
5. Elimination of the chemical action of the metal.

I propose reviewing these points seriatim.

### 1. Immediate Action.

I discovered that the biological action of heat precedes in a marked degree its chemical or physical action, a fact which led me to believe that it would be possible to stop the heat action at a point that would secure the desired biological results, while eliminating the disadvantages attending the latter stages.

I ultimately accomplished this by applying heat to such an extent only as is absolutely necessary to bring about the destruction of the living organisms, which of course vary according to the liquid treated. As soon as this physiological effect has been produced a sudden rapid cooling must take place and the liquid must not be allowed to cool gradually, the intermediate temperatures being harmful. This sudden cooling, immediately after sterilisation, renders it possible to limit the action of heat to this effect alone and to prevent any chemical or physical action of decomposition or alteration.

### 2. Equal Distribution of Calorific Effect.

Any portion of the liquid which is over heated is affected in flavour and brilliancy by the coagulation and precipitation of those nitrogenous albuminoids which are usually present in alimentary liquids. The affected portions mix with and ultimately contaminate the whole liquid. On the other hand any portion which is insufficiently heated is not sterilised, and the propagation of the micro-organisms will still proceed rapidly therein, thus infecting the rest of the liquid. It is therefore indispensable that both the heating and cooling should be absolutely even throughout all the parts of the liquid.

This is chiefly attained in my apparatus by the following features: horizontality, small diameter of cylinder as compared with length, and oscillation. I have by these means obtained an absolute evenness of action, such as could not be obtained with any of the older non-oscillating apparatus, fitted with agitators and stuffing-boxes, which could never remain tight when subjected to alternate heating and cooling. All this entailed constant expansion and contraction, which resulted in loss of gases and altered the liquids treated.

### 3. Absolutely Air-tight Apparatus.

The gases contained in the liquids, apart from their influence on taste, are also the vehicles of the chief volatile aromatic principles of the alimentary liquids, such as vapours of ether or vegetable essences, various alcohols, &c. Any escape of gases would entail the loss of some of these indispensable constituents and consequently an alteration of the liquids. It is necessary, therefore, that the entire apparatus should be perfectly air-tight so as to retain the hot gases under high pressure.

This was difficult to attain in view of the constant and successive expansion and contraction above referred to, but the general arrangement, by which complete evenness of action is obtained, also allowed of the construction of an apparatus hermetically closed in every part. In this way I have been able to sterilise water at 120° C. whilst retaining all the gas originally held in solution in it.

### 4. Complete Re-absorption of the Gases and Vapours.

It is not sufficient to retain the gases by hermetically closed apparatus, but the gases and volatile constituents of the heated liquids must be re-absorbed and re-dissolved.

In order to attain this I relied upon the following facts:—

1. The tensions of the gases and vapours vary directly as the temperature. These tensions can never be sufficient to attain the desired object.
2. The liquid treated expands in direct proportion to the temperature.
3. Every degree of temperature through which a liquid is raised when heated in an hermetically closed vessel may be expressed by a definite augmentation of pressure for each degree. A definite co-efficient of solubility of the gas contained in the liquid is also established for every degree through which the liquid is raised.

The pressure due to expansion is the one to which serious attention must be paid; for if the apparatus were entirely filled, and heat applied until the vessel burst, this would only be effected by expansion and not by the pressure of the gases evolved, which would be kept within restraint by reason of the co-efficient of solubility above referred to.

Guided by these facts I have found that by regulating the level to which I fill the apparatus I can cause the gases to become re-dissolved so soon as the pressure of expansion is removed by cooling.

I have found that as a rule 2 per cent. of the entire capacity of the apparatus must be left empty.

### 5. Elimination of the Chemical Action of the Metal.

In experiments made with different alimentary liquids in tinued or copper vessels, I noticed the rapid and intense reactions which take place between these metals and the liquids. These reactions are due chiefly to the action of the organic acids on the metals, producing gallates, malates, &c.; they are also due to the formation of metallic hydroxides by which the albumenoids and nitrogenous substances are precipitated. This accounts for beer, wine, &c., becoming turbid when heated in metal vessels as above mentioned.

Numerous researches and analyses led me to the conclusion that silver is the only metal which is not subject to these reactions, and which can be used in constructing sterilising apparatus.

All other metals employed, even nickel and aluminium, give these reactions. I therefore silver-plated my apparatus internally, and can now heat the liquids without the slightest metallic action.

I have thus been able, by observing the foregoing principles, to ensure the following conditions:—

1. Complete and evenly distributed sterilisation.
2. No change of taste or flavour.
3. No dissociation or alteration of chemical composition.
4. The preservation of all the gases and volatile constituents without alteration of taste.
5. No alteration of brilliancy.

The apparatus I have designed for beer, wine, milk, &c., consists of a cylinder of silver-plated metal the length of which is at least six times its diameter, fitted with a pressure gauge, a dial thermometer, a water gauge, taps, &c.

This cylinder contains the liquid to be sterilised and has internally a set of circulating tubes which communicate with a jacket, which surrounds the apparatus. The entire structure is placed on trunnions so that it can be easily oscillated to such extent that the top and bottom of the cylinder can be reversed. When the apparatus is ready and its hermetical condition has been verified by carefully examining the joints it is first necessary to ascertain that it is perfectly clean and the liquid is then allowed to enter from below. The water gauge is marked to show the extent to which the apparatus may be filled and this corresponds to an empty area of 2 per cent. of the volume capacity of the machine, to allow for the expansion of the heated liquid. When the apparatus has thus been filled the cock by which the liquid enters and that by which the air escapes are carefully closed and hot water at about 102° above the sterilising temperature. This water passes through the tubes, runs into the jacket which surrounds the apparatus and then flows off.

In 10 minutes the sterilising temperature, which is about 65° C. is attained and then the hot water must be stopped. The liquid is left exposed to this temperature for 15 minutes during which the cylinder is repeatedly oscillated by being turned through half a revolution both to the right and to the left. The pressure then rises to 5–6 atmospheres varying with the quantity of gas contained in the liquor. After this period of 15 minutes ordinary cold water is let in through the tap C. This water passes through the same circuit as the hot water and in about 10 minutes brings the liquid back to its original temperature. In the case of lager beer and liquids which it is desired to maintain at a low temperature the ordinary cold water is stopped and is replaced by iced water at 0° C. In 10 minutes the liquid is thereby brought down to 2–2½° C. Thus the total time occupied by an operation is: for heating, 10 minutes; for resting, 15 minutes;

for cooling, 20 minutes; or a total of 15 minutes. Taking into account the time occupied in filling and emptying the apparatus, the operation does not take more than from an hour and a quarter to an hour and a half, so that six or eight operations can be carried out in a working day. A single workman can perfectly manage the apparatus as all that is required is a little general attention, and that the cocks should be properly opened and shut.

After sterilization it is necessary that the liquids should be drawn off in such a manner as not to expose them to the germs contained in the air which can be done by isobarometric decanting. In the same way it is necessary to see that the vessels destined to receive the sterilised liquids are themselves free from all germs which might develop in the liquids. This is secured by means of steam, boiled water, or sulphurous acid.

Water must be heated to 120° C, and this must be done economically. With this object the water is first decanted and filtered by any of the well known methods, and then fed through recuperators into a steriliser, all of which are filled with water. The steriliser is the same as that described above, except that it is of course unnecessary to silver plate the apparatus, and that it does not oscillate. I proceed as described for beer, wine, milk, &c., except that I must use steam to obtain the temperature. The water contained in the recuperators is destined to be used in the second operation, and I avail myself of the steam when spent in the steriliser and generally of all spare heat still available to subject this water to preliminary heating by which a great saving is effected. Pumps in the steriliser and compressed air in the recuperators may be used for transferring the water if sufficient fall cannot be obtained. With a steriliser of 10 cubic meters capacity I can sterilise 100 cubic meters or 22,000 gallons of water per day, double this if working day and night. Thus it will be seen that a battery of these sterilisers could easily deal with the water supply of a city, and the cost entailed would be small. I have submitted my system to a number of eminent experts who have all expressed their satisfaction.

The following is an account of experiments with water carried out at Liège:—

Water taken from the River Meuse was found to contain 16.9 cc. of gas per litre, and when sterilised in my apparatus it was found to contain 16.7 cc. per litre, so that there had been practically no loss of gas. On the other hand, experiments made at the Bacteriological Laboratory showed that the water when first taken from the river gave in cultures on gelatine plates and in peptonised broth, maintained at 20–22°, an average of 2,230 microbe colonies per cubic centimetre. Most of these colonies were bacillus fluorescens, liquefaciens, bacillus subtilis and bacterium coli. This same Meuse water after sterilisation in my apparatus was found to be absolutely free from living germs, nor did cultures on gelatine plates or in peptonised broth show any development of micro organisms, even when maintained at 37°.

Besides this a hectolitre of water sterilised by my method was taken, and to this was added a litre of broth containing a culture of bacillus subtilis. This micro-organism is one of the most resisting to all methods of desirution, and chiefly to heat. It will live in ordinary boiling water, and its tenacity of life can be compared to that of the anthrax bacillus. It is far more resisting than the germs of cholera and typhoid fever. The emulsion was found on examination to contain 7,380 germs of bacillus subtilis per cubic centimetre. Fifteen minutes in my steriliser at a temperature of 120° absolutely killed all these germs.

The conclusion drawn by Dr. E. Malvoz of the Bacteriological Laboratory of the University of Liège, who made these experiments, is that by my system polluted water containing the most resisting germs can be sterilised in a quarter of an hour at a temperature of 120°.

Extensive experiments were made with beer at Brussels by Dr. van Laer. They were of a most exhaustive character, and may be briefly referred to as follows:—

In the first trial, lager beer was submitted during fifteen minutes to a temperature of 65°, and then cooled suddenly to its original temperature of 7°. After pasteurisation the

liquid remained bright. The persons who had assisted at the operation witnessed no appreciable alteration either in the colour, taste, or smell of the pasteurised liquid.

The samples were analysed before and after treatment with the following results:—

#### ORIGINAL GRAVITY OF WOLF 1173 BEER.

	Non-treated Beer.	Treated Beer.
Apparent extract .....	Grammes, 374	Grammes, 374
Real extract .....	5'475	5'475
Alcohol .....	4'63	4'63
Nitrogen per 100 cc. ....	0'77	0'72
Total acidity (cc. NaH <sub>10</sub> N <sub>10</sub> ) ..	24'0	24'0
Carbonic acid in volume per 100 cc. ....	98'5 Degrees.	94'5 Degrees.
Specific rotatory power ..	16'4	16'4
Number of organisms per cc. ....	1240 cells of yeast and microforma.	None.
Remarks .....		Absence of copper and lead.

Samples of this beer were forced during 15 days to a temperature of 30° C. After this the non-pasteurised liquid was examined to find out whether, when submitted to the incubation it had undergone any appreciable alteration in composition.

The following are the results of this examination:—

	Non-treated Beer.	Treated Beer.
Apparent extract .....	Grammes, 372'5	Grammes, 374
Real extract .....	5'325	5'475
Alcohol .....	4'51	4'63
Nitrogen per 100 cc. ....	0'79	0'72
Total acidity (cc. NaH <sub>10</sub> N <sub>10</sub> ) ..	31'8	24'0
Carbonic acid in volume per 100 cc. ....	98'5 Degrees.	94'5 Degrees.
Specific rotatory power ..	15'7	16'4
Number of organisms per cc. ....	Incalculable num- ber of elements.	None
Remarks .....	Beer turned thick deposit, bad taste.	Bright, good taste without deposit.

As the result of these experiments, Dr. van Laer has certified that beer may be kept unaltered in composition, appearance, and flavour for an indefinite period.

My system of sterilising liquids will no doubt be applied to many useful purposes in the various industries. The chief purposes to which it can now be applied seem to be—

1. Preserving beer and preparing it for export.
2. Maturing certain beers.
3. Medicinal beer.
4. Preserving wine and preparing it for export.
5. Sterilising the wine must, previous to placing therein pure races of yeast.
6. Champagne. Avoiding long storage in the cellars and the necessity of removing the ferment of yeast from the bottles.
7. Preserving cider and preparing it for export.
8. Preserving milk and preparing it for export.
9. Sterilising potable waters and water destined for surgical purposes in hospitals.
10. Sterilisation of the wash in distillation in order to introduce pure races of yeast which yield pure alcohol.
11. Sterilising large quantities of meat extracts, and forwarding them in large receptacles.
12. Preserving large quantities of fruits and syrups.
13. Sterilising infusions of coffee, tea, and cocoa.

14. Sterilising the products of the secretions of microbes, in lieu of sterilisation by means of porcelain filters, in the new methods of inoculation.

I have given much attention to these various applications of my methods, but a detailed account of my investigations under each of these heads would lead me beyond the scope of this paper.

#### DISCUSSION.

The CHAIRMAN in inviting discussion desired, at the request of the author, to convey his thanks to Mr. De Mosenhal for his very able translation and adaptation of this most interesting paper.

Mr. A. GORDON SALAMON hoped that the paper would receive the attention not only of brewers but of those who were competent to pronounce an opinion on the merits of Mr. Kuhn's work as applied to the sterilisation of potable waters. It appeared to him that the results obtained—as proved by the analyses submitted—were of the greatest importance from a hygienic standpoint. For the first time, they had a process capable of dealing with great bulks of water so as to leave them absolutely free from disease germs, without expelling the dissolved gases, or impairing the flavour of the fluid. If that were so, Mr. Kuhn had indeed conferred a benefit upon humanity. Educated in his father's brewery at Clermont-Ferrand, where M. Pasteur made nearly the whole of the experiments in connection with his work, "*Etudes sur la Bière*"; and receiving his initiation into the science of Bacteriology from the great Pasteur, Mr. Kuhn had worked hard at this subject for many years past. For more than a year he had experimented on a large scale on the pasteurisation of beer for use in casks; and though he failed at first in securing homogeneity of pasteurisation, he did obtain results which showed that the gases in the beer were not affected or expelled by the process of sterilisation, nor was the taste of the beer altered. Later, he made the important discovery that certain dissolved nitrogenous substances were, under the influence of heat, acted upon by metals or their hydroxides, silver being the only available metal which would withstand this influence and prevent the brilliancy of the beer from being impaired. Then he secured homogeneity of pasteurisation by introducing the principle of oscillation into the apparatus. Now, as the result of his long series of experiments, he came before them with a process ready not only for the brewer, but for all those who were interested in the preparation of beverages. With regard to its possible application in the brewery, he gathered that the process could only be applied to beer already brewed, *i.e.*, that in order to produce a bright beer it was necessary to start with it bright; nor did the process make a bright beer any brighter. At any rate, there would not seem to be any advantage in passing beer through the sterilisation apparatus and then contaminating it with findings. But even with that limitation it would be of the utmost importance to be able to secure the immunity of our beer from disease, and to export it in casks with full assurance that it would arrive at its destination free from false ferments or deposits and as bright as when it was shipped. This would constitute a new era for the export beer trade of this country, and would possibly be the means of enabling it to compete against the lager beer which had done so much harm to our export trade. In the course of his experiments, Mr. Kuhn had made a further discovery of considerable importance with respect to the determining temperatures of the life history of various yeast organisms. The death temperatures for many of these organisms had been already determined; but Dr. Kuhn had submitted them to intermediate temperatures with this remarkable result. He found that the animation or vital functions of the organisms might be suspended, and that the degree of temperature to which they were heated was a factor in determining the time during which the suspension of animation lasted. Thus, if it were known that a certain export beer was going on a voyage of two months duration, it would be possible to suspend the animation of the ferment for that period, with the certainty that it would return to life at the end of that period and give its natural condition to the beer.

Mr. E. G. HOOPER agreed with Mr. Salamon that the subject was of the utmost importance to the brewing industry of this country. English brewers prided themselves on producing a beer which was sound and capable of standing for a considerable period; but one could not be oblivious of the fact that it would be of great advantage if the beer were also absolutely sterile. The process was equally worth the attention of all those industries which were concerned with the production of aerated waters, and so-called temperance beverages. All these industries would, doubtless, avail themselves of the process if it were practicable. He did not gather that the process was applicable to beer *in cask*, as Mr. Salamon's remarks implied.

Mr. SALAMON regretted that he had not made himself clear on that point. He meant that this was the first practicable attempt at dealing with such a bulk of beer as would permit of sterilised beer being placed in cask. Hitherto, brewers had been restricted to pasteurisation in bottle, and they all knew with what result.

Mr. HOOPER, continuing, said there could be no doubt that if the process could be relied on to produce the results laid before them that night, it would advance pasteurisation to a point never before reached. His past experience of pasteurised beer was that it usually showed considerable deposit and was never effectually sterilised; and whenever the pasteurisation had been effected by heat the beer usually had a mawkish flavour. It was a most essential feature of the process before them that the flavour of the liquid treated was not affected by it.

Mr. F. WILSON had carried out several experiments on the sterilisation of beer in champagne bottles some 35 years ago. He had found no difficulty with the gas, because the bottles resisted the pressure well; but the flavour of the beer was so objectionable that the process was abandoned. He would like to know whether tin was among the metals which were to be avoided on account of its action on the liquid. There was no difficulty in keeping pasteurised beer; he had kept it for 10 years sound and satisfactory in every respect except flavour, which was not only caramel-like, but intensely bitter. That objection did not occur in lager beers, because the quantity of hops used in them was much less than in English beers. He was doubtful whether Mr. Kuhn's process could be satisfactorily applied to the heavily hopped beers of England.

Mr. W. LAWRENCE feared that the process of sterilisation, applied as recommended in the paper, would not yield so good a beer as if it were left un-sterilised, as the ripening action of the beer would be arrested before it had got into thoroughly good condition. He had tried apparatus made of various metals, and had found most of them injurious; therefore he considered bottles best. In his opinion, the great question raised that evening was the sterilisation of water. The difficulty was not in sterilisation, but in persuading people that any such process was necessary. With regard to the loss of gas from water so treated, that was not an important question. He had followed the discussion of this question at the Health Congress held last July, and had exhibited a sample of sterilised water before that Congress. The analysis of that water showed that the gases escaped in the following order: nitrogen, oxygen, carbonic acid. The first and last of these were both undesirable in drinking water, and the oxygen was re-absorbed. The great question in regard to water was not so much the sterilisation as taking away the salts of lime which led to gout and rheumatism. That was what his process did. He could sterilise and remove all the hardness from water at the ordinary boiling temperature either in a small apparatus or up to a hundred thousand gallons per hour. But with regard to the sterilisation of other liquids, that could only be done satisfactorily by such a process as Mr. Kuhn's.

Dr. S. RIDEAL asked whether any experiments had been made in the apparatus with reference to spore-bearing and pathogenic organisms.

Mr. G. W. MACINDOE, while admitting the scientific value of the process, thought that the cost was likely to be very high.

Dr. G. HARRIS MORRIS had also had some experience in the sterilisation of English beer in bottle, and could confirm all that Mr. Wilson had said as to the undesirable flavour produced in that way. The same flavour was not noticeable in pasteurised lager beer, probably, partly for the reason given by Mr. Wilson, and partly because it was masked by the flavour peculiar to lager beer. If the process could, as suggested by the author, be applied to beer in cask, it would, no doubt, be a great boon to the trade, but there appeared to him to be practical difficulties in the way. They were told that the beer, after passing through the apparatus, would go into the cask bright, and that no further fermentation would then take place. They knew, however, that English beer rarely contained any great amount of gas at any one time, and it appeared to him that such amount as it did contain when the beer was exported, would be lost during transit, and that the beer would arrive in a flat, unpleasant, and unsaleable state. With regard to the suspended animation, but not destruction, of the yeast cells, owing to the adoption of certain temperatures, that was perfectly correct, and he believed that continental pasteurisers had been aware of, and taken advantage of, it for some years past. The great point in the author's process, as applied to English beer, would be the absence of any flavour due to sterilisation. If that could be done and the beer would subsequently condition well, the process would be of inestimable benefit to the English trade. With regard to the sterilisation of water by this process one point had not been mentioned, namely, whether there would be deposition on the tubes due to the hardness of the water, and if so, whether this would affect the efficiency of the method.

Mr. D. HOWARD thought that interest in the paper was not confined to the brewing trade, there being a vast number of cases, such as the preserving of liquid foods, or the preparation of drugs, wherein the great difficulty to be overcome was the prevention of decomposition. As a rule, the object was attained by antiseptic rather than by septic methods, heavy doses of some germicide often being put into the material to be preserved. In the early days of bacteriology far too little thought was taken whether the macro-organism might not suffer by the means taken to prevent the spread of micro-organisms, whether a thoroughly sterilised milk containing a large dose of antiseptic might not ultimately determine the existence of a baby as well as a microbe. But just as in surgery, septic methods were superior to antiseptic, so a method which opened out the possibility of sterilising solutions before use was superior to a process for disinfecting solutions. He heartily commended the process, therefore, to the attention of pharmacists and those who prepared liquids to be used as tonics. Possibly, also, it might lead to the displacement of alcoholised tinctorial drinks by something more wholesome, if less exhilarating.

Dr. G. LINDSAY JOHNSTON considered that the subject of the paper concerned the medical profession in a special degree, as the use of sterilised water in surgery was becoming more and more important every day. In the most advanced hospitals of Europe the antiseptic method of treatment was entirely obsolete. The object of surgery was to heal wounds by first intention, or primary union of the parts. To this end, it was necessary not only to remove pathogenic germs, but to prevent the irritation of the tissues, which their access to the wound gave rise to. The organism referred to in the paper (*bacillus subtilis*), was comparatively innocuous. Far more important were the streptococci, and it was impossible in dealing with wounds to use an antiseptic which would kill these germs, because of the irritation which it caused to the tissues. Consequently, if surgeons wanted to secure an immediate and perfect union of the parts, it was impossible to use an antiseptic; and such immediate union was, in some cases (such as cataract of the eye) absolutely necessary to ensure a successful operation. It was for this reason that he expected Mr. Kuhn's process to yield valuable results in connection with surgery. One other point in connection with Mr. Kuhn's experiments he would like to refer to. Treatment with boiling water would kill most of the micro-

cocci, but it would not always kill their ova or spores; certainly it would not kill the spores of the *bacillus anthracis*. This could only be successfully dealt with by successive boilings, the germs hatched from the spores during the cooling being killed in the next boiling. By having at the hospitals a supply of sterilised water produced by Mr. Kuhn's process, this difficulty would be easily got over, and at least one department of surgery would thus be brought to a higher state of perfection than it had yet reached.

Mr. W. THOMAS regarded the process as an extremely useful one, but thought it was subject to limitations. The destruction of organic life in liquids was very important, but how were the liquids to be dealt with afterwards? Hitherto, antiseptics had been relied on. Mr. Kuhn's process would avoid that necessity, but there would be the countervailing one of keeping the sterilised liquid in closed vessels, or the protection would be lost. This difficulty applied equally to potable waters and to chemical or medicinal preparations. No doubt sterilised water could be with care preserved for the purpose referred to by Dr. Johnson; but he greatly doubted the practicality of supplying it through the mains for general consumption. Under the ordinary limitations of domestic conditions, two supplies would be untrustworthy, because the most readily accessible tap would always be used, whether it were the "safe" one or not; and the expense of sterilising the whole town's supply of water would be prohibitive. He did not raise these points as objections to the process, but because it was desirable that in considering a new method, its limitations should be taken into account. The same remarks applied to some extent to the sterilisation of beer. Granted that the flavour was not affected, it would be an advantage to have sterilised beer in vessels. Glass was trustworthy for this purpose, but he doubted whether it would be possible to obtain casks which, after months of travelling, would be proof against the access of bacteria.

Mr. O. GUTTMANN said that the remarks of several speakers had led him to make a mental calculation with respect to one of the most important applications of the process, namely, the purification of water for town use. The result was to show that in order to supply sterilised water to a town of, say, 100,000 inhabitants, it would cost 5,000l. per annum for fuel alone. As this would mean an increase in the rates to the extent of 4s. in the £, he had not much faith in the application of the process in that way.

Mr. C. G. CRESSWELL remarked that, though the application of the process to beer, water, foods, and drugs had been discussed, no one had referred to its adoption in the case of wine. He reviewed the experiences and difficulties he had met with in an attempt to so treat the light natural wines of Italy, Spain, and Portugal as to admit of their being imported for consumption in England. The results of those experiments proved that for red wines containing tannin, sterilisation was not necessary, but that for white wines either the removal of the albuminoids upon which the bacteria lived, or the destruction of these latter by sterilisation of the liquid, was necessary, and for that purpose Mr. Kuhn's process appeared to be the most rational method that had yet come to his knowledge.

The CHAIRMAN, referring to Mr. Guttmann's criticism, thought that that gentleman had not taken into account all the conditions of the problem. At any rate, he for one could not agree with his calculation. He would like to know the number of heat units lost in heating a specific quantity of water by the process.

Mr. GUTTMANN observed that he had only made a rough mental calculation, but that he thought it would be found to be within the mark.

Mr. H. DE MOSENTHAL, replying for the author, said he feared that in his efforts to condense the immense amount of material with which Mr. Kuhn had supplied him into a comprehensive form, he had perhaps laid the process open to questions and doubts which would not have arisen had all

the author's work on the subject been before the meeting. It had rightly been said that one of the most important applications of the process in this country would be that of enabling brewers to export their beer in casks, thus permitting English beer to compete with that made in Germany. Mr. Kuhn had actually applied the process to English beer, and the only reason why the analyses of lager beer were quoted was that he (the speaker) had thought it best to choose those certificates which had the most scientific character, *i.e.* in which the analyses bore testimony to investigation. Members might rely, however, that English ales had been tested in the same way, and that their flavour had remained quite unimpaired. He understood that the author attributed this to the reabsorption of the gases and vapours, which he had endeavoured to explain in the paper. He was assured, too, that experiments with English casks had proved them to be quite equal to retaining the liquor in good condition during the time necessary for transport. With regard to the point raised by Dr. Johnson, he would understand how impossible it was to carry out a series of experiments with every individual microbe; therefore, that micro-organism had been taken which was known to be the most resistant, namely, the bacillus subtilis, and it was shown that by treatment at a temperature of 120° C., with six atmospheres of pressure, the spores of this bacterium were killed. As to wine, the experiments carried out in France had been unnumbered, and had given complete satisfaction to the most eminent experts. In fact, in every direction in which it had been tried, the success of the process was attested by the evidence of the highest authorities. He recognised the difficulties of making people appreciate the necessity for sterilising water. On the continent, however, the importance of doing so was beginning to be appreciated. Mr. Kuhn was now making an installation to supply the barracks at Antwerp with sterilised water.

### INDIA-RUBBER.

BY T. CHRISTY, F.R.S.

Mr. T. CHRISTY exhibited specimens of different sorts of rubber, specially with the view of showing that rubber can be extracted by water. In the first instance the Landolphia was shown with the roots and boughs as cut from the living tree, next the stems after they had been boiled; the next stage was the debris of the bark and the rubber still hanging on to one end of a twig which otherwise was perfectly clean and free from any succus; then there was the mass as it fell into the pan with the bark mixed with the gum. It was then shown in different stages of treatment up to the Landolphia rubber as sent into commerce. Another Landolphia was shown from the Congo: this had been wound off direct from the tree into a ball and dried in the course of winding. Another exhibit was Almadina, so-called from the man who discovered it and worked it out in West Africa; it also goes by the name of potato gum. This gum has most interesting properties, which have been fully explained in the scientific papers, especially by Mr. Lascelles Scott. From a series of experiments lasting over four years, it was found that by placing in a box, open to the sun and rain, some of the very best india-rubber and gutta-percha, some pure Almadina, and also Almadina mixed with india-rubber and gutta-percha, at the end of the experiment the best rubber had almost disappeared and was quite worthless, whereas the india-rubber and gutta-percha mixed with Almadina remained perfectly sound and with full elastic properties. He obtained some tons of Almadina, melted it, and added to it a considerable quantity of water and some tannic acid. This was well stirred and it took up a large quantity of water. When the mass was sufficiently kneaded it was put into bags and allowed to cool, and then sent

down to some large india-rubber works, and the proprietor was so pleased with it that he offered to take any quantity at 1s. 6d. to 1s. 10d. per lb. This rubber, of course, had a quantity of water in it, allowance had to be made in charging the weight when it was handed to the railway of at least 20 per cent. As practical manufacturers on a large scale had now admitted its great value, he then met them and told them that he could no longer continue to manufacture this gum, and that he was prepared, if they gave him a sufficient order for the raw material, to give them all the information. Suffice it to say that they gave the order, but the foreman resented it very much and did all he could not to use this rubber, until his place was handed over to another man who thoroughly understood the valuable properties of Almadina. The consequence was that a very much higher class of goods was turned out of these works and large contracts made; this shows how difficult it is to overcome prejudices.

Another gum also obtained by being boiled was chicle gum. This came from Mexico, and was known to Americans as the base for their chewing gum. Small pieces were prepared for those who desired to experiment with it. He had sent a sample to one of his friends, who was certainly one of the most advanced men in the rubber trade, and explained to him the most simple manner of testing it, *viz.* chewing it; he did so, and he wrote back saying that he was delighted with the material and wanted a quantity for experiment, and, if it went down to a certain price, to put his name down for the first supplies. This gum was also found useful in plaster making and pills.

In conclusion there were many other gums which he believed would advantageously yield to the treatment of cutting down the boughs and boiling them in water, finally extracting the rubber as the mass cooled. He had sent a request to several places where the rubber trees were growing wild, suggesting that this plan should be tried.

### ANALGENE (ORTHO-ETHOXY-ANA-MONO-BENZOYLAMIDO-QUINOLINE).

BY E. JAHN.

Mr. E. JAHN exhibited some interesting samples, representing the intermediary products in the manufacture of analgene. Analgene is one of the recent synthetic remedies used chiefly in the treatment of neuralgia and of sundry pains of nervous origin. It has no action on the heart and no unpleasant symptoms are produced by its administration. The colour of the urine of persons having partaken of analgene, however, very often becomes dark red. The red colour is due to the decomposition product of analgene in combination with uric acid. A sample of this substance was among the exhibits, labelled "Muriate of *o*-oxy-ethyl-*a*-amido-quinoline." The solution in water is bright red.

The following is a list of specimens exhibited:—

1. Quinoline-*o*-sulphonic acid, commercial.
2. Quinoline-*o*-sulphonic acid, pure.
3. *o*-Oxyquinoline, commercial.
4. *o*-Oxyquinoline crystals.
5. *o*-Oxyquinoline, sublimed.
6. *o*-Oxyquinoline ethyl-ether.
7. Sulphuric-*o*-oxyquinoline ethyl-ether.
8. Nitrate of *a*-Nitro-*o*-ethoxyquinoline.
9. *a*-Nitro-*o*-ethoxy-quinoline, commercial.
10. *a*-Nitro-*o*-ethoxyquinoline, commercial.
11. Hydrochloride of *o*-oxyethyl *a*-amido-quinoline.
12. *o*-Oxyethyl-*a*-amidoquinoline, commercial.
13. *o*-Oxyethyl-*a*-amidoquinoline, pure.
14. Analgene, crude.
15. Analgene, pure.
16. Hydrochloride of *o*-Oxyethyl-*a*-amidoquinoline.

Analgene is a derivative of quinoline, and has the following formula:—

It is prepared by introducing into the quinoline molecule consecutively an ethoxy-group in the ortho-position and a substituted (acid radicle) amido group in the para-position.

On treating oxyquinoline with caustic soda and ethylbromide, ethoxyquinoline is obtained, which by the action of nitric acid is converted into ethoxynitroquinoline, and this substance is then reduced to the amido form in the usual way. The amido derivative is treated with benzoylchloride and soda in aqueous solution, and thus yields the product in question. This crude analgene is thoroughly purified by repeated crystallisation from alcohol, and in its pure state forms a white crystalline powder insoluble in water, soluble in acids, readily soluble in hot and sparingly so in cold alcohol. As a criterion of its purity, it melts at 208° C. and leaves no residue when ignited on platinum foil.

#### *o*-Oxyethyl- $\alpha$ -Amidoquinoline Hydrochloride.

It has been proved that in the human system analgene is either destroyed entirely, or separation of the benzoyl group takes place with complete oxidation of the residue. Where a separation of the benzoyl group occurs, the urine is always of a dark colour, caused by the action of the free amido product on the uric acid. This may be proved in two ways:—

1. By adding oxyethylamidoquinoline to urine in its normal state. After shaking, and, if necessary, warming, the intense coloration takes place, the intensity varying according to the quantity added from a luminous red to a dark brown red. This coloration is caused by the combination of oxyethylamidoquinoline with uric acid, which produces exactly the same colour when in solution.

2. By isolating the amido compound from the urine after the latter has absorbed the benzoyl product. When soda is added, the colour which is at first red is changed to yellow. On extracting with ether and subsequent evaporation and drying of the extract, the amido compound is obtained not in a pure state, but its presence is unmistakable. The residue when taken up with water and mixed with a solution of chloride of lime yields the light rose colour characteristic of ethoxyamidoquinoline. It disappears gradually when left standing, but instantly on heating. Another reaction proving the presence of ethoxyamidoquinoline in urine may be made as follows:—The urine is acidified with hydrochloric acid, this renders the colour brighter, then some ice and a few grains of nitrite of soda are added, whereupon the liquid turns to a light yellow. On adding a solution of  $\beta$ -naphthol disulphonate of soda, the colour becomes a dark cherry red. When heated with ferric chloride, the red urine turns to a deep red colour.

## PHOSPHOR COPPER AND BRONZE.

BY C. MCCOMBIE.

THE more free from pores and the more homogeneous an alloy is, the stronger, tougher, and more elastic is the casting from it.

Bronze and other alloys of copper in the liquid state contain oxygen, and the casting therefrom is porous in proportion to the volume of oxygen. But if phosphorus be introduced into the liquid mass it eliminates the oxygen by combining with it, and thus prevents the production of porous castings.

The tin contained in alloys is not easily crystallised, except on the introduction of phosphorus into the mass. Two crystallised metals form a more homogeneous alloy than two metals, one of which does not crystallise. Accordingly phosphor-bronze is far more homogeneous than bronze without phosphorus.

Phosphorus furthermore renders alloys highly fusible. Thus the molten mass will fill the very minutest parts of the mould and produce most exact castings.

Phosphorus also reduces the loss in castings, and lessens the expense in making bronze.

The introduction of phosphorus into a molten mass of metal has not heretofore been accomplished without considerable loss of that substance, and up to the present it has not been found possible to introduce into the copper more than 10 per cent.

Mr. Schenckler has, however, quite recently discovered a process by which he gets 20 per cent. of phosphorus into the copper, this being the highest percentage that copper will take.

This phosphor-copper imparts to any alloys all the qualities enumerated above, but it may also most advantageously be used for the renovation of old bronze, brass, and scrap gun metal.

Alloys hardened by an addition of tin lose in toughness and are rendered brittle in proportion to the percentage of tin used. The new phosphor-copper when added imparts to the alloy any desired degree of hardness, and not only produces that effect, but at the same time enhances the strength, toughness and elasticity of the casting.

Finally, alloys containing phosphor-copper have the advantage of not being liable to oxidation.

This phosphor-copper is cast in plates that may readily be broken up into small pieces of equal weight. On adding it to the liquid mass it at once thoroughly mixes with it without developing those stifling vapours so obnoxious to foundrymen.

The samples submitted contain—

	Per Cent.
Phosphorus .....	10
" .....	12½
" .....	15
" .....	18
" .....	20

**Phosphor Bronze.**—The degree of hardness imparted to phosphor-bronze is dependent on the quality of phosphor-copper added to the alloy. It naturally varies with the purpose the casting is intended for.

MR. EUSTACE CAREY IN THE CHAIR.

# ON THE CALCULATION AND COMPOSITION OF BLAST FURNACE CHARGES AS APPLIED TO THE SMELTING OF LEAD AND SILVER ORES.

BY ERIC F. WATSON, F.I.C.

In the process of working ores in blast furnaces we can in general distinguish between two distinct constituents in the ore apart from those which are volatile.

The metal to be recovered and that non-volatile component part accompanying the metal and which is to be slagged.

It sometimes happens that the constituents of an ore to be slagged consist of such a variety and quantity of such elements that the temperature they are submitted to is in itself sufficient to cause the charge to melt, thus reducing it without the addition of fluxes. This of course is the most economical method.

In most cases, however, the ores are of such a composition that they do not admit of being reduced directly, but only after the addition of the corresponding fluxes. In the latter case the metallurgist will (taking due consideration of the properties of the metal to be reduced and the nature of the constituents to be slagged) avail himself of such fluxes as best suit his purpose, or whenever practicable (and which is the best method of procedure) classify his different ores in such a manner that when mixed the one replaces in the other the necessary slagging material and thus gives to the whole the requisite fusibility.

In working lead ores in blast furnaces whether they have to be previously roasted or not the metallurgist will always bear in mind the volatility and ready fusibility of lead, and try to produce a slag, melting at the lowest possible temperature in order on the one hand to increase the output of metal, and on the other to run through within the shortest possible time the greatest amount of ore with the minimum expenditure of fuel.

Now before we can produce a slag of the proper composition so as to admit of a complete reduction of the metal, it is before all things absolutely essential that the chemical composition of the ore be known quantitatively; then only can one learn the amount of elements to be slagged.

To obtain such an analysis is now-a-days no hard matter, although in a great many cases and especially in large works where ores of various composition are being treated, it becomes not only complicated but almost impossible to analyse each separate batch of ore, simply because the time and cost would make the final process of treatment too expensive.

In such cases the metallurgist is obliged to ascertain the nature and quantity of the constituents to be slagged from previous analyses, or other data well known to him, so that he may be in a position to calculate the most suitable composition to give to the charge.

The ores to be smelted at the works I have at present in my mind, and which I shall take as a practical illustration of my paper, are of the most varied and always changing composition, they contain besides gold, silver, lead, and copper, silica which is most predominant and iron in the form of iron sulphide ( $\text{FeS}_2$ ) as well as manganese, aluminium, calcium, and magnesium in varying quantities. The lead, copper, and a greater portion of the silver occur in combination with sulphur, whilst the gold is to a large extent in the metallic state, only a small portion of it appearing to exist in combination with other metals. The usual method of procedure is to first roast in reverberatory furnaces and then smelt with the addition of the necessary fluxes in the blast furnace obtaining as the principle product argentiferous and auriferous pig lead.

The resulting slag is to be a ferrous silicate and is to have as nearly as possible the composition of a mono silicate, but far more economical purposes is calculated on an oxygen basis of 1:1.5 making it  $\frac{1}{2}$  mono and  $\frac{1}{2}$  bisilicate.

I will explain what I mean by this. A monosilicate has the composition—

R = a metal combined with one atom of oxygen.

In these two slags the oxygen in the base is in proportion to the oxygen in the acid.

In the monosilicate as 1 : 1

„ bisilicate as - 1 : 2

By adding the amounts of oxygen together we get  $2 : 3$  or  $\frac{2}{3} = 1 : \frac{3}{2} = 1.5$ , and it is more economical to do this for the simple reason that we require a less amount of base or iron flux. The base to be used as fluxing material is composed for the greater part of ferrous oxide. According to the analysis and nature of the ores the first thing we should proceed to do would be to classify them into groups.

A convenient classification is the following:—

Under the *First Group* come all dry silver ores (i.e., low grade silver ores) containing no pyrites, or at least pyrites only in small quantities.

Under the *Second Group*. All pyritic ores including matte; and under the *Third Group* all lead ores.

It may be well for me to mention here that when I speak of matte I am referring to roasted iron pyrites  $\text{FeS}$ , i.e., the amount of matte the pyrites is capable of producing, since this is the chief constituent in our ores next to silica and provides us at once with a most suitable means for slagging off a portion of the silica. (I shall work out an example later on so as to show you more clearly what I mean by the “calculation of fluxes.”)

The analysis of group one have shown by practice that the greatest proportion of silica is 80 per cent, whilst the smallest amount of base is equal to 20 per cent. lime ( $\text{CaO}$ ) which substituted in the form of slagging material is equivalent to 20 per cent. of iron.

If it is intended to make the dry silver ores smelt readily it is better to have a small excess of ferrous flux rather than too little and for this reason the assumption is made that the assay gives 80 per cent. silica and only 20 per cent. calcium oxide = 20 per cent. iron.

Likewise in the pyritic ores of the second group, in order to ascertain whether they are readily fusible or if fluxing material is wanting, a determination of the iron and silica must be made.

In fact, in all the pyritic ores it is necessary, by means of assaying, to ascertain the amount of matte they are capable of producing, since this gives us the basis upon which to calculate the contents in iron of the ore available for slagging purposes.

It has been found, according to all the matte and iron assays that have been made, that there exists a constant proportion between the matte assay and actual amount of iron present in the pyritic ores, from one and the same mine, for which reason all pyritic ores have also been classed into four groups as the result of a good many assays and iron determinations made:—

	Per cent. Fe.
In the first group ores containing.....	72
„ second „ „ „ .....	58
„ third „ „ „ .....	51
„ fourth „ „ „ .....	37

of the matte contents.

According to this subdivision, therefore, the amount of iron is calculated by multiplying the amount of matte by that number in per-centages in the pyritic ore in which it was contained. This may at first sight not seem quite clear. I will therefore give an example.

Suppose we have made an assay of these pyritic ores and obtained as a result 40 per cent. of matte.

Now say this ore has come out of the 4th group in which every 100 parts of matte yield 37 parts of iron, then we get the following proportion:—

$$\frac{37 \times 40}{100} = 14.80 \text{ per cent. Fe.}$$

i.e., the above ore giving 40 per cent. of matte contains 11.80 per cent. of iron.

The amount of silica contained in the pyritic ores is then ascertained as follows:—

Since the iron is contained in the ores as  $\text{FeS}_2$ , the equivalent amount of sulphur corresponding to the iron must be first calculated, and the amount of  $\text{FeS}_2$  thus found subtracted from the dry weight. The remainder is then taken as silica and other earthy bases and put down (as in the case of the low grade silver ores) as consisting of 80 per cent.  $\text{SiO}_2$  and 20 per cent.  $\text{CaO}$ .

By this means we arrive at the amount of silica, earthy bases, and by roasting the pyritic ores we also ascertain the quantity of the  $\text{FeO}$ .

If we find the amount of base thus calculated sufficient to make the silica present fusible (i.e., by the formation of the desired silicate) then the addition of an iron flux is not necessary. On the other hand, if the amount of base is in excess then ore may be added, but if there is too much silica and too little base present then the necessary amount of iron flux must be added in order that the ore may melt effectively.

The lead ores we should treat in precisely the same manner. A determination of the lead would be made so as to ascertain if the addition of an iron flux is necessary before they will melt or not.

This estimation of the lead serves only to ascertain whether the lead occurs as oxide or as sulphide in case analysis of the ore should not be to hand. Its equivalent of oxygen or sulphur is first calculated, and the difference between  $\text{PbO}$  or  $\text{PbS}$  and dry weight taken as silica. The necessary amount of  $\text{FeO}$  being then calculated corresponding to the excess of  $\text{SiO}_2$ .

In practice, however, when one is continually smelting the same ore it is customary to draw out once and for all a set of tables which show at a glance the amount of iron and silica required for a certain percentage of lead and matte contained in the ore, thus giving directly the quantity of ferrous flux to be added in order to make the lead ores fusible. These tables are of course founded on the result of a series of assays.

The iron flux is used in the form of brown iron ore (limonite) or in other words hydrated oxide of iron which contains on an average 50 per cent. of iron and is considered an excellent fluxing material.

On these bases every calculation is made, and one can depend upon it that if the calculation has been properly carried out, the charge will melt in the reverberatory as well as in the blast furnace.

In works I have visited where such a class of ores as I have mentioned is treated, this method of calculation and fluxing is resorted to, and it has proved itself to be the best and most economical, and enabled a set of blast furnaces to be worked for a period of two years without any stoppages whatsoever for overhauling. If we look at this method of calculating the charge from an economical point of view, we may still be led to raise the objection that too much silica has been taken into account necessitating thereby the use of an extra amount of iron ore. But this objection does not appear to be sufficient since the presence of a small excess of  $\text{FeO}$  would prevent the danger and assure us of a ready fusibility of the charge, and in case the resulting slag shows itself to be too liquid (a matter readily ascertained as soon as the first charges have been down) the excess of  $\text{FeO}$  could always be neutralised by the addition of dry silver ores always at hand.

And now let me work out for you here an example of an average ore to be smelted, and show how we should proceed to calculate out the fluxes in the ordinary course of events. Let us suppose it is required to calculate the furnace charge, tonnage of bullion and matte and assay composition. Also analyses and percentage of copper in matte for a furnace of daily capacity of 150 tons under the following conditions:—

## Analysis of Ore.

## Excesses in Fluxes.

	Per Cent.	
$\text{SiO}_2$ .....	28.00	Limestone ( $\text{CaO}$ ) 50 per cent. excess.
$\text{Fe}_2\text{O}_3$ .....	33.00	Iron ore ( $\text{FeO}$ ) 60 per cent. excess.
$\text{CaO}$ .....	6.00	
$\text{Cu}$ .....	17.00	Loss of Au, Ag, and Cu in smelting
$\text{Al}_2\text{O}_3$ .....	6.00	3 per cent. each.
S .....	10.00	(of which 8 per cent. goes in matte found
		by practice and analysis of matte).

In silver the ore runs 15 oz., and in gold  $\frac{1}{10}$  of an oz.

Here we have both a bullion and matting problem. The first question to consider is that sulphur has more affinity for copper than for iron.

The loss in copper must therefore first be deducted before calculating the matte, i.e., 3 per cent. of 17 = 0.5 leaves 16.5 per cent. Cu. Next how much sulphur does 16.5 per cent. Cu require in matte formation.

According to our matte tables calculated on the formula  $\text{Cu}_2\text{S}$ .

16.5 Cu require 4.186 per cent. S.

We are given 8 per cent. available sulphur, therefore  $8 - 4.186$  leaves 3.814 per cent. S to combine with iron in matte formation. This 3.814 per cent. S we find requires 6.82 per cent. Fe.

The composition of matte therefore per 100 tons of ore is as follows:—

Cu .....	16.5
Fe .....	6.82
S .....	3.94
	<hr/> 31.32

The next consideration is the combination of Fe and  $\text{SiO}_2$ , and as we require a ferrous silicate all the iron must be calculated on the basis of  $\text{FeO}$ . (For simplicity, I have finally calculated as pure mono silicate  $\text{FeO} \cdot \text{CaO} \cdot \text{SiO}_2$ , and not as a mixture of mono and bisilicate as previously stated.) First then deduct amount of iron taken by the sulphur from the amount in ore analysis:—

33 per cent. $\text{Fe}_2\text{O}_3$ = 20.70 $\text{FeO}$ .
6.82 Fe = 8.56 $\text{FeO}$ .

$20.70 - 8.56 = 12.14$  = the amount of iron in the ore available for slagging purposes.

We find next the—

28 per cent. $\text{SiO}_2$ require 33.60 per cent. $\text{FeO}$ .
Available $\text{FeO}$ = 20.94

Therefore amount to	= 12.66 $\text{FeO}$ .
be fluxed in	

Next to calculate from flux analysis the amount of iron ore required for 100 ton charge of this ore.

Since the iron ore contains 60 per cent. excess we get the following simple proportion  $60:100::12.64:x = 21.1$  = tons of iron ore necessary for fluxing 100 ton of the ore to be smelted.

Similarly take the estimation of lime equivalent in ore—

CaO, .....	= 6 per cent.
6 per cent. $\text{Al}_2\text{O}_3$ equivalent to CaO = 9.88 per cent.	

Therefore  $15.88 = \text{lime value in ore}$ .

As in the case with iron, so here we must also determine the amount of lime required by 28 per cent.  $\text{SiO}_2$ , and we find that the lime required by the  $\text{SiO}_2$  in ore to be smelted

= 26.32 per cent. $\text{CaO}$ .
Available lime in ore = 15.88 per cent. $\text{CaO}$ .

Therefore the amount	= 10.44
to be supplied by flux	

Since the limestone flux contains 50 per cent. excess  $\text{CaO}$  we need only multiply 10.44 by 2 to get the amount necessary for 100 tons = 20.88.

The tonnage of fluxes for 100 tons of ore are therefore :—

Iron Ore.....	21.10
Limestone.....	20.48
	<hr/>
	41.58
Ore .....	100.00 tons,
	<hr/>
	141.58 tons.

All these calculations have now to be readjusted since the capacity of furnace charge is 150 tons, and we have so far only calculated to 100 tons plant.

The following proportion you will find gives us the true composition of our charge—

141.58:150::100::x = 105.94 tons of ore in 150 ton charge.
141.58:150::21.10::x = 22.35 " " iron flux " "
141.58:150::20.48::x = 21.69 " " limestone " "

149.78 = approximately 150 tons.

If we readjust the 31.32 tons of matte made on 100 tons of ore to absolute ore charge, i.e., 150 tons, we get  $31.32 \times \frac{150}{100} = 31.77$  tons of matte.

To find the percentage of copper in matte; in 31.32 tons matte we have 16.5 per cent. Cu = 52.68 per cent. copper.

The amount of bullion produced is calculated as follows:—  
105.94 tons of ore  $\times 45$  oz. = 4767.3 oz. = gross amount of silver in ore. Loss = 3 per cent. = 143.01; therefore 4767.3 oz. - 143.01 leaves 4623.29 = nett amount of silver in ore.

The gold per ton = 0.2 oz.; this on 105.94 tons = 21.18 oz. = gross amount of Au in ore; loss = 3 per cent. = 0.635 oz.; therefore 21.180 oz. Au. - 0.635 = 20.545 oz. = nett amount of gold in ore.

In the analysis of the ore to be smelted I have not shown any lead. In order therefore to complete the problem let us assume that there is 12 per cent. PbO. This does not to any great extent affect the calculation since the metal is to be reduced, though the amount of elements to be slagged would be slightly less. 12 per cent. PbO = 11.12 per cent. Pb = tons of lead in 100 tons of ore or 11.78 tons of lead readjusted to absolute ore charge of 105.94 (roughly 106 tons).

Deducting 3 per cent. for loss we get as the nett amount of lead produced 11.43 tons.

This completes the problem as far as the calculation of the fluxes goes. Of course I could go much further by giving you a statement showing the financial considerations of this problem, but I have not deemed it necessary. It only remains now to insure a thorough mixing of the whole, and for this purpose layers of ore and flux are laid alternately on top of one another, and cut vertically when required, the cutting showing a stratified appearance.

The best practical evidence we can then have as to the right composition of the charge is its behaviour on roasting in the reverberatory furnace. If it already begins to melt on roasting we can take it for granted it will melt still more readily when charged into the blast furnaces. In contradistinction to what I have been saying, I might give you an instance I heard of of unsuccessful rule of thumb smelting where the works had to be closed up and abandoned simply because about 30 per cent. of the metals were being lost in the slags, and this was proved by the fact that some more competent smelters came along, bought up these old slags and actually made a profit out of them.

In conclusion let me admit that I am fully aware how delicate a matter it is for me to pretend to give any opinion as to the organisation of smelting works to such men as yourselves who have much more practical experience than myself, but I have ventured to say this much in order to draw more attention to what certainly lies at the root of all successful smelting, viz., systematic assaying and analysis, and the giving of the proper composition to the charge so as to combine all the useful elements in such due proportion as to extract the greatest amount of metal.

SESSION 1894-95.

Friday, January 4th, 1895:—

Mr. R. Le Neve Foster. "The Prevention of Smoke arising from Intermittent Firing in Various Chemical and Allied Processes."

Mr. R. J. Flintoff. "The Formation of Mazonia in developing Aniline Black on Cotton."

Meeting held Friday, 7th December 1894.

MR. R. FORBES CARPENTER IN THE CHAIR.

In the half hour before the reading of papers which is allotted to discussion Mr. Levinstein referred to several laboratory experiments which were made by Behring previous to the introduction of antitoxin in hospitals. In the first instance a small measured quantity of the diphtheric poison from Löffler's diphtheria bacillus was injected into a guinea-pig, when death followed; then a calculated quantity of antitoxin was injected into another guinea-pig, and a quarter of an hour afterwards the same quantity of the diphtheric poison which previously proved a fatal dose, was injected, when no symptoms of diphtheria developed. Finally a number of cc. of the diphtheric poison was poured into a test tube, to this were added so and so many cc.'s of antitoxin. This mixture was injected into another animal when again no symptoms of diphtheria or any other symptoms were noticeable. These experiments prove without doubt in Mr. Levinstein's opinion that the antitoxin neutralises and makes the true diphtheric poison of Löffler's bacillus innocuous. How far these remarkable results obtained with animals will be confirmed in treating human beings suffering from true diphtheria, and how far no other ill effects may follow such treatment, only time can definitely decide. Several chemists are at present engaged in the investigation of the chemical constitution of antitoxin, and if they should be successful in their labour, there is no reason why antitoxin may not be one day synthetically produced without the intermediate use of animals. Mr. Levinstein then showed three bottles, each containing about 10 cc. of fluid-healing serum, bottle (1) with 600 immunity units; bottle (2) with 1,000; bottle (3) with 1,500 units. The serum had been prepared by the Farbwerke Hoechst a M. under the personal supervision of Professor Behring and Professor Ehrlich.

PIPE COLUMNS FOR SAVING CHAMBER SPACE,  
IN THE MANUFACTURE OF SULPHURIC ACID.

BY PETER S. GILCHRIST.

In these days of severe competition, manufacturers have to look very closely into the cost of production, to see that each article is produced at the lowest possible cost. In no branch of business has competition been felt more keenly than in the chemical industries. Manufacturers re-model their plants to maintain efficiency, so as to cope with newer plants that are erected from time to time, and which com-

prise the latest modern improvements, for the advantages in manufacturing certainly lie with the latter. In this branch of industry, nothing plays so important a part as sulphuric acid, and it is to the manufacture of this I confine myself, but more especially to the chamber process.

The construction of chambers is the same in general, but these differ materially in their relative sizes, usually being

long, so as to get the maximum amount of capacity from a minimum consumption of lead, the longest chambers being generally at the first part of the system, and reducing towards the end, the last one usually being of small capacity. Chambers are now built in America, with a width of 30 ft., and a height of 20 ft., this being wider than is generally found in English works.

NO. 1. PIPE COLUMN.

As to the length of chambers, there are wide differences of opinion, personally I prefer short chambers. The longest one the writer has had experience with was in Baltimore Md., being 225 ft. long, but it was found difficult to obtain uniform working throughout.

In a chamber, say 60 ft. in length, there is no doubt a higher yield of acid proportionally obtained, in comparison with a longer chamber, for the gases in traversing the chamber naturally become weaker, owing to condensation of the gases in progress: this is shown by the drips and also by an analysis of the gases.

You are all acquainted with Professor Lunge and Dr. Naef's experiments, showing how unequal the formation of acid is in the chambers, and how the curve of acid formation rises to a certain point, (in the first chamber about 50 ft. from the front), and then takes almost a horizontal move-

ment until it enters the next chamber, when the curve again rises, and so on.

Anyone watching closely the passage of the gases from one chamber to another must see that it causes a great reaction to set in, consequently followed by an increased production of sulphuric acid.

The reasons for this are obvious, the vapours strike against the surfaces of the chamber ends, and the sides of the connection, causing the particles forming to interact more quickly. Again the gases in passing through the small aperture, are better mixed, and are cooled by radiation from the surfaces of the lead.

With small chambers this result is repeated oftener than with large ones, so the work accomplished in a corresponding amount of chamber capacity must necessarily be in favour of the small chambers.

The oftener this increased reaction takes place in the system, the more work can a given chamber space accomplish, and it is with this in view we aim to diminish

the chamber space, and probably eventually to do without any.

NO. 2. PIPE CASE BETWEEN GLOVER AND FIRST CHAMBER.

To this end the writer and F. B. Hacker have devised the "Pipe Column," it is a small tower 4 ft. by 3 ft. 6 ins. by 13 ft. 6 ins. high, with horizontal lead pipes burnt to the sides, and so placed as to continually break the course of the gases, as they pass through. See sketch No. 1.

The column is cased in on two opposite sides, facing the ends of the open pipes, one side being left open at the bottom, and the other at the top, which is connected with a stack, by this means a strong current of air is continually drawn through the pipes, or artificially cold air can be forced through.

Acid lites are put on the top, for acid to pass down, or steam may be introduced into the tower, along with the inlet gases.

The column sits in a strong wooden frame, the bottom of the tower being carried on four spiral springs, of such resistance as just to take up the expansion of the lead, as it usually expands in the same proportion as the chamber side sheets, this prevents any wrinkling or cracking of the lead connections to the chambers.

The casing around the tower which forms the flues, is made of one inch and a quarter tongued and grooved

narrow flooring boards; the stack of light galvanized iron. The tower is constructed so that it can easily be got at, all burning being outside, the pipes are also flanged and burnt on the outside, making a strong and compact tower.

The weight of lead used can be varied according to the amount of work the column has to do, 10 pound per square foot, at the first part of the system, and eight pounds per foot towards the end.

Sometimes we use a pipe case in the place of a column, this is simply a square or rectangular horizontal connection, with pipes as in the column, see sketch No. 2.

The pipe columns can be placed between the Glover and the first chamber, between the several chambers, and between the last chamber and Gay-Lussac tower, if necessary, but it is only essential in very warm climates.

The gases in passing through the column become very thoroughly mixed, by coming in contact with each successive layer of pipes, causing the particles forming to interact very rapidly, and the moist surfaces upon which the gases impinge are conducive to a great chemical reaction, owing to the very rapid formation of sulphuric acid.

The heat of this reaction is carried off by means of cold air passing through the pipes, which is very important.

The gases, in coming in contact with the surfaces of the pipes, are attracted momentarily (partially due to the moisture present, and also to the cooler surfaces exposed), give up the heat due to the reaction caused by the formation of sulphuric acid, and the liberation of nitrous acid gas, also lowering the temperature of the main body of gases.

This in turn causes a repellant movement, which communicates to the numerous particles in their upward passage through the column, so that a more complete mixing is obtained than by simple obstruction.

Sufficient moisture must be present to make the re-action efficient, and it is essential that it be applied so as to cover the surfaces of the pipes.

The simplest way is by introducing steam along with the inlet gases, say at the top of the chamber, about 10 feet

from the column, the nozzle of the pipe, pointing towards the inlet; this has worked well in practice.

Weak acid could be passed down the tower, which would absorb some of the heat, by passing vapour into the next chamber, and thus it would assist the cooling, but against this is the cost of pumping and attention. At the latter end of the system, steam is the best medium for introducing moisture to the columns.

So many obstructions to the gases as the numerous pipes present, suggest to the practical mind one of the greatest evils in chamber working, namely, bad draught; but such is not the case.

The columns average 14 square feet in area; less than half of this is taken up by the pipes, and after allowing for friction, it still leaves ample passage-way.

In text-books on the working of chambers, we are told in draughting-chambers, to let the first one work with

NO. 3. PIPE CASE BETWEEN LAST CHAMBER AND GAY-LUSSAC.

a good pressure, two-thirds of the way, or thereabout, normal, and the last chamber a good suction.

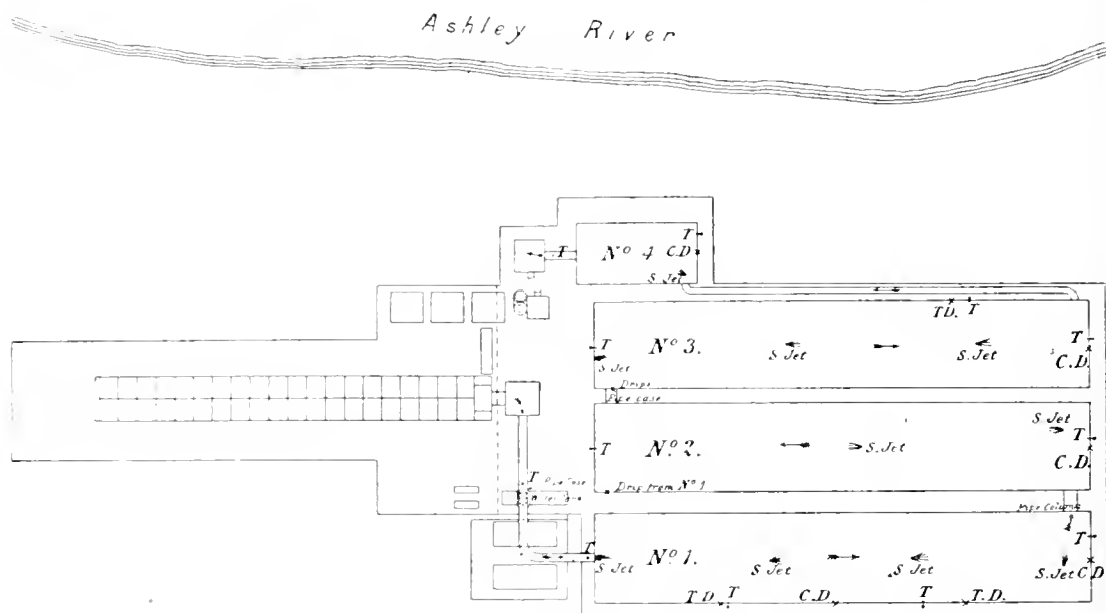

To do this is simply a question of construction, for if the connections are larger, we cannot attain it.

This has been the case with the pipe columns in combination with short chambers, a strong pressure being on all of them, and at one of the works where they are in operation, even a strong pressure at the lutes on the Gay-Lussac tower.

This suggested to the writer the desirability of complete control of the escape gases, when under such conditions as are here presented. A wind storm coming up suddenly would play great havoc with the chamber workings, especially in America, when the exit pipe is direct from the top of the Gay-Lussac tower, draughting into a large chimney being seldom used; so to prevent such a condition occurring, an automatic damper is placed in the exit pipe from the Gay-Lussac tower.

This prevents the sudden withdrawal of any large body of gas, even with a wind travelling at fifty to sixty miles an hour, as the valve in the damper reduces the outlet as

necessary. The percentage of oxygen in the escape gases varies very slightly by this arrangement. The first application of the pipe columns was in November 1892, at the

NO. 4. PLAN OF THE WANDO PHOSPHATE COMPANY'S CHAMBERS.

works of the Wando Phosphate Company at Charleston, S.C. They were added on a small scale to an existing plant of 246,000 cubic feet, consisting of four chambers, the first three being each 160 feet long, the last 40 feet (Glover and Gay-Lussac towers); using lump pyrites, see sketch No. 4.

There was a small pipe case introduced between the Glover and the first chamber,  $3'6'' \times 4'0'' \times 6'6''$  with 66,  $2\frac{1}{2}$  inch pipes.

Between the first and second chamber a pipe column,  $3'10'' \times 4'0'' \times 13'6''$ , with 110 pipes.

Between the second and third chambers a pipe case,  $3'4'' \times 4'0'' \times 5'6''$ , with 56 pipes. And on re-building their second Gay-Lussac tower, they added a pipe case,

$3'0'' \times 3'0'' \times 5'0''$ , with 70 pipes in the down pipe between the two towers, their object being to cool the gases completely before going into the final tower.

A test over a long period gave a cubic capacity of a little under 17 cubic feet per 1 lb. sulphur per 24 hours, using 3.6 per cent. nitre, and giving a yield of 4.8 lbs. of 50° Beaumé acid per 1 lb. of sulphur.

There is but little acid made in the last two chambers, no steam being used in these.

The chambers will stand more pyrites furnaces being added, but in lieu of this, when increasing they will probably reduce the chamber space, using part for a set of fines furnaces.

NO. 5. PLAN OF THE DARLINGTON PHOSPHATE COMPANY'S CHAMBERS.

The following are the temperatures:—

Entrance to first pipe-case, 230° F.

No. of Chamber.	Front.	Back.
	° F.	° F.
1	205	200
2	165	163
3	125	120
4	100	90

Atmospheric temperature, 83° F.

The acid leaving the bottom of the Glover tower is 325° F. I mention this as it will be of interest to some of you, showing what high temperatures are sometimes got in warm climates.

Oxygen, 5.5 per cent. and .5 grains sulphuric anhydride per cubic foot in the escape gases. In this case the pipe columns were too far apart to work to good advantage.

At the time the pipe columns were added, they changed from sulphur to pyrites when burning sulphur; the chamber pace was 21.15 cubic feet per 1 lb. of sulphur per 24 hours, nitre 4.29 per cent. on the sulphur, yield 4.4 lbs. of 50° acid per 1 lb. of sulphur.

This shows an increase of 29.1 per cent. in the yield of acid made, not taking into consideration the change from sulphur to pyrites. It also shows a reduction in the consumption of nitre of 16.1 per cent.

These tests were taken in the corresponding months during the warm weather.

These columns are doing excellent work to day, without any appreciable wear, for on a recent examination of the pipes, they were found in excellent condition; and though the gases enter the first pipe case at 230° F. and sometimes above, there has been no repairs upon it whatever.

The second application of the columns was at the works of the Darlington Phosphate Company at Darlington, S.C., the August cyclone of 1893 having blown down all the chambers.

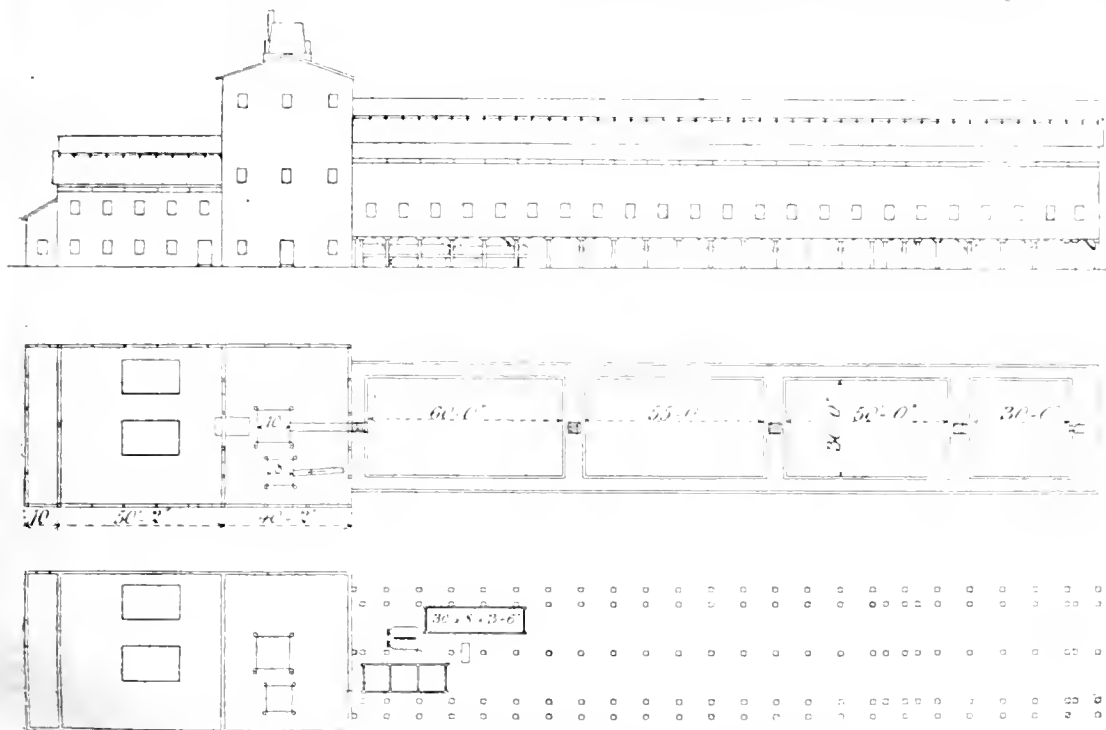

The original plant consisted of three chambers, having a total capacity of 129,500 cubic feet, with a small coke tower in the rear, using Johnson's mechanical fines furnaces, with no nitre recovery, making at the outside 11 tons of 50° Beaumé acid per day.

The present plant consists of four small chambers, the first one only 15 feet long, its object being to catch the dust; the second 60 feet, the third 50 feet, and the fourth 13 feet, having a total capacity of 100,800 cubic feet, with coke tower in the rear, using the same furnaces and no nitre recovery. See sketch No. 5.

Between each chamber there is a pipe column, averaging 3' 10" × 3' 5" × 13' 6", with 150 2½ pipes between the last chamber and the coke tower, a small pipe case, 3' 6" × 1' 10" × 6' 0" long, with 56 pipes 1' 10" long.

A test for 81 days gave the following:—

Pyrites burnt per day 14,304 lbs., averaging 11.6 per cent. sulphur, two-thirds being Virginian ore and one-third Spanish, actually yielding 12.12 per cent. sulphur. This is an equivalent of 6,025 lbs. of sulphur, being 16.5 cubic

NO. 6. PLAN OF THE SAVANNAH GUANO COMPANY'S CHAMBERS.

feet of chamber space per 1 lb. of sulphur per 24 hours, and in the cooler months was under 15 cubic feet, nitre consumption 13 per cent.

The average yield of acid for this period was 14 tons of 50° Beaumé acid (2,000 lbs. per ton) per day, or 1.65 lbs. of 50° Beaumé acid per 1 lb. of sulphur.

As this means an increase over the total chamber area of seven-tenths of an inch, calculated as 50° acid, one can readily appreciate the amount of work done in the system.

The average temperature of the chambers were as follows:—

No. of Chamber.	Front.	Back.
	° F.	° F.
1	220	222
2	178	178
3	156	154
4	123	102

This is after passing the pipe case.

Atmospheric temperature 73° F. Average oxygen in the escape gases 6.6 per cent. Average acidity in the escape gases 0.81 grains sulphuric anhydride per cubic foot.

The result of the application of the pipe column over the original plant is as follows :—

Reduction in the size of the chambers 21.84 per cent. Increase in the yield of sulphuric acid made 28.18 per cent., equal to a total increase of 50.02 per cent.

The last to put in these columns was the Savannah Guano Company, of Savannah, Ga. These works were also destroyed by the same cyclone, just leaving the furnaces standing, and these were much injured.

The original plant consisted of three chambers, having a total capacity of 126,000 cubic feet, with Glover and Gay-Lussac towers, and two Spence fires-furnaces, making 80 tons of 50° Beaumé acid per week, using 5 per cent. nitrate of soda.

The plant now consists of four chambers, the first 60 feet long, the second 55 feet, the third 50, and the last 30 feet, having a total capacity of 117,000 cubic feet, with Glover and Gay-Lussac towers, and the two Spence furnaces.

Between the Glover tower and the first chamber a pipe case 3' 3" x 4' 6" x 6' 0" with 68 2½-inch pipes, between the several chambers a pipe column 3' 6" x 4' 0" x 13' 6" with 150 pipes, and a case 3' 0" x 3' 0" x 5' 0" with 60 pipes, between the last chamber and the Gay-Lussac tower. The latter was placed to dry the gases before entering the absorption tower, but it has not been found necessary.

No. 7. SECTION OF IMPROVED PIPES.

For a time this plant worked below 15 cubic feet, when the atmospheric temperature in the shade reached 96° F., but it was found that the two Spence furnaces could not maintain this heavy work, so they have had to cut down till the present production is only 112 tons per week, which gives an increase of 40 per cent., added to a reduction in chamber space of 7.7 per cent., or a total gain of 47.7 per cent.

The company may add another furnace later so as to get the full advantages of the chambers.

The temperatures run as follows :—

No. of Chamber.	Front.	Back.
	° F.	° F.
1	268	210
2	176	173
3	132	120
4	101	100

Lowest atmospheric temperature 71° F., highest 97° F. Oxygen 5.5 per cent. Nitre, 3.5 per cent. Escape gases, 63 grains sulphuric anhydride per cubic foot.

The amount of acid made in the first and last pipe case could not be measured, the pipe column between the first and second chamber at normal work showed 1,231.08 pounds of 50° Beaumé acid per 24 hours. The column between the second and third chambers, 1,125 pounds of 50° acid, and the one between the third and fourth chamber 472.1 lbs. 50° acid, or a total of 2,831.18 lbs.

The total capacity of the three columns is 583.2 cubic feet, which gives a yield of 8.85 per cent. of the total make of acid, and on a basis of 21 cubic feet per pound of sulphur, equals 226 times as much chamber space as the towers occupy, without taking into consideration the acid that is produced in the Glover tower.

But this is not the only results obtained by the columns, for the gases as they leave the columns have become so thoroughly mixed, that a stronger reaction has set in, so that the yield of acid in the chamber following is much above the average, being plainly shown by the yield of acid at drips, corresponding with drips of the same capacity and location in ordinary chambers.

No. 8. IMPROVED PIPE COLUMN.

The chamber working is much simpler with the columns, being less liable to oscillations, for a disturbance in any part of the chambers is generally neutralised by the gases simply passing through one of the columns.

They require no special attention, especially when steam is used as a means of introducing moisture, as was the case in the foregoing citations, the ordinary drips of the chambers being all that is necessary to regulate them, even when the steam is introduced from the top of the chamber, the nozzle pointing towards the inlet, so that the steam enters along with the gases, for this affects the drip at the end of the chamber, and as long as this is kept steady the column is also, for it bears a corresponding relation to the drip.

As we usually use a reducing valve for the steam, so as to always get a normal pressure, it was found on one of the sets of chambers on this system, that it ran for four consecutive weeks without any of the steam valves being touched, the drips scarcely varying one degree.

In giving the temperatures of the various chambers in the Darlington and Savannah citations, they are all taken at the same relative positions at a height of 5 feet from the floor, and 6 inches in the chamber.

As the passage ways, separating the chambers, are at the outside 7 feet wide, it is interesting to note how great a change takes place in this short distance, it shows that the pipe columns effect a large amount of cooling.

All of the plants mentioned have not been tested to their fullest capacity, as the furnaces have been the limit in all instances, and especially as it so at the Charleston and Savannah works.

No. 9. IMPROVED PIPE COLUMN TO BE PLACED BETWEEN THE GLOVER AND THE FIRST CHAMBER.

So far I have only put one column between each chamber, and a small pipe case between the Glover tower and the first chamber, these at the most having only 150 pipes, with smooth surfaces.

Further recent improvements consist in using corrugated pipes, in lieu of plain pipes, with a strengthening rib in the centre, as they present relatively larger surfaces to the gases, than can be got by plain pipes. See Fig. 7.

Again, on the top of each pipe, when burnt to the side of the column, a saucer is formed, the object being to retain a greater amount of moisture, or rather weak acid, the pressure of which will still improve the reaction going on in the column. In looking at section of pipe No. 1 in sketch 7, it is apparent that a larger area of moisture is presented than if plain, upon which the gases impinge, and again the ribs on the sides of the pipes form a rough surface, which will enable to attain a better mixture of the gases.

Now I propose to put two pipe columns, as shown in sketch No. 8, side by side, between the chambers, still retaining the same size, but embodying the new improvements, using section of pipe No. 1 which has 16 per cent. more surface than the plain pipes used, increasing the number of pipes in each column 35 per cent., or a total increased exposed surface of 56 per cent., this would make the increase by using two towers 3.32 times as much.

Instead of a small pipe case between the Glover tower and the first chamber, I propose to substitute a double column as shown in sketch No. 9, using section of pipes No. 2 or No. 3, so that in case of much dust coming over from the Glover it would not remain on the pipes, this would increase the amount of work done 5.93 times as much as formerly.

A little of the nitrous acid passed down this tower would be of advantage, care of course being taken that denitration is fairly complete, as the more nitrous gas present the more work can be accomplished.

It is not only important to do as much work as possible whilst the gases pass from one chamber to another, but to do it as early in the process as possible; and as the columns will always have proportionally, a larger percentage of oxygen and nitrous gas than in the surrounding chamber space, it becomes an important factor in the chamber arrangements.

The limit of reduction of chamber space by this system, stands in the ratio to the number of columns used, ten cubic feet of chamber space per one pound of sulphur per twenty-four hours, can easily be obtained with a limited number of columns. How much lower than this by using additional columns I cannot say, but it is most probable that it would be very much lower.

The important question in all diversions from usual methods, is costs? When land is dear, a small structure is advisable, but in any case under this system, the cost is much less than when ordinary chambers are erected, especially is it so when climatic changes render it necessary to have expensive buildings, so as to protect the chambers from excessive heat and cold, as is necessary in America, and on the continent.

These pipe columns can be readily added to existing plants, so that increased production can be obtained without additional chamber space.

#### DISCUSSION.

Mr. GEORGE E. DAVIS said he had listened with very great interest to the paper, but was strongly of opinion that the inventors had not made out their case. Some months since he had carefully studied some figures that appeared from the pen of Mr. Gilchrist in the journals of the American Chemical Society for November 1893 and July 1894, and they appeared to be identical with those given in the paper that night with the exception of those of the Savannah Guano Company. He did not think it right to compare a new mode of manufacture with such antiquated methods as working without nitre recovery; the latest and most improved installations should be used for comparison, and they had in this country many vitriol works (working without the aid of pipe columns), giving results that would evidently astonish the inventors of these appliances. In the old-fashioned days in which he began his career as a vitriol maker (working without nitre recovery), 24 cubic feet per lb. of sulphur per 24 hours were considered the normal working space requisite, and if any less than this was provided, the nitre consumption was abnormal, while, on the other hand, if the space was increased, very little (if any) good was experienced. It was, moreover, well known at that time that the more nitrous the chambers were kept, the more work could be done in a given space. For instance, in works A, six chambers, 34 cubic feet per lb. sulphur nitre consumption, 8.2 per cent.; works B, six chambers, 22 cubic feet per lb., 8.4 per cent. nitre; works C, 20 cubic feet per lb., 9 per cent. nitre. Each of these was the average of six months working. According to the present paper the new works of the Darlington Phosphate Company appeared to have no system of nitre recovery, and to consume 13 per cent. of nitre when working with about 16 cubic feet per lb. of sulphur. As to the results of the working of the Savannah Guano Company, where they had pipe columns and Glover and Gay-Lussac towers, the description seemed a little ambiguous; the author appeared to say "for a time the plant worked below 15 cubic feet," and the nitre consumption was 3.5 per cent. To his mind there was nothing startling in the foregoing work, for to his own knowledge there was a works in Widnes in 1876, using as little as 2.9 per cent. of nitre; but as he could not be sure of the exact chamber space he refrained from quoting it further. Of one works, however, he could speak, wherein 63 tons of pyrites were burned weekly in three chambers working with 14 cubic feet of chamber space per lb. of sulphur, wherein the nitre consumption was only 1.8 per cent. This was not accomplished by the aid of pipe columns, but by the provision of ample absorbing space which was the real solution of the problem of how much acid could be made in a given chamber space. He had designed and re-organized a good many vitriol plants during the past 20 years, and there was no difficulty in working with a normal amount of nitre in as low a chamber space as 8 cubic feet per lb. of sulphur, and without pipe columns, a result twice as good as the lowest capacity mentioned in the paper that night. Of course, starting with a normal chamber space, the per-centage of nitre necessary would increase as they overloaded the chambers with work, and of this he had had very good experience. In one works with three chambers, the per-centage of nitre used, over a period of three months, when working with 15 cubic feet per lb. sulphur was 3.4 per cent. For a further period, when the space was reduced to 10 cubic feet, the nitre consumption was 5 per cent.; while when the pyrites was further increased so that the space was reduced to 8 cubic feet per

lb. of sulphur, the nitre consumption ran up to 7.1 per cent. If the absorbing space had been increased as the chamber space was reduced, the nitre consumption would have remained nearly normal. But it must not be forgotten that as the chamber space was reduced so the per-centage of oxygen in the waste gases increased, and the problem of absorbing the nitrous gases from a weaker mixture had to be encountered, and this was not, even at the present moment, sufficiently recognised.

He verily believed that the importance of the pipe column had been over estimated, the crux being the complete absorption of all the nitrous gases that it was possible to absorb. If this were done the amount of vitriol that could be made in a given chamber space was simply astonishing to practitioners of the old school.

Every vitriol maker knew that if the chambers were underworked, a very pale straw colour only was requisite in the final chamber, while when the chambers were "pressed" it was necessary to work them much darker in colour; in fact, working with a normal chamber space, nitrous gases equal to 200 lbs. of nitrate of soda had to be sent into the chambers for every ton of sulphur entering at the same time. In a plant working without nitre recovery, this quantity must all be "potted," but where absorbing and denitrating towers exist, the 200 lbs., say  $x$ , was made up of two quantities  $y$ , the amount potted, and  $z$ , that introduced through the medium of the Gay-Lussac acid. With an abnormal chamber space, a factor  $n$  would readily let them see what should be potted, and how much should be introduced into the Glover tower, as nitro-sulphuric acid. If  $n$  equalled that factor, and  $x$ , the total nitre to be introduced, then— $nx = y + z$ , when  $n = 1$ ,  $x = 200$ .

The paper made some reference to the necessary draught for chambers. It was, however, quite clear that no constant formula could be laid down for an abnormal chamber space; still, with a normal chamber space, he firmly believed no better rule could be followed than the old fashioned one of working the damper so that the gases in the last chamber "scarcely knew their own mind," i.e., were almost in equal balance with the atmospheric pressure.

The CHAIRMAN said that Mr. Gilchrist appeared to have been aware of the rocks on which previous application of the principle of mixing and scrubbing the gases on their passage from chamber to chamber had broken down. In the Thyss tower, the grids being too close together, the draught of the burners was obstructed too much, and the heat developed caused great wear and tear of lead. Both these drawbacks were overcome in Mr. Gilchrist's pipe column. Their importance in saving chamber space did not seem to be due so much to the work they themselves performed in percentage of acid made, as in scrubbing out the mist of nitro-sulphonic acid, decomposing this with the steam present, and in liberating nitrous acid again for fresh work in the next chamber. Mr. Gilchrist, at his request, made arrangements for measuring the acid, and running from the three towers at the Savannah Guano Company's works, the latest plant erected, and this amounted to 8.5 per cent. of the total make made in 583 cubic feet of space. He also, at his request, gave the figures of air temperature in summer working, the time of most unfavourable conditions for acid-making even in England, and much more so in the Colton belt, where in this case the temperature ranged from 71° to 97° F. As regarded the similar piece of apparatus of Professor Lunge, the Platt tower tried at Widnes, the results were not encouraging as to the amount of work done by the tower itself (*cide* Journal, 1893, p. 991), for Mr. Carey reported that the difference in total acidity between inlet and outlet was only about 2 grains  $\text{SO}_3$  per cubic foot, 30 inlet, 28 outlet, and of the 30, 14 grains only existed as  $\text{SO}_3$ , the remainder being in the form of mist as nitro-sulphonic acid. There was, moreover, no apparent effect in the reduction of chamber space necessary, as in Mr. Gilchrist's results, or as in the results Professor Lunge gave of the working of the Platt towers at a Bohemian works placed between a set of two chambers, where the second chamber men had next to nothing to do; it made no acid, serving as a drying chamber before Gay-Lussac's columns. He considered the result of low-chamber space combined with the nitre

economy, when working under such trying atmospheric conditions, bore remarkable testimony to the efficiency of the apparatus Mr. Gilchrist had described, and in adapting which to a set of new chambers he had carried out Professor Lange's recommendation to have chambers about half the present length of 120 feet, though the discussion of the validity of the reasons which Professor Lange gave for adopting this form would lead them too far that night.

## ON A NEW CLASS OF LAKE PIGMENTS.

BY CARL OTTO WEBER, PH.D., F.C.S.

IN A paper published some time ago\* I discussed the question of producing fast shades on cotton with the benzidine dyes in particular and the acid dyes in general. I pointed out that this problem would be solved by the discovery of some compound which would be as satisfactory a lake former for the sulpho group, as tannic acid is for the amido group, or as alumina or chromic oxide for the orthodihydroxyl group. There are, of course, already compounds known which, in many cases, are capable to act as lake formers in the sulpho group, barium in the form of barium chloride is very extensively used for this purpose in the manufacture of lake pigments. But the chemical behaviour of these barium lakes, simply being that of barium salts of colour acids, and the attempts of converting these lakes into compound lakes like the tannin-antimony or alumina-lime lakes so far having proved fruitless, it is evident that the fastness of these barium lakes against acids and alkalis can be a slight one only, so that they are quite unsuitable for textile purposes. The fact that all sulphonated dyes, without exception, are wool dyes, forming, as I have shown in a former paper (this Journ., 1894, 120), lakes with the substance of the wool itself unmistakably indicates the class of compounds, amongst which we may expect to find a lake former generally applicable for all sulphonated dyes.† If we remember that lanuginic acid, a product of the decomposition of some of the proteids with baryta, is capable of forming excellent lakes with carboxylated and sulphonated dyes, there is little room for doubting that a lake former generally suitable for lake formation with all acid dye stuffs may be found amongst the large class of compounds classified under the head of proteids. The whole of our experience regarding the dyeing of wool and silk endorses this view, which, in the face of the remarkable lake-forming properties of lanuginic acid, may even be extended to the amido acids resulting from the decomposition of the proteids by acids and bases. It must, however, not be assumed that lanuginic acid already answers all our requirements for a lake-former in the sulpho group. In the first instance there is the difficulty of producing this compound sufficiently cheap for practical purposes, and further the vastness of the lanuginic lakes still leaves very much to be desired.

In the paper above referred to, I ventured the opinion that the remarkable fastness of the benzidine dyes when printed on calico with albumin thickening, the goods being steamed afterwards, could not very well be explained by the assumption of the coagulated albumin acting as a protective cover for the dye, but that a true chemical action (lake-formation) between the albumin and the dye was highly probable. It is even possible that the steaming of the albumin colour causes a deeper alteration of the albumin than its mere coagulation, and that the products of such an alteration then act as lake-formers. Indeed I have shown in the paper already referred to that conversion products of albumin, such as peptones, possess the property of forming well defined and very beautiful lakes with the

sulphonated dyes. I therefore considered this subject of sufficient theoretical and practical interest to examine the lake-forming properties, first of the best known of all proteids, of egg albumin, which I may add were found to be practically identical with those of blood albumin.

The series of experiments was begun with the study of the behaviour of one of the substantive dyes against albumin. The dye used was Cassella's diamine scarlet B., the product of the combination of tetrazodiphenyl with phenol and  $\beta$ -naphthol-7-disulphonic acid, the phenol-hydroxyl of this compound being finally ethylated. The formula of this dye is therefore—

This dye was selected first on account of its great solubility in water, so that fairly concentrated solutions remain perfectly clear even in the cold, and further on account of its not forming a precipitate on the addition of dilute acids. These properties of the dye obviously remove any liability to mistake the cause and nature of a subsequently observed precipitate. Moreover, there are in this dye besides the sulpho groups no other lake-forming groups, since the isolated hydroxyl group, as I showed in a paper read before this Society (this Journal, 1893, 659) some time ago, has no lake-forming properties whatever.

On adding a solution of diamine scarlet to a solution of egg or blood albumin, a precipitate occurs either at once or on standing, according to the concentration of the solutions. This precipitate is rather slimy, and therefore very difficult to filtrate. Neither is the complete precipitation of the dye possible without using an enormous excess of albumin; but by heating the incompletely precipitated mixture to 80° C. on the water bath, complete precipitation of the dye takes place, and the albumin lake separates out in the form of bright scarlet flakes. This lake can be easily filtered and washed, the filtrate, even when using boiling water for washing, being perfectly colourless. As might be expected, the fastness to soap of this lake is rather unsatisfactory. Treatment with soap solution (10:1000) at 50° C. slowly decomposes it. Equally sensitive is this lake against the action of caustic alkalies, ammonia, and alkaline carbonates. On addition of acetic acid, however, to these solutions the lake is again precipitated with all its original properties. On drying this lake on the water-bath or in an air-bath, or in vacuo at ordinary temperature, it diminishes greatly in volume, and is eventually obtained as a dark red horny mass, which, however, in the mortar is easily reduced to a fine powder of a very deep and brilliant scarlet colour. When suspended in water the dried lake, even on prolonged boiling, shows no sign of swelling, neither does the water show any coloration. Soap solution at 80° C. scarcely affects the lake, only on prolonged boiling the soap solution exhibits a very slowly-increasing coloration. Dilute solutions of the alkaline carbonates, even at boiling point, are without any appreciable action, but hot solutions of the caustic alkalies dissolve the lake rather quickly.

It must, however, be observed that this scarlet lake prepared as above described, cannot be a uniform body. According to the amount of the excess of albumin used, this lake evidently represents a mixture, and probably not even a homogeneous one, of the lake proper with coagulated albumin. It appears that the precipitation above described takes place in two stages. In the first instance, the lake proper separates out, which is later on enveloped by the coagulating albumin. This, no doubt, is the reason of the depth of coloration of the lake entirely depending upon the quantity of albumin used for precipitation; but this being so it is of course possible that the albumin lake I obtained differs in its properties more or less from these lakes in the pure state, and it might further be objected that the precipitates I obtain, in the manner above described, are no lakes at all, but merely occlusions of colouring matter in the coagulated albumin. It was, therefore, important to devise a method for the preparation of these lakes in a state of purity. This is easily done by adding an excess of

\* Chem. Zeit. XVIII., 1894, pp. 528, 563.

† Barium chloride is not so applicable, many of the sulphonated dyes not being precipitated by it.

acetic acid to the mixture of the solutions of albumin and dye. On the addition of the acid the scarlet lake is immediately precipitated, and the precipitation, even when working in the cold, is nearly complete. Neither the scarlet nor albumin being precipitated from their solutions by acetic acid, there can no longer be any doubt as to the precipitate formed under these conditions being an albumin lake. On heating the acidified mixture on the water-bath, the precipitate which at first is rather curdy, becomes increasingly finer in texture, and forms eventually a mass of exceedingly fine particles. At this stage every trace of the colouring matter has been precipitated. Providing a sufficient quantity of acetic acid having been used, this precipitate cannot contain any free coagulated albumin, and it must therefore represent the albumin lake in a practically pure state. The precipitate is now filtered and washed neutral, first with warm then with boiling water. The precipitate upon the filter does not possess any sliminess, and has no tendency to clog or cake as do the precipitates containing free albumin. On drying this lake, it also shows, however, the property to shrink very considerably in volume, and when perfectly dry to form horny pieces which are, however, distinguished from the lakes containing free albumin by their much deeper and at the same time brighter colour. The physical condition of many lakes in the dry state depending very much upon the nature of the liquid evaporating from them during the drying process, it appeared feasible that by expelling the water from the lake, instead of by evaporation by displacement, first with absolute alcohol, and then with ether, better results might be obtained. But this treatment was found not to have the desired result, and it seems that after the removal of the extraneous water the lake represents the conditions of a hydrate which, on subsequent drying, loses its water of hydration, and is converted into an anhydride, a process which, in the case of these lakes as in other cases with which we are more familiar,\* is accompanied by a very considerable shrinkage in volume. The horny pieces of pure albumin lake are easily pounded into an almost impalpable powder possessing a very strong and brilliant scarlet colour. The chemical behaviour of this pure lake is practically identical with that of the lake containing free albumins.

The behaviour of albumin against diamine scarlet is typical of its behaviour against all sulphonated or carboxylated dye stuffs, whether they belong to the benzidine series or not. Consequently the sulphonated basic dyes, the numerous azo dyes, and all sulphonated nitro colouring matters without exception can be converted into albumin lakes in the above described manner. This is very much more than any of the lake formers for acid dye stuffs known at the present time will do, and this method of lake formation will no doubt attain to some importance in the future, especially for the manufacture of paste colours for stained paper, and wall paper, and it will, I believe, also be of considerable interest to calico printers for the production of some very useful styles, ranging between the present mordant and pigment styles. The fastness to light of these albumin lakes far surpasses that of the corresponding barium lakes, and all those acid dyes which like crystal ponceau, patent blue, naphthol yellow, naphthol green, and scores of others are not precipitated at all by barium chloride, and for this reason are either totally unavailable at present for the purposes of lake making, or require the use of circuitous and expensive methods, leading after all to at best only moderately satisfactory results, all these dyes form readily excellent lakes with albumin, by the above described treatment. One of the most valuable features of these albumin lakes is the fact that the shade of the lake obtained with any acid dye exactly corresponds to the shade the same dye produces on wool or silk. Barium lakes many a time exhibit a disappointing difference in this respect, which in numerous cases rendered some of the finest dye stuffs quite useless for the purpose of the lake manufacturer.

It appeared now interesting to examine the process of lake formation in the sulpho group by means of albumin, also with such colouring matters which contain other lake forming groups besides the sulphur group. I showed in a former paper (this Journal 1893, 657) that dyes containing different lake forming groups in the molecule, in order to form satisfactory lakes, require lake formation in every different lake forming group. This is the reason why the precipitation of the sulphonated basic dyes with barium chloride is either impossible (acid magenta, Thioearmine, &c.) or yields indifferent results only. If, however, we effect lake formation in the amido group of these dyes, by means of tannic acid, at the same time as in the sulphur group by means of barium chloride, we obtain lakes which are in every respect satisfactory. But on the other hand I showed that in dyeing wool with sulphonated basic dyes, neither simultaneous nor subsequent treatment with tannic acid is required, in fact the dyed wool is utterly indifferent against it. From this I concluded that in the dyed wool, both the lake-forming groups of these dyes have undergone lake formation with the substance of the wool itself. Albumin should therefore be expected to behave similarly against this class of dyes.

On adding to a solution of Patent Blue B (Meister,

Lucius and Brining), a solution of albumin, it is found impossible to effect even an approximately complete precipitation of the coloring matter; indeed, on filtrating this mixture it is found that, although it has become rather turbid, almost the whole of the dye and the albumin pass together through the filter. On adding acetic acid in excess to this turbid mixture it becomes again quite clear, but on heating it on the water bath to 90° C. the beautiful albumin lake of patent blue B separates out. Only traces of the dye escape precipitation.

As we see from the above formula, patent blue B, besides the two lake-forming sulpho groups, contains also a lake-forming amido group, and the question arises as to whether both the different lake-forming groups, or only one of them, and which, contributed to the formation of the lake. Taking into account the observations made in a former paper (this Journal, 1893, 656), regarding lake formation with dyes containing several heterogenous lake-forming groups in the molecule, it is highly probable that the two sulpho groups, as well as the amido group of the patent blue, have undergone lake formation in the albumin lake. An experiment easily demonstrates the fact that neither barium chloride, nor tannic acid will precipitate patent blue, although a mixture of these precipitants will do this readily. This experiment, therefore, seems sufficiently convincing to assume that in the albumin lake both the sulpho groups and the amido group have suffered lake formation. This conclusion is essentially supported by the fact that tannic acid is without the slightest effect upon this lake, whereas the presence of a free amido group in it would, according to numerous former experiences, cause a material alteration of the shade of the lake. If, on the other hand, we assume for the moment the amido group of the dye to have undergone lake formation, but the sulpho groups still being in the free state, the absolute insolubility of such a lake would be quite inexplicable in the face of the fact that even such an energetic lake former in the amido group as tannic acid by itself absolutely fails to precipitate this dye. It will be seen, therefore, that albumin, like wool, must possess the capability to fix sulphonated basic dyes through lake formation in their sulpho group as well as in their amido group.

This, of course, involves that albumin must be capable of also forming lakes with ordinary basic dyes, not containing the sulpho group, just as we have already proved

\* Dehydration of aluminate or ferric hydrates. It is interesting to note that these hydrates which dry very much in the same way as the above described albumin lakes are capable to exist, like albumin, in a colloidal state.

its capability to form lakes with simply sulphonated dyes not containing any other lake-forming groups. To test this important point a solution of 10 grms. of egg albumin in 1000 cc. of water was mixed with a solution of 0.5 grms. of benzaldehyde green, 5 grms. of sodium acetate, and 5 cc. of acetic acid (80 per cent.) in 100 cc. of water. The mixture remained perfectly clear, but on heating it at 86° C. on the water-bath a precipitate rapidly increasing in quantity soon begins to form, and eventually the whole of the dye is precipitated in the form of a most brilliantly-tinted green lake. The behaviour of the other basic dyes is analogous, though it must be observed that the readiness with which the precipitation is initiated varies considerably for the different basic dyes, and the same is to be said of the completeness of the precipitation. This is a perfect analogy to the varying readiness and completeness with which the different basic dyes are taken up by wool. These lakes of the basic dyes with albumen exhibit a remarkable resistance against dilute inorganic and organic acids. Decomposition only takes place on prolonged boiling of the lakes with dilute sulphuric, hydrochloric, or nitric acid. The fastness against alkalis of these lakes surpasses that of the lakes of the sulphonated dyes; they are particularly resistant to soap solution.

The above offers conclusive proof of the existence of albumin lakes of the basic dyes and further furnishes additional evidence of the striking analogy between the lake-forming properties of albumin and wool and silk. We can, therefore, no longer doubt that in the albumin lakes of sulphonated basic dyes the lake formation extends to both the sulphur group and the amido group. The capability of albumin to form lakes with basic dyes cannot be considered to be for itself of any practical importance in view of the excellent qualities of tannic acid for this purpose. The fastness of the albumin lakes of basic dyes is not superior to that of the corresponding tannin lakes and while the latter on treatment with antimony salts are converted into compound lakes of considerable fastness, no similar treatment and conversion is at present possible for albumin lakes. Nevertheless there might under certain circumstances an albumin lake be preferable to a tannin lake, owing to the oftentimes surprisingly great difference between the shade of the albumin lake and the tannin lake of the same dye, which difference is identical with that exhibited by the same dye when applied to cotton and wool or silk.

Of the colouring matters the lake-forming properties of which are merely a function of hydroxyl groups, the eosin group in its tinctorial behaviour stand nearest to the acid dyes proper. On adding to a solution of 10 grms. of albumin in 500 cc. of water a solution of 1 gm. of eosin GGF (Casella) in 100 cc. of water no precipitate appears, and although addition of acetic acid causes a slight turbidity, the mixture passes completely through a filter. On heating in the water bath a distinct precipitate appears at 85° C. and at 90° C. the eosin is completely precipitated. This illustrates in a particularly striking manner the remarkable lake forming power of albumin as, excepting the salts of the heavy metals, the precipitation of eosin by means of inorganic salts is either very incomplete or fails altogether.

I have repeatedly mentioned that the isolated hydroxyl group is a most indifferent lake former. For lake formation it is practically available only in the nitro-colouring matters, and even in these cases it is rather doubtful whether indeed the hydroxyl group is the lake-forming group and not a hydrogen atom to which the proximity of the nitro group imparted acid functions similar to those possessed by the hydrogen atoms of the halogen acids. This appears highly probable if we remember that the acidifying tendency of the nitro group is strong enough to convert so unquestionable a base like diphenylamine into an equally unquestionable acid like hexanitrodiphenylamine. A similar phenomenon appears in the fact that naphthol yellow S

is not as might be expected a monobasic acid, but a strong dibasic acid. The nitro colouring matters have so far proved of small importance for the manufacture of lake-pigments, owing to the lack of a satisfactory precipitant. All the more remarkable is therefore the fact that naphthol yellow S which in this respect proves particularly refractory, easily yields most beautiful lakes with albumin. The mixture of the solutions of albumin and naphthol yellow remains perfectly clear, but already on addition of acetic acid, an abundant precipitate begins to form. Heating on the waterbath for a short time completes the reaction. It is interesting to observe that the shade of this lake is again identical with the one produced by naphthol yellow on wool, whereas the inorganic lakes of this dye are conspicuous by their disagreeable brown or orange shade.

We now come to that interesting class of dye stuffs which besides the sulfo group contain the orthodihydroxyl group. That the sulfo group of these dyes will be capable to enter into lake combination with albumin appears practically certain, but the question as to the behaviour of the orthodihydroxyl group itself, and also its possible influence upon the lake-formation of the sulfo group requires examination. The incapability of ordinary alizarin to dye un mordanted wool renders the possibility of lake formation between the orthodihydroxyl group and albumin also rather improbable, but it nevertheless appears worth while to establish this fact beyond doubt by direct experiment. On account of its insolubility in water, the use of ordinary alizarin paste in this experiment will have to be avoided as conducive to errors, and our first task is therefore to find a means to bring the alizarin into aqueous acid solution, the acid of course again merely serving the purpose of preventing coagulation of the albumin. Very dilute solutions of this description are obtained on acidifying alkaline, preferably ammoniacal, solutions of alizarin with acetic acid. Better results are, however, obtained by acidifying with acetic acid solutions of alizarin in borax. By this means strongly acid solutions of alizarin of considerable concentration can be prepared. On adding such a solution of alizarin to a solution of albumin no precipitate appears, nor does the heating of this mixture to 96° C. even when prolonged for hours, produce the looked forward to result. It is therefore evident that the orthodihydroxyl group does not carry the property of forming lakes with albumin. In the face of this fact the behaviour of alizarin sulphonic acid, alizarin S, against albumin appears particularly interesting. The sulfo group of this dye places the possibility of the formation of an albumin lake in this group of the dye beyond doubt; but such a lake would still contain the free orthodihydroxyl group, owing to the above shown incapability of this group to form an albumin lake. An albumin lake of Alizarin S would therefore possess all the properties of ordinary alizarin.

On adding a solution of alizarin S to a solution of albumin, no precipitate occurs, but the mixture assumes a deep crimson colouration which, however, on addition of acetic acid changes into brown. Many hours heating of this mixture on the water-bath does not produce the slightest trace of a precipitate; but on the addition of alumina sulphate or acetate, a copious Turkey red-coloured precipitate is thrown down. This precipitate is the albumin-alumina lake of alizarin S. The fastness of this lake against alkalis and soap exceeds that of the previously described albumin lakes, but is much inferior to that of alizarin S dyed upon wool.

This behaviour of alizarin S against albumin is particularly interesting, as it furnishes a striking confirmation of the result I arrived at in a former paper (this Journal, 1893, 636), namely that lake-formation in dyes containing heterogeneous lake-formers in the molecule is only possible by providing for each of the different lake-forming groups according to their specific lake-forming tendencies. Thus I showed that sulphonated basic dyes which should be able to form lakes with either barium or tannic acid do neither, but are readily converted into most beautiful lakes on simultaneous treatment with these two lake-formers. Similarly we find now that the prospective capability of

alizarin S to form lakes with either albumin\* or albumin† cannot be realised, but that these two lake-formers combined at once produce the intended result. Albumin being as I showed not only a lake-former for the sulpho group, but also for the amido group is therefore by itself able to precipitate sulphonated basic dyes in spite of their heterogeneous lake-forming groups. But against alizarin S albumin behaves exactly as barium chloride against sulphonated basic dyes; no precipitate occurs until the lake-forming tendencies of the coexisting heterogeneous group, in this case the orthodihydroxyl group are satisfied.

The observations made in the above experiments already contain the material for the elucidation and explanation of a number of facts in connection with wool and silk dyeing. But before entering upon this subject it will be advisable to extend this investigation to some other members of the proteid class, an intention which I hope to put into operation before long.

### DISCUSSION.

Dr. WEBER, in reply to a question raised by Mr. Flintoff, as to whether the lakes produced in the manner referred to in the paper were fugitive or not, said that in a former paper he had pointed out that it was not the dye alone which determined the fastness to light, but the lake-former with which it was combined. In dyeing Diamine fast red on cotton, an extremely fugitive shade was obtained, whereas if it were dyed on wool one got one of the fastest scarlets it was possible to dye. As a matter of fact, on the Continent, fast red on wool was considered to be almost as fast as alizarin. In dyeing diamine or benzidine scarlets on cotton, one always got more or less bright shades which were more or less fugitive; but, if on the contrary, one dyed these scarlets on wool one got a fast colour. It was an absolute truth that the fastness of the dye was not an inherent quality of the dye alone, but depended very much upon the way in which the latter was applied. In other words, unless the dye had a chance to enter into lake-formation one could not expect a satisfactory degree of fastness. This was a fact very clearly borne out by Hummel's researches "On the fastness of artificial dye stuffs," and in most cases the fastness of any dye that could be applied to wool was immensely greater than the fastness of the same dye on cotton. The albumen lakes were also at least four times as fast to light as the corresponding barium lakes. The reason for this it was difficult to state, but the fastness was there. This relation between the fastness of a dye and its lake-formation was strikingly shown by what he had termed "half-lakes," as, for instance, the barium lake of a sulphonated basic dye. Such a lake was exceedingly fugitive, owing to the lake-forming amido group being left in the free state. If one added to such a half-lake tannic acid, this amido group underwent lake-formation, and the fugitive half-lake was now converted into a fast compound-lake.

\* In the sulphonic group. † In the orthodihydroxyl group.

Meeting held in the Durham College of Science,  
Newcastle-on-Tyne, on Saturday, November 24th, 1894.

MR. GEO. T. FRANCE IN THE CHAIR.

### PRESENTATION TO DR. J. T. DUNN.

DR. DUNN, who has occupied the position of Honorary Secretary and Treasurer to the Newcastle Section since its formation, has been obliged to resign that office in consequence of his appointment to the Headmastership of the Plymouth Technical Schools.

After letters of regret for non-attendance had been read from Sir Lowthian Bell and Mr. Alfred Allhusen—

The CHAIRMAN said that they were met together to do honour to Dr. Dunn. There were few members then present who were present at the founding of the older Newcastle Chemical Society, to which for three years before and 11 years after its amalgamation with the Society of Chemical Industry Dr. Dunn had acted as Secretary. During these 14 years nothing had ever transpired to mar the complete confidence they felt in him, and they all had had occasion to admire the thorough but quiet and unostentatious way in which the duties of the secretaryship had been performed. He would call upon the Secretary to read a letter which had just been received from the General Secretary on behalf of the President and Council of the Society. The Council wished to place on record their appreciation of the valuable services Dr. Dunn had rendered to the Society and to join with the Newcastle Section in their expressions of goodwill and gratitude towards him.

He had much pleasure in handing to Dr. Dunn, on behalf of the subscribers, a silver kettle, together with a purse of gold as a small token of the esteem in which he was held amongst them.

The kettle bore the following inscription:—

"Presented to J. T. DUNN, D.Sc. (together with a purse of gold), by the Members of the Newcastle Section of the Society of Chemical Industry, as an indication of the high esteem in which he is held and in recognition of his valuable services as Honorary Secretary during the past 14 years, 24th November 1894."

MR. JOHN PATTINSON had been associated with Mr. Dunn both during his connection with the old Society and since it was merged into the Society of Chemical Industry. No friction had ever arisen in any part of Dr. Dunn's work and the Committee had always felt that they could place perfect reliance upon his judgment and prudence. The spontaneous way in which the Members of the Section, which was not a large one, had contributed towards the testimonial fund, showed how they all valued his work.

He (Mr. Pattinson) wished to express his personal regret at losing Dr. Dunn from the North, though the fact that he was leaving them to fill an important educational post was

some slight compensation. He trusted that he would find Plymouth as pleasant a place as Newcastle had been to him.

Prof. P. P. BENSON, D.Sc., though he felt that he inadequately represented that body, would yet like to say a word on behalf of the Durham College of Science, of which Dr. Dunn was one of the most distinguished students as he also was the most distinguished graduate in science of Durham University. Dr. Dunn was a colleague of his for eighteen months, and during that short time he formed a high opinion of his powers which a friendship of nearly twelve years only served to confirm. He entertained a high opinion of Dr. Dunn's work in the educational world, and was glad to think that he was to carry the name and fame of the College into southern climes.

Dr. Dunn, in reply, said that it was very gratifying to him to receive such a testimonial from the Members of the Section with all of whom his relations had always been pleasant. Since the time, (exactly 14 years ago) when he first joined the old Society it had undergone many changes. In the old days the Society at Newcastle edited and published its own transactions, and he was selected to act as its secretary on account of his combining a knowledge of chemistry and of shorthand. The work had been always to him a pleasure and it was a very great pleasure to him to think that his efforts had been appreciated not only by the local members, who had given him such a valuable token of their esteem, but also by the Council of the Society. He could not but think that they had spoken of his work in terms beyond his deserts. That all had gone smoothly was really due to the good feeling existing amongst those with whom he worked. Though he hoped to find Plymouth the pleasant place it had been pictured to him, there was no danger of his ever forgetting the city of his birth, Newcastle, where so many years of his life had been spent.

January 1895.—Mr. Jas. O. Sullivan: "Note on the Estimation of Cane Sugar."

Meeting held at University College, Nottingham,  
on Wednesday, November 21st, 1894.

MR. J. M. C. PATON IN THE CHAIR.

### THE MINIMUM PROPORTIONS OF CARBON-DIOXIDE AND OF NITROGEN IN AIR WHICH ARE EXTINCTIVE OF DIFFERENT FLAMES.

(ABSTRACT.)

PROF. CLOWES gave an account of a series of experiments carried out by himself and M. E. Feilmann, B.Sc., with the object of ascertaining the minimum proportions of

carbon dioxide and of nitrogen, which, when mingled with air were extinctive to the flames of various combustible liquids and gases. He explained the method of experiment, which consisted in mixing the measured volumes of air and of the gas by the motion of a light ball, so as to avoid the solvent action of water on carbon-dioxide. After proving that the method yielded mixtures accurately in the desired proportions, the trials were made by introducing the experimental flame into mixtures of air and gas, which were varied in proportion until the flame was immediately extinguished, but continued burning for a short time in a mixture containing 1 per cent. less of the extinctive gas. The influence of the products of combustion was by this procedure eliminated. It was found that the size of the flame had no influence on the extinctive proportions.

The table on page 1156 summarises the average results obtained.

The results obtained show:—

(1) That carbon dioxide exerts a uniformly more powerful extinctive effect than nitrogen does. This may possibly be partly due to its high density, which renders the movement of air to feed the flame sluggish.

(2) That the different wick-fed flames are extinguished by a strikingly uniform proportion of the extinctive gas. These flames were noticed to gradually diminish in size and die down, evidently owing to the supply of combustible material to the flame being diminished in amount by the reduction of temperature in the flame.

(3) That the extinctive proportion for the various gas-fed flames varied widely, and did not appear to be deducible from the composition and chemical nature of the gas which was burnt. The extinctive proportion for a coal-gas flame was much larger than that for the wick-fed flames; whilst the extinctive proportion for the hydrogen flame was extraordinarily high.

The gas-fed flames increased in size during the process of extinction, instead of diminishing as in the case of the wick-fed flames. This appeared to be due to the fact that the supply of combustible was maintained independently of the flame itself, and that the flame had to increase its surface in order to obtain the supply of oxygen necessary for its combustion in air containing a diminished proportion of that gas.

Attention was directed to practical advantage derivable from the large proportion of carbon dioxide (58 per cent.) necessary to extinguish the hydrogen flame. The author had described an ordinary miner's safety-lamp, in which a hydrogen flame could be burnt at will instead of the oil flame for the purposes of delicate and accurate gas-testing. It is now found that by burning the hydrogen flame beside the oil-flame in parts of the mine where the atmosphere might contain large amounts of carbon dioxide, the extinction of the oil-flame was not attended with "loss of flame" in the lamp; since the hydrogen flame never suffered extinction and served to rekindle the wick in fresh air, after the oil-flame had been extinguished by a foul atmosphere. This had proved to be a great convenience to exploring parties in the mine after a fire or explosion; and it was the direct consequence of the resistance of the hydrogen flame to extinction by carbon dioxide.

Recent experiments (J. R. Wilson: American Journ. Pharm. 50, No. 12) made upon rabbits had thrown considerable doubt on the statement that the proportion of carbon dioxide in the air which extinguished an oil-flame or a candle-flame was irrespirable; this was a matter to be decided by physiological experiments. But it might be taken as finally established by the experiments described in the present paper that about 15 per cent. of carbon dioxide was at once extinctive to ordinary illuminating wick-fed flames; although 33 per cent. was requisite to at once extinguish a flame of coal-gas; whilst a hydrogen-flame did not suffer extinction until 58 per cent. of carbon dioxide was present in the air.

#### DISCUSSION.

MR. G. J. WARD said that they were in the habit of burning under their boilers waste gas from the blast furnaces. Roughly speaking the gas contains 30 per cent.

Combustible Substances Burnt.	Extinctive Proportion of Carbon Dioxide added to Air.			Extinctive Proportion of Nitrogen added to Air.		
	Percentage added.	Percentage Composition of Mixture, O : (N + CO <sub>2</sub> ).		Percentage added.	Percentage Composition of Mixture, O : N	
Air, dried, absolute .....	14	18.1	81.9	21	16.6	83.4
Alcohol, methylated .....	13	18.3	81.7	18	17.2	82.8

Coal-gas .....	33	14.1	85.9	46	11.3	88.7

of carbon monoxide, 6 per cent. carbon dioxide, 4 per cent. of hydrogen and hydrocarbons, and 60 per cent. of nitrogen. Approximately 85 per cent. of air is required to burn the mixed gases. After the addition of air the mixture would contain about 89 volumes of CO<sub>2</sub> and 11 volumes of oxygen in every 100 of non-combustible gases, a mixture which was extinctive for carbon monoxide according to Dr. Clowes' experiments, and yet combustion took place under their boilers. Could Dr. Clowes explain this?

Mr. R. L. WHITELEY did not agree with the argument that, because a rabbit could live in air which contained a certain large percentage of carbon dioxide, therefore a human being could also. He thought that animals accustomed to live above ground should be experimented upon if anything like satisfactory conclusions were to be arrived at.

Dr. STAFFORD said that there seemed to be some considerable difference of opinion with regard to this matter. Recent experiments tended to show that they had been accustomed to over estimate the dangerous qualities of carbonic acid gas as a constituent of respiratory air. Considerable quantities of CO<sub>2</sub> might be added to air before it becomes fatal to an animal breathing it. In this connection Dr. Whitelegge speaks of CO<sub>2</sub> in respiratory air as the "harmless index." It would appear that the use of oil-stoves for warming rooms—in place of open fires—is not so objectionable as might appear. Providing that the combustion of the oil is complete—the CO<sub>2</sub> produced does not appear to be harmful—fairly adequate ventilation being allowed for. Recent research seems to show that the deleterious properties of expired air lie more in the volatile organic material given off than in the CO<sub>2</sub> expired.

Mr. F. J. R. CARULLA referred to the power of the lamp for keeping a flame alight in atmospheres where the oil-flame went out, which seemed to the speaker an extremely valuable discovery. As bearing on that subject he would mention a case that he had read of. Somebody had fallen into a well, into which it appeared impossible for anybody to descend for the purpose of rescue, as candles were tried, but they went out on reaching a certain depth. Seeing this, one of the onlookers suddenly asked for an umbrella, much to the surprise of the others. This was supplied, and to the astonishment of the people around, one person opened it, tied a string to it, let it down into the well, brought it up and repeated the operation several times. The result was that the foul gas was displaced by the introduction of fresh air, and the atmosphere was rendered respirable. He was reminded of the incident when he saw Dr. Clowes mixing the air in the glass tube with a ball.

Dr. CLOWES, in reply, said that the conditions under which the furnace gas, mentioned by Mr. Ward, was burnt, were sufficiently different from those of his own experiments to account for the difference in the result. Part of the extinctive gases was mixed beforehand with the combustible gas, and the combustion of hot gas took place in a heated space, which would tend to maintain the flame. He remarked also that hydrogen was present as well as carbon monoxide. The conditions were therefore entirely different from those he had worked under, and the conclusions arrived at in the paper were not applicable to Mr. Ward's case.

Mr. FEILMANN stated that unpublished experiments, which were now in progress, proved that under different conditions the extinctive proportion was subject to variation.

The CHAIRMAN said that, besides in coalmines, men were overcome by irrespirable gases in distilleries, breweries, and other chemical works. The men were dragged out and brought round, but they had no means of knowing the composition of the atmosphere in which the man had been. He said, too, that it would not do for workmen to know that air which contained sufficient carbonic acid to extinguish flame did not necessarily destroy life. It would lead to their incurring carelessly unnecessary risks, and consequently there would be more lives lost through accidents.

PROFESSOR A. SMITHIELLS IN THE CHAIR

## THE BACTERIOLOGICAL ANALYSIS OF WATER. PART I.

BY F. W. RICHARDSON, F.R.S., F.R.M.S., ETC.

THE analysis of waters for their potability is one of the most vexed questions which the chemist is required to answer. Until within the last few years many chemists were under the impression that some five or six analytical data were sufficient to allow of the acquittal or condemnation of a water; yet it has been too often made painfully evident that the opinions of analysts differ very widely as to the character of a given sample; even when the same analytical data have been obtained. Some lay great stress upon the presence or absence of nitrites and nitrates, while others have laid down a fixed boundary for the free and albuminoid ammonia. To add to the confusion resulting from so many conflicting ideas the bacteriologists now adduce very strong facts to throw discredit upon the merely chemical analysis of a drinking water.

Drs. Dewar and Ogle (Report of the Commissioners to inquire into the Metropolitan Water Supply, 1893, § 141 and § 142), with other scientists, acting in an official capacity, have recently declared that the water-question has in fact passed from the domain of chemistry into that of biology; and, in confirmation of this, it is shown that waters containing large amounts of organic matter can be drunk by a population with impunity, while waters with so small a proportion of organic constituents as almost to defy detection may actually be of the most poisonous character.

In order to ascertain whether this were really the case, I divided a sample of Bradford town's water into two equal portions, and to one of these I added a drop of a typhoid (enteric) fever stool. The chemical analysis gave:—

	Unpolluted Water.	Polluted Portion.
Total solid matter..... Grains per Gallon.	7·6	8·9
Organic and volatile matter...	1·1	1·3
Saline matter .....	6·5	6·7
Chlorine.....	0·50	0·54
Nitrites.....	None	None.
Nitrates .....	None	None.
Free ammonia .....	0·03	0·08
Albuminoid ammonia.....	0·03	0·04

From these data the contaminated water would have been pronounced as "potable"; yet the bacteriological analysis gave:—

	Unpolluted Water.	Polluted Portion.
Bacillus typhi abdominalis..... In 1 cc.	None	All present. Total 68,430.
" coli communis .....	None	
" viridis pallescens .....	None	
" putrificus coli.....	None	
" fluorescens liquefaciens .....	12	
" albus.....	36	
" aerophilus .....	104	
Micrococcus aquatilis.....	100	
	312	

One finds micrococci so small that 16 trillions of them would only weigh a single grain, and if we assume that an average bacillus measures  $2\mu \times 1\mu \times 1\mu$ , 300,000 millions would be required to equal to this weight. Microbes contain 80 per cent. of water and 2 per cent. of nitrogen, and as by the Wanklyn albuminoid-ammonia process only a portion of the total nitrogen is liberated as ammonia, we are not far from the truth in stating that 0·01 mgrm. of ammonia thus obtained would represent 10,000 millions of these bacilli! In the case of actual pollution by infiltration through soil, we are aware that for every microbe present there is an incomparably larger proportion of decomposition products—such as free ammonia, nitrites and nitrates; nevertheless it is certain that great numbers of dangerous microbes are repeatedly found in waters given as pure by chemical analysis. Chautemesse and Widal found numerous typhoid bacilli during the epidemic at Pierrefonds in well-water, which contained only very small proportions of nitrogenous matter; and Macé (Traité Pratique de Bactériologie, 1892, 694) asserts that pathogenic germs can vegetate and multiply enormously in distilled water, utilising such minute proportions of organic matter that the most refined chemical methods fail to discover them. One domestic sewage gave me as many as 36 millions of microbes in 1 cc., and many of these were bacilli of the colon (*B. coli communis*, &c.); yet one part of this diluted with 1,000 parts of a good drinking-water increased the organic constituents so slightly that the quality of the water appeared to be scarcely affected; yet to culture media this mixture yielded a superabundance of objectionable microbes.

In considering such startling facts as these it is well not to lose sight of the truth that the nature of the organic matter present in a water has much to do with its power of supporting germ-life. In striking illustration of this I record the following experiments:—I made dilute solutions of the substances named with sterilised water, and then thoroughly re-sterilised the mixtures, and, after cooling, infected each with an equal but minute amount of typhoid bacilli. After two days' continuance in the dark at 60° F. the proper dilutions were made and the usual bacteria-flask cultures were initiated.

	Microbes in 1 cc.	Ratios.
(1) 0·05 per cent. domestic sewage..	55,080	58·9
(2) 1·00 " " " ..	244,800	257·0
(3) 0·01 " peptone .....	2,550	2·7
(4) 0·05 " " .....	117,000	123·0
(5) 0·01 " cane sugar .....	950	1·0
(1) 1 grm. of the dry sewage organic matter gave .....	110,160,000,000	116,000
(4) 1 grm. dry peptone gave .....	2,340,000	26
(5) 1 grm. dry sugar gave .....	95,000	1

These results illustrate the necessity of a chemical as well as a bacteriological analysis. Experiments are in progress with reference to the "germ-development power" of waters, as this should prove a useful factor.

It is in this connection that one may find some value in the total microbial richness of samples, as a large number of microbes may indicate either some source of aerial pollution or the presence of decomposing organic matters capable of supporting the rapid development of pathogenic germs. Dr. G. Roux (Précis d'Analyse Microbiologique des Eaux, 1892, 262) not only emphasises, this fact, but affirms that the quantity of micro-organisms in a water is of the greatest importance in enabling us to judge of its quality. A large number of chemists adduce apparently strong reasons for ignoring these data of the water-bacteriologist; it is urged that a very large proportion of microbes are quite harmless, and though they might not care to repeat Dr. Emmerich's experiment of drinking sewage with, as he has stated, some slight benefit to himself! yet they consider mere numbers of germs not necessarily an

evil sign. Macé (Traité Pratique de Bacteriologie, 1891, 712) gives the following table to express the qualities of waters in terms of their microbial contents:—

Bacteria per 1 cc.	
Very good waters contain . . .	0— 50
Good waters contain . . . . .	50— 500
Mediocre waters contain . . . .	500— 3,000
Bad waters contain . . . . .	3,000— 10,000
Very bad waters contain . . . .	10,000—100,000 and above.

A sceptical attitude towards these figures is for the present advisable. Dr. Migula (Centralblatt für Bakteriologie, &c., 1890, No. 12), of Carlsruhe, shows the necessity of counting not merely the numbers but the species present in a water, as he has frequently found that waters with a comparatively small number of germs often contain more pernicious species than others with larger totals, thus proving the importance of the species-determination.

The only attempt at a recognition of this principle is seen in the statements of the "liquefying" and "non-liquefying" colonies which a water is capable of yielding to nutrient gelatine. I have abandoned this distinction as valueless. The assumption is that the liquefying microbes are more harmful than the non-liquefying; now in waters one finds some 22 species (Dr. Frankland's "Micro-organisms in Water," 1894, 398) of microbes pathogenic either to men or animals, and of these I find that 14 are liquefying and 8 are non-liquefying, while the germs pathogenic to man are divided equally between the two classes; but as cholera and anthrax germs can only occur very rarely in our water supplies, while the typhoid bacillus and its congener bacillus coli communis are frequently to be sought, and as both these are non-liquefying organisms, we may fairly rule the distinction out of court as a guide to the potability of a water. Roux (*lib. cit.* 192) shows that the ideas of Proust, who gave forth this distinction, are quite at variance with his own observations; inasmuch as the waters of the Seine, though much more impure than those of the Rhone, contain infinitely less liquefying microbes. In confirmation of Roux's assertion, Lacassagne notes that corpses decompose much more quickly in the Rhone than in the Seine; attesting to the larger proportion of liquefying organisms.

I find that a far better method for making a general distinction between harmless and more or less objectionable microbes is to submit a portion of the water to a temperature of blood heat (98° F.) for 12 hours, and then determine the proportion of micro-organisms existing. I was led to try this process after a consideration of the fact that all pathogenic microbes not only resist, but under suitable conditions largely multiply at the body temperature; while the majority of harmless microbes, such as the commonly occurring *Bacillus albus* and *Bacillus aquatilis*, speedily perish. As examples of the utility of this method I adduce a few results:—

	Pure Upland Surface Waters.		ATyphoidised Water.	A Polluted Well Water.
	A.	B.	C.	D.
Before exposure to 98° F.	112	28	85,500	12,204
After exposure to 98° F.	2	0	51,500	8,000
Microbes surviving 98° F., per cent.	1.78	0	60	66

As further evidence of the dangerous character of C and D, I may note that both contained a considerable number of facultative anaerobes. If the heating is continued for longer than 12 hours the surviving microbes begin to multiply enormously, particularly in waters rich in organic matters; after continuing the heating of D another 12 hours each cc. yielded 110,000 colonies to nutrient gelatine.

A sharp process, of value at all events as affording negative evidence of bacteriological impurity, is to take 1 cc. of the water in a sterilised pipette, giving about 40 drops for the 1 cc., and add a drop to each of 40 sterilised tubes of bouillon; exposing the tubes to 98° F. for 12 hours. One part of sewage in 1,000 parts of sterilised water will give an abundant growth in every tube, while really good waters will show at the most a very few developments; indeed, several waters thus examined by me have not given a single growth, thus affording a speedy indication of bacteriological purity. In every case it is advisable to count the total colonies a water is capable of yielding; to this end the majority of bacteriologists use plate cultivation. My experience of such cultivations is anything but satisfactory; although I have set apart a special laboratory for this work and have taken considerable precautions against the invasions of dust, reducing the average number of germs in the air to about two per litre, yet blank gelatine plates almost always show some colonies. Should penicillium spores find their way on to the plates, the spores will rapidly extend and contaminate all the cultures, as I have repeatedly found. Roux (*lib. cit.* 153) notes the same objection, and affirms that the plates are sufficiently long exposed to the air before and after the solidification of the gelatine to receive contamination with aerial germs. With Roux I agree that it is somewhat "eventual" for an observer to pretend that he can discover by the superficial character of the colonies the number of germs which have been aerially deposited.

I place my faith upon bacteria flask cultivations. I have had specially made a considerable number of large, flat-bottomed shallow flasks, and find that these can be readily charged with nutrient gelatine, and can be as easily sterilised, while blank experiments show that in introducing 1 cc. of a water there is practically no risk of aerial pollution. Although one cannot as readily apply the microscope to these flasks as to the plates, yet one can apply a very fair magnification and can also obtain prick-cultures from the colonies. A Wollfhuigel's counting-plate and a 1-inch objective enable one to make a very satisfactory enumeration of the colonies. The plate contains 144 sq. cm. divisions, and some of these are sub-divided into nine; if one of these smaller divisions contains ten colonies, then—

$$(\frac{1}{2} \times 3.14) \times 9 \times 10 = x, \text{ number of colonies.}$$

Dr. Griffiths (Chemical News, May 1893, 234) recommends a species of Hesse's tube, the sides of which are coated with nutrient gelatine; by means of a spray 1 cc. of the water can be distributed over the surface of the medium. I have tried this method, and discard it because the liquefying colonies speedily spread themselves over the sides long before the colonies are entirely developed; thus the counting becomes difficult and even impossible. Pétri's dishes are useful for certain kinds of work, but are not as convenient for general purposes as the flasks.

The full bacteriological analysis of a water requires much labour, and it is not within the scope of this paper to describe the methods by which it is accomplished; sufficient it must be to indicate the general principles of procedure. By making a number of dilutions of the sample with sterilised water and by inoculating with these a large series of nutrient gelatine and bouillon tubes one is able to arrive at that stage when some tubes are unaffected by germs, while others contain pure cultures. By utilising various media for the further study of the pure cultures so obtained, and by noting their microscopical features and measurements and reaction to dyes, they may be finally classified.

The table on page 1159 expresses some of the results thus obtained, and may be of interest as showing the relation of chemical composition to bacterian contents.

F is indeed a rare example, as the 1 cc. taken did not contain a single microbe! It is worthy of note that this water was quite free from nitrites, nitrates, and albuminoid ammonia, and that it was drawn from an artesian spring.

B was drawn from under the peat near the sea, and although containing a large excess of saline and organic matter, and doubtless possessed of enormous germ-development power, was none the less free from objectionable

microbes; this is surely further proof of the absolute necessity of a chemical as well as a bacteriological analysis. E was a water contaminated by typhoid dejecta. A and C were pure upland surface waters.

Public analysts are occasionally called upon to analyse waters which have been suspected as the cause of an outbreak of enteric (typhoid) fever, and there can be but little doubt that in a large number of cases, for reasons already indicated, the chemical analysis must not merely often fail to show that the water is dangerous, but it will be always valueless in proving the absence or presence of the specific bacillus, the discovery of which can alone be sufficient to condemn the sample on the main charge. Even to professional bacteriologists the detection of typhoid germs in water is admittedly a very difficult task. Considerable progress has been made recently in this direction, and we may yet hope to discover more certain methods for the discovery of this microbe.

Before reporting the results of a number of experiments made with this object in view, it will be necessary to note certain facts, the apprehension of which lies at the very door of the inquiry. Dr. Arthur Gamgee (Text-book of the Physiology and Chemistry of the Animal Body, Part II., 437), in his recent classical work, gives a table of the chief micro-organisms which normally inhabit the human intestine, and to these we may add several more as regularly inhabiting the intestinal tract and urinary passages; in all some 16 species of microbes, some of which are always to be found in human sewage. The principal microbe which is sure to be found in any water contaminated with typhoid is not that of the typhoid itself, but the *bête noir* of the water-bacteriologist—*Bacillus coli communis*. The latter bacillus far exceeds in number that of the specific *B. typhi*, even in typhoid stools; this has been my experience at least. I have found that the secretions or excretions of

*B. coli* com. soon prove fatal to *B. typhi*, and that the latter soon disappears from a mixture containing the two microbes. This is the reason why the bacteriologist often fails to find the specific bacillus in waters certainly contaminated by typhoid; but he is sure to find *B. coli* com.—a microbe perhaps more resistant to conditions of temperature and antiseptics than any other. This germ is not difficult to discover, and from subsequent considerations it will be seen that its discovery in appreciable numbers in any water should be sufficient to condemn it as capable of communicating enteric fever.

Dr. E. Henke (Centralblatt für Bakteriologie, &c., 1894, 481) has recently proved the great ubiquity of *B. coli* com. in nature, and states that it plays a much greater rôle in the outer world than has hitherto been suspected; that after death it speedily penetrates to the spleen, liver, kidneys, and even to the heart's blood; and that it has been found in strumitis and several other affections. J. H. Kellog (Centralblatt für Bakteriologie, &c., 1894, 132) charges this bacillus with having produced a typhus epidemic in the case of a well-water polluted by infiltrations from closets, and shows that by passage through the human body this germ acquires all the virulence of *B. typhi*. It is only in this way that we can account for a number of the typhoid epidemics quite untraceable to any infection by the specific bacillus itself. The Lyons School of Bacteriologists and Macé (Traité Pratique de Bactériologie, 1891, 435) have long maintained the typhogenicity of *B. coli communis*. Quite recently, Chantemesse (La Semaine Médicale, 1894, 215) has shown that the waters of the Vanne, Avre, and Dhuis caused the spring epidemic of typhoid in Paris, although only virulent *coli* bacilli and no typhoid bacilli could be found in these waters. These facts are sufficient to show that the presence of *B. coli communis* in any water must be regarded with suspicion as certainly indicative of

pollution with faecal matters. In the next paper, I hope to show the best methods for the detection and enumeration of these microbes, with several analyses illustrating the relations which exist between the chemical composition and the bacteriological contents and biological capabilities of waters.

#### DISCUSSION.

Mr. T. A. GLENDINNING pointed out the importance of the qualitative examination for the bacteria in water, and also the difficulty of distinguishing between pathogenic and very similar non-pathogenic species—as, for example, in the case of *B. coli communis* and *B. typhus*,—only two distinguishing features being known. Even inoculation experiments on animals did not give satisfactory evidence that the organisms were harmful to man, because the same organism affected different animals differently.

Mr. H. R. PROCTER said that the difficulty of carrying out inoculation experiments in this country added materially to the difficulties of the subject.

The CHAIRMAN thought that it was doubtful whether it was possible or even desirable that analysts should, in the ordinary routine of work, take up the bacteriological side of water examination. This could only be really satisfactorily done by State or municipal laboratories with a specially trained staff.

Mr. F. W. RICHARDSON, in reply, said that he had already indicated some very useful qualitative modes of testing the bacteriological quality of a water; for instance, the determination of the total number of bacteria which could be grown from a sample of water before heating it to 98° F. for some hours and after such treatment, gave useful indications as to the nature of the microbes present; the non pathogenic organisms were very largely killed by this heating. In reply to Mr. Glendinning, there were some eight methods of distinguishing *B. coli communis* from *B. typhus*, and he also thought that the department of bacteriology relative to water-analysis could be satisfactorily cultivated by chemists; indeed, it was impossible for an analyst to give a definite dictum as to the real quality of certain waters unless he could say something as to their microbial contents.

---

Meeting held on Monday, December 3rd, 1894, at the  
Yorkshire College, Leeds.

PROFESSOR A. SMITHells IN THE CHAIR.

#### ON THE ACTION OF CERTAIN ANTISEPTIC SUBSTANCES ON YEAST.

By HAROLD H. MANN, B.Sc., A.I.C.

SINCE the time at which Pasteur, by his brilliant researches on the micro-organisms of fermentation, first opened out the world of bacteria to science, the study of antiseptic action, and of antiseptic power has been approached in a variety of ways. Yet, although considered by a great number of observers as a hygienic, physiological, medical, or commercial question, the investigation of the chemical role of any antiseptic substance seems to have been almost entirely neglected. Even to this day researches on very similar if not identical questions often lead to entirely opposing results, and this cannot be in all cases due to errors of work, but must be regarded as a consequence of our almost complete lack of knowledge as to the rationale of the action of the antiseptic in any particular case.

Acting therefore on the advice of Professor Duclaux, of the University of Paris, I have during the past year turned my attention to the study of one problem involved in this hitherto almost unploughed part of the field mentioned above. Taking yeast as a typical micro-organism, I have attempted to consider the question of the relation between the antiseptic power of a substance, and the quantity of yeast on which it was made to act.

By most observers this influence has been entirely left out of consideration, and the strength of the antiseptic solution necessary to destroy a micro-organism has been regarded as independent of the quantity of organism there present. That this position is not in all cases true has, however, already been shown in several cases. Take chloroform as an example. Here Duclaux showed, in opposition to Liebig, that while this body (when an aqueous solution is completely saturated with it) stopped the commencement of fermentation, yet it was powerless to produce the same effect when fermentation had actively commenced, *i.e.*, when the number of cells had sufficiently increased to succeed in continuing their action in spite of the substance added. With borax a similar effect can easily be produced, and, in this case, if the amount of yeast used be sufficiently increased, the dose of borax can be augmented with impunity without hindering the completion of the fermentation.

The work which I am about to detail is, however, concerned with the action of certain metallic salts, and with that of phenol on yeast cells. These latter were sometimes used in the form of a pure culture of *saccharomyces cerevisiae*, and sometimes, when the quantity became too large to be conveniently prepared in the laboratory in that of ordinary commercial beer yeast.

The antiseptic power of a substance has been usually measured, in the past, by two methods. The one of these consists in measuring the exact amount of antiseptic which, added to a nutrient liquid containing the yeast cells, would absolutely prevent their growth, and the other in finding the strength of antiseptic solution necessary to destroy the reproductive power of the organism in question, even when removed to the most favourable conditions. However good these methods may be in theory, I found them very long and tedious to carry out in practice. The process was therefore modified so that only enough antiseptic was added to partially prevent the growth, or destroy the reproductive power of part only of the cells used, as the case might be.

In order to carry this out by the method first mentioned the following process was adopted:—Several samples of nutrient liquid, containing an equal amount of the antiseptic to be used, were prepared, sufficient to partially prevent the growth of yeast. These were sown with different determined numbers of yeast cells, and left to develop under the same conditions for an equal length of time. After this development had taken place, the numbers of cells present in a sample taken from each liquid were counted. At first, this counting was done under the microscope, by means of one of the pieces of apparatus in use for counting the corpuscles of the blood. It was soon found, however, that the amount of yeast necessarily present, in order that an accurate numeration of the cells should be possible by this method, was too large to allow for the free development of each cell in the liquid, although it was very far from being the maximum which could exist there.

Microscopic counting was therefore abandoned, and cultivation of the cells contained in a sample of the liquid on nutrient gelatin was substituted for it. This gelatin was composed of 100 grms. cane-sugar, dissolved in water, inverted with a little acid, and neutralised; 40 grms. barley sprits, boiled with 1 litre water and filtered; 200 grms. gelatin; the whole made up to 2 litres, filtered, and sterilised. By this means an extremely small number of cells could be counted, small enough to allow their free development while also permitting their accurate numeration. This is shown in the following experiments, where, as would be expected, the number of cells found after development is approximately proportional to the quantity originally introduced. In the column headed B the numbers of cells are given which would be found were the method absolutely exact (taking, of

course, one of the numbers actually found as basis), while the column A represents the relative numbers added:—

	Number of Cells Added.	A.	Number of Cells Found.	B.	Time of Action.
I.	(1) Not determined, but	1	14.0	12.0	Hours. 3½
	(2) proportionally, as in A.	2	24.0	24.0	3½
	(3)	4	48.0	48.0	3½
II.	(1) Not determined, but	1	19.0	19.0	6
	(2) proportionally, as in A.	2	44.0	38.0	6
	(3)	3	56.0	57.0	6
III.	(1) 13	1	23.5	21.5	17½
	(2) 26	2	46.5	43.0	17½
	(3) 104	8	171.5	172.0	17½

As previously stated, however, we can also investigate antiseptic action by determining the amount of antiseptic required to destroy the subsequent developing power of the organism. Looking at the question in this light I made some experiments in the following manner:—A small and a large number of cells were put into equal volumes of an antiseptic solution, *not sufficiently strong to kill all*, and after different lengths of time, say for instance, 10 minutes, 20 minutes, and half an hour, samples were taken. The number of cells in these which were still living, was determined (after washing the sample from antiseptic in sterile water) by culture on gelatin. By comparison of the numbers thus obtained it can easily be seen whether the antiseptic power of the substance in question is variable with the number of cells on which it has to act.

For the first series of experiments phenol was used as the antiseptic substance. Employing the method first named, the following table shows that upon the power of this antiseptic the quantity of yeast present exercises little, if any, influence.

	Number of Cells Added.	A.	Cells Found.	B.	Strength of Phenol.	Time of Action.
I.	(1) ..	1	32.0	32.0	0.013	Hours. 2
	(2) ..	2	62.0	64.0	0.013	2
	(3) ..	4	128.0	128.0	0.013	2
II.	(1) 2,315	1	15.0	17.0	0.053	3½
	(2) 4,630	2	36.0	35.0	0.053	3½
	(3) 9,260	4	69.0	60.0	0.053	3½
III.	(1) 92	1	22.0	19.5	0.05	16½
	(2) 384	2	39.0	39.0	0.05	16½
	(3) 532	1	18.5	23.5	0.04	17½
IV.	(1) 1,064	2	43.5	47.0	0.04	17½
	(2) 2,128	4	93.5	94.0	0.04	17½

Here A and B retain the meanings they possessed in the previous table.

These results are confirmed by the following experiments, carried out according to the second method. Here  $x$  is the number of cells used in the one case, while  $y$  represents the number (taken from the same culture) employed in the other. The ratio  $\frac{y}{x}$  will, therefore, show any variations which may occur in their relative values.

	Time of Action.	$x$	$y$	Ratio $\frac{y}{x}$
Minutes.				
I.	(1) 5	97	220	2.4
	(2) 10	86	220	2.56
	(3) 15	74	182	2.46
II.	(1) 6	208	450	2.16
	(2) 11	198	420	2.15

Here the phenol was employed of a strength corresponding to 0.55 per cent.  $C_6H_5OH$ .

Such being the results obtained with phenol, the same methods were applied to a representative of the salts of the heavy metals possessing antiseptic properties, namely, copper sulphate. The following table represents the numbers obtained by the first method above given. Here, however, B represents the relationship between the number of cells found after the development in each series. The result of a blank experiment is given in each case where the conditions were exactly the same as in that opposite to which it is placed, save that no antiseptic was introduced into the nutrient liquid.

	Number of Cells Added.	A.	Number of Cells Found.
I.	(1).....	1	87.0 (Blank Expt. = 45)
	(2).....	2	167.0
	(3).....	4	417.0
II.	(1).....	1	178.5 (Blank = 234)
	(2).....	2	438.5
	(3).....	4	801.5
III.	(1).....	1	260.0 (Blank = 405)
	(2).....	2	569.0
	(3).....	4	1,160.5
IV.	(1).....	1	355.0 (Blank = 583)
	(2).....	2	761.0
	(3).....	4	1,344.0
V.	(1).....	1	237.5 (Blank = 330)
	(2).....	2	565.5
	(3).....	4	1,265.5

	B.	Strength of $CuSO_4$ .	Time of Action.
Per Cent.			
I.	(1).....	0.01	Hours. 18½
	(2).....	0.01	18.
	(3).....	0.01	18.
II.	(1).....	0.005	18.
	(2).....	0.005	18.
	(3).....	0.005	18.
III.	(1).....	0.016	18.
	(2).....	0.016	18.
	(3).....	0.016	18½
IV.	(1).....	0.016	21½
	(2).....	0.016	21½
	(3).....	0.016	21½
V.	(1).....	0.013	21.
	(2).....	0.013	21.
	(3).....	0.013	21.

From the repeated excess of the number of cells found with the higher proportions of yeast over those which would be expected, calculating on the basis of those introduced, it may safely be concluded that the antiseptic effect of a copper sulphate solution becomes less on augmenting the amount of yeast on which it is made to act. This effect is also seen in the following experiment conducted according to the second method.

Time of Action.		a.		b.		Ratio $\frac{a}{b}$	
Minutes.							
I.	10 and 10½	425.0		935.5		2.2	
	20½ and 20	381.5		886.5		2.32	
	30½ and 31½	204.0		487.5		2.41	

(Strength of  $\text{CuSO}_4$  solution = approximately 0.2 per cent.)

It is then sufficiently evident that the power of copper sulphate solution is weakened when brought into contact with a large amount of yeast, and the question now arises. How is this weakened effect produced?—The simplest hypothesis is undoubtedly that which supposes a fixation of the metal by the yeast.

To test this hypothesis, a quantity of commercial yeast was treated with copper sulphate solution, filtered, and washed until the washings were free from copper. On calcining the yeast which remained, and testing the residue for copper, a distinct reaction was repeatedly and always obtained. We may then conclude that a fixation of copper does occur. This has already been pointed out by Will. (*Zeit. für das gesamte Brauwesen*, 1893) as the result he obtained on treating yeast with copper sulphate solution, but he did not further investigate the cause of the fixation. This now remains to be done, as well as to determine the conditions under which it takes place. Does it vary in amount with the time of action? with the dilution of the solution of antiseptic? or with the condition of the yeast? Further it is wholly due to the soluble contents and products of the organism, or is it partially fixed by the cell-wall?

In order to resolve these questions the solution of copper sulphate was allowed to act directly on the yeast. On filtering, a measured portion (50 cc.) was taken for analysis, and the copper therein determined. Knowing the quantity originally present in the same volume of the liquid, the amount fixed by the yeast was readily obtained.

On heating the yeast to 100° C. with water, not only is the organism killed, but coagulation of the albumen and forcing out of the contents of the cell ensue. The first experiments were relative to the amount fixed comparatively under these, and under the ordinary conditions, after different periods of time. The copper was determined by precipitation with zinc, and in these particular experiments the amount of yeast corresponding to each number given, contained about 1 gram. of dry matter.

Time of Action.		A.		B.	
		Amount Fixed (Cu).		Amount Fixed (Cu).	
Hours.	Minutes.	188°0	...	183°0	...
1	179°0	9°0		..	
1	175°0	10°0		17°0	
4	177°5	10°5		17°5	

(The quantities of copper given under A and B represent the amounts corresponding to 1 gram. of, in A ordinary yeast, and in B, yeast which has been previously heated to 100° C.)

In answer to the question as to whether all is fixed by the soluble products of the yeast, experiment answers in the negative. On washing the yeast with boiling water until the solution obtained gave no longer the reaction for

phosphates (these forming probably the substances most adherent to the cell itself), treating the residue with copper sulphate solution, and again washing until free from this metal, copper was still repeatedly found to have been fixed in appreciable quantity. Evidently then the insoluble material of the cells take some part in the fixation of copper during these experiments.

On the other hand, the soluble products are responsible for by far the greater portion of the effect, and it was interesting to know in what state the copper was precipitated by them. A portion of the precipitate produced by copper sulphate in yeast water was therefore washed until free from soluble copper. On treating the residue with dilute nitric acid a part dissolved containing the whole of the copper, leaving a gelatinous mass on the filter paper free from this metal. This gelatinous mass had evidently been carried down with the copper containing part of the precipitate. On determining the copper and the phosphoric acid in two equal portions of the filtrate, they were found to be in approximately the proportions necessary to form the second phosphate of copper—

thus—

$$\text{Ratio } \frac{\text{P}_2\text{O}_5}{\text{Cu}} \begin{cases} \text{Found} = 0.8 \\ \text{Theoretical for } \text{Cu}_2\text{H}_2(\text{PO}_4)_2 = 0.89 \end{cases}$$

It very probably consists essentially of this substance.

The question now arose: Does this phosphate of copper act as an antiseptic when introduced into nutrient fluid? On sowing a trace of *saccharomyces cerevisiae* under these circumstances, it was found that no culture supervened. This may, however, be due, not to the action of the above insoluble phosphate of copper, but to that phosphate possibly produced by its partial solubilisation by the acid phosphate of potassium undoubtedly present in the nutrient liquid. The filtered liquid was, in fact, found after the experiment to contain a trace of copper.

Another series of quantitative experiments was now undertaken in which, instead of separating yeast and solution by filtration a centrifugal machine was employed, thus avoiding several objections which might possibly have been raised against those done under the previous conditions. In addition the copper was here determined by the potassium iodide and thiosulphate method. Here are the results of the experiments. All those in each series contained the same amount of yeast, but in B a stronger solution of copper was used than in A, while C, usually similar to either A or B, as far as quantity was concerned, acted upon yeast which had previously been heated to 100° C. Each number given corresponds to a volume of solution of 50 cc.

	Time of Action.	Amount Fixed (Cu).			Total Amount Cu originally in A, B, and C.	
		A.	B.	C.		
	Hours.	Mgms.	Mgms.	Mgms.	Gm.	Gm.
I.	(1)	$\frac{1}{2}$	1.7	2.0	1.2	A = 0.0212; B 0.053
	(2)	$7\frac{1}{4}$	2.7	3.0	1.2	C = 0.0206
II.	(1)	$\frac{1}{2}$	3.3	4.0	..	A and C = 0.0176
	(2)	$7\frac{1}{4}$	..	6.0	3.5	B = 0.088

As a result of these experiments with copper sulphate, I think it may be taken as proved, that a fixation of the metal by yeast does take place, that it is slightly increased in amount as the time of contact becomes greater, that the amount thus fixed is practically the same after heating to 100° C., as previous to the operation, and that the influence in this case of the concentration of the solution is only very slight. Further, that while the greater portion is fixed by the soluble contents and products of the yeast, some at least is taken up by the cell substance itself.

Having obtained such results with copper it became interesting to know whether other metallic salts behaved in a similar manner. Ferric sulphate, lead acetate, and

mercuric chloride were therefore successively used. Though in all cases a fixation was shown to take place, yet it differs either in quantity or conditions in each case.

Perhaps the most nearly allied to that of copper is the action of mercury. In this case the fixation is however very much greater in amount. The figures given below show the amount fixed under various conditions. A, B, and C have the same meanings as in the above given results, and separation of yeast and solution was again effected by means of the centrifugal machine. The mercury was determined by the method of Haunay (by titration with potassium cyanide), either in its original form or in the modification by Chapman Jones (*Journ. Chem. Soc.* 1892).

	Time of Action.	Amount Fixed (Hg).			Total Mercury originally in A, B, and C (50 cc.).
		A.	B.	C.	
I. { (1)	Hours. 1	Megms. 27.0	Megms. 44.0	Megms. 28.5	A and C = 0.135
(2)	24	31.5	..	37.0	B = 0.405
II. (1)	1	52.5	..	55.5	A and C = 0.1515
III. { (1)	1	12.5	..	..	A = 0.106
(2)	5	128.5	278.5	..	B = 0.588

It will be seen that the amount fixed is extremely high. Even in the last case where no less than 0.25 gram. are shown as fixed, the quantity of yeast corresponding to each sample only contained about 0.6 gram. of dry matter.

When we came to an iron salt, another important difference presents itself. Up to this point the effect produced by previously heating the yeast to 100° C. has not been very great. It rises to large proportions in the case now before us, namely, that of ferric sulphate, and this is doubtless due to the insolubility of the acid phosphate ( $\text{FeH}_2(\text{PO}_4)_2$ ) which will be formed at the expense of the acid potassium phosphate of the cell contents (this being probably the only phosphate of potassium occurring inside the cells).

The following are the results of experiments on this question:—

	Time of Action.	Amount Fixed (Fe).			Total Iron originally in A, B, and C.
		A.	B.	C.	
I. { (1)	Hours. 2	Megms. 6.9	..	26.0	A and C = 0.029
(2)	22-24	8.2	..	26.0	.. ..
II. { (1)	21	6.2	..	21.9	A and C = 0.215
(2)	9	8.9	..	22.5	.. ..

In these cases the separation was again effected by filtration, but by means of a reversed filter, thereby doing away with a great many objections to the process of filtration applied for this purpose in its ordinary form.

Nevertheless, centrifugal force was again adopted in the next series, that bearing on the effect of concentration of the solution on the amount of metal fixed. Here it was once again made evident what an important part this may play in the question we are considering.

	Time of Action.	Amount Fixed (Fe).			Total Iron originally in A, B, and C.
		A.	B.	C.	
I. (1)	Hours. 22-24	Megms. 9.2	Megms. 19.3	..	Grm. A = 0.0132; B 0.066
II. { (1)	1	9.6	21.5	..	A = 0.0109
(2)	18	9.9	27.1	..	B = 0.0433

We now arrive at the list of the metals which have been used, namely lead. This evidently acts as a precipitant of many of the organic matters in yeast. The results, especially as concerns the series I., II., and III. are only approximate. The lead was in all cases estimated as chromate, according to the process recommended by Fresenius, and the salt used for these experiments was in all cases the acetate.

The numbers are as follows, where, as in previous cases, the yeast was separated by the centrifugal machine.

	Time of Action.	Amount Fixed (Pb).			Total Lead originally in A, B, and C.
		A.	B.	C.	
I. { (1)	Hours. 1	Megms. 75.0	Megms. ..	Megms. ..	Grm. A = 0.128
(2)	2 1/2	..	85.0	..	B = 0.405
II. { (1)	51	15.0	44.0	91.5	A and C = 0.194
(2)	18	..	..	94.5	B = 0.405
III. { (1)	1	41.0	49.5	79.0	A and C = 0.069
(2)	20	..	75.5	..	B = 0.379
IV. { (1)	1	38.8	48.0	..	A = 0.076
(2)	19	..	70.0	82.5	B and C = 0.379

These results taken as a whole confirm one another and place this metal by the side of iron, differing from it, however, in the much larger total quantity fixed by about the same quantity of yeast.

Such, then, are the results obtained with the metallic salts, an examination of whose action has formed the principal portion of this paper. The conclusions to be drawn from a consideration of the results may be briefly stated as follows:—

(1.) That in the case of certain metallic salts possessing antiseptic properties, the amount of antiseptic required in order to kill the yeast cells, varies with the quantity of these last, in the sense that it becomes greater as the amount of the latter augments. With phenol this effect has not been shown with certainty to exist.

(2.) That with the aforementioned metallic salts, namely those of copper, lead, iron, and mercury, this effect is due to a fixation of the metal by the yeast. This fixation varies in amount with the different metals, and may vary with the time of action, with the dilution of the solution, and with the condition of the treated yeast. This seems, indirectly, to give grounds for objection to their use as antiseptics in practice, owing to the rapid exhaustion, say, of a solution of mercuric chloride at 1 in 1,000, which must ensue.

(3.) That this fixation takes place, partly at any rate, by precipitation of the metal as phosphate. At the same time, however, it is fixed in a more intimate sense in the cell-wall. It may cause, in addition, the precipitation of some part, at any rate, of the organic cell materials.

In conclusion, I can only express my sincerest thanks to Professor Duclaux, who first suggested the work to me, and who has, during its whole progress, been ready with help, advice, and suggestion. I would also here acknowledge my obligations to his chief assistant, Dr. Fernbach, who has ever been at hand to afford all the valuable aid of which I might stand in need.

#### DISCUSSION.

Mr. F. W. RICHARDSON asked whether the author had noticed any difference in the shape of the cells under the influence of different antiseptics, and whether he had observed that very small quantities of the antiseptic increased, instead of diminishing the rapidity of growth of the organisms. Minute quantities of mercuric chloride and also of boric acid had been observed to exert such an influence on the growth of *saccharomyces cerevisiae*. He thought that for the determination of small quantities of copper, titration with potassium ferrocyanide was to be preferred to precipitation with zinc.

Dr. CAMERON referred to the interest, from a medical point of view, of investigations such as that of Mr. Mann, and more especially of chemical work on the substances produced during the growth of micro-organisms.

Mr. H. R. PROCTER pointed out that the antiseptic power of the salts examined was to some extent comprehensible, as they were absorbed by the organisms and chemically changed, but the action of phenol which apparently underwent no change, and was neither absorbed nor destroyed, was very difficult to understand.

Dr. LEWKOWITSCH asked the author what proofs he was able to give that the fixation of the metallic salts by the yeast was due to the formation of metallic phosphates, and pointed out that physical processes, such as absorption, probably also played a part in the fixation. It is well known, for example, that charcoal fixes considerable quantities of many bodies which cannot be removed by washing.

Dr. EWAN agreed with the last speaker, and thought that the salt must also pass into the cell to some extent by diffusion through the cell wall.

The CHAIRMAN (Professor Smithells) commented on the interesting nature of the action of phenol, which appeared to be independent of the quantity of yeast acted upon, within fairly wide limits.

Mr. MANN, in reply, said that he had not noticed that  $\text{CuSO}_4$  had any influence on the shape of the yeast cells, but that very small quantities of phenol caused the yeast cells to stick together, so that they formed long chains like those of *S. pastorianus*. Very minute quantities of  $\text{CuSO}_4$  had been observed to stimulate the growth of yeast. Phenol appeared to be quite unchanged by its action on yeast, though it is not easy to determine accurately the quantity of phenol in the solutions. He thought that small quantities of copper could be most accurately determined by precipitation with zinc, though the method was tedious. Pure cultures of *S. cerevisiae* were always used in his culture experiments. The insoluble substance obtained from the yeast which had been treated with  $\text{CuSO}_4$  solution contained copper and phosphoric acid in the proportions in which they exist in copper phosphate.

In addition to the copper absorbed as phosphate, however, there was another portion the absorption of which was doubtless due to some physical action, perhaps absorption by the cellulose of the cell wall. He thought that osmosis was not a factor of importance, as this additional fixation took place also with cells which had been disintegrated by boiling.

of oils used was considerably altered. I need not enter into any description of the old system, as I cannot claim to be very familiar with it, but it seemed to lay great stress on the exclusion of mineral oil, under which term in practice all unsaponifiable matter was included.

I need not trouble you with the details of the present system further than to say that whatever the original intention of the framers may have been, in practice, in Yorkshire at least, when a mill is being rated, the chemist, if he is consulted, is asked to determine the flash-point of the oil (minimum  $171^\circ \text{C.}$ ), and the unsaponifiable matter, the risk being considered greater as the percentage rises, the classes being under 30 per cent., above 30 per cent., and below 50 per cent., and above 50 per cent. An undertaking is asked for from the oil merchant or manufacturer supplying the oils, which unless the very highest possible rate is to be charged, disclaims the presence in the oils in question of any linseed, rape, cotton seed oil, &c., &c., not forgetting mineral oil,\* which term dies hard in insurance schedules. As the oil manufacturer, especially if he recovers oil from the cloth manufacturers' waste soap liquor, cannot be supposed to know what oils were originally used, and as in most cases detection of the oils named is almost impossible in such complicated mixtures as black or brown cloth oils, he makes no scruples in signing this undertaking. Indeed, I understand that the unanimity displayed by the oil trade in disclaiming the use of all and sundry oils objected to, and the practical impotence of the insurance companies in the face of this, has led recently to the abandonment of this written undertaking scheme altogether, and the insurance companies rather rely on the price paid for the oil, perhaps rather a more rational proceeding, but still on an essentially wrong principle, as it presumes that an oil that is good from a cloth manufacturers' point of view—scouring properties, &c.—is safe from the insurance standpoint.

Now, instead of getting a supposed character with the oil from the oil manufacturer which is of little value, and a determination of the unsaponifiable which means nothing from the insurance point of view unless perhaps, that an oil, high in unsaponifiable constituents, is in all probability a very safe oil as far as liability to spontaneous combustion is concerned, I have always considered that retaining the flash-point as at present, oils should be tested by some simple and easily applied method to ascertain their liability to spontaneous combustion as compared with some standard oil or mixture of oils (probably a standard mixture of mineral and olive oil would be best) when spread on cotton waste.

I am sorry that I am unable to bring any such apparatus to your notice to night as the result of my work.† But in the course of my experiments I obtained some results which I think open a question that should be dealt with before any fresh regulations are issued.

I was working with cotton seed oil, and in comparing the behaviour of neutral cotton seed oil with that of free fatty acids derived from it, when heated to  $110^\circ$ – $150^\circ \text{C.}$  spread on cotton wool, I found that the cotton wool treated with the free fatty acid, invariably browned much more rapidly than the cotton wool containing the neutral oil.

Examining this further, both in the case of cotton seed and olive oils, I obtained the following results.

I should say that I selected cotton wool for my experiments as being a form in which pure cotton could be readily obtained, and as giving quicker results than cotton waste or cloth.

The experiments were carried on in an ordinary copper water jacketed oven, the water being at boiling point, the cotton wool, about 15 grms., containing 50–60 grms. of oil or fatty acid, being placed in a porcelain basin, a thermometer stuck in the heap, the stem of which protruding through the top opening of the bath allowed the temperature to be read off.

\* No account is taken of the difficulty or rather the impossibility of detecting mineral oil proper in presence of the hydrocarbons formed when an oil is distilled.

† There is an apparatus, "Ordways," in use in America, but it has not been adopted in this country.

## SPONTANEOUS COMBUSTION OF OILS SPREAD ON COTTON.

BY WILLIAM McD. MACKEY.

### PART I.

#### EFFECT OF FREE FATTY ACID.

I HAD hoped to give a paper on this subject later on in the session, but I found that it would be impossible for me to carry the experiments any further in the time at my disposal, and as the experiments done seem to have an important bearing on fire risks in cloth mills where cotton or mixtures containing cotton are used, I think it better at this juncture to give my results in the form of a preliminary note.

About two years ago the insurance companies, or those of them that are known as the tariff offices—being all bound to assess risks according to one code, including nearly all the British offices—is-ued new regulations bearing on the rating of mills, and in this the rating according to the kind

Parallel experiments with the oil and fatty acids derived from the same stock of oil were done in each case.

It should be mentioned that when the fatty acids were used wet, immediately after washing, the neutral oil was also washed before the experiment.

The following short tables give my results.

TABLE I.  
COTTON-SEED OIL ON COTTON WOOL.

Neutral Oil.	Free Fatty Acids.
Time 1½ hours; temp. below 100° C.	Time 1½ hours; temp. 151° C., maximum attained.
" 8½ " " 121° C., maximum attained.	" "

In this and the following experiments the heap attained a maximum temperature and then gradually declined; thus, in the fatty acids experiment the temperature rose to 151° C. in 4½ hours, and in 7 hours had fallen to 130° C. The neutral oil attaining its maximum, 121° C., in 8½ hours, and in 13 hours falling to 113° C.

In neither case did the cotton wool actually fire, though in that of the fatty acids experiment it was very strongly charred.

I cannot say that the oil, though called neutral oil, was really so, as I neglected to test it for acidity; in all probability it contained 1 or 2 per cent. of free fatty acid.

TABLE II.  
OLIVE OIL ON COTTON WOOL.

Neutral Oil.	Free Fatty Acids.
Time 2½ hours; temp. 96·5° C.	Time 2½ hours; temp. 165° C., max.
" 8½ " " 173·0° C., max.	" "

In this case I afterwards found that the oil called here neutral, really contained 8·7 per cent. of free fatty acids, stated as oleic acid.

TABLE III.  
OLIVE OIL (another Sample) ON COTTON WOOL.

Neutral Oil.	Oil containing 50 per Cent. Free Fatty Acids.	100 per Cent. Free Fatty Acids.
Time 3 hours; temp. 100° C.	169° C.	192° C., max.
Time 3½ hours; temp. 103° C.	187° C., max.	" "
Time 6½ hours; temp. 202° C., max.	" "	" "

In these three parallel experiments the neutral oil was absolutely neutral, the small amount of free fatty acid originally present (0·9 per cent.) having been dissolved out with alcohol, the oil being afterwards thoroughly washed with water. That containing the 50 per cent. free fatty acid was made up by adding the calculated amount of free fatty acid (derived from the same stock of oil) to some of the original oil.

TABLE IV.

The following results were obtained with olive oil on pure wool:—

Neutral Oil.	Free Fatty Acids.
Time 4½ hours; temp. 109° C., max.	130° C., max.

The neutral oil was from the same stock as that used in the experiments, results of which are stated in Table II.

The question now arises as to what really takes place in the case of cotton seed or olive oil fatty acids, as compared with the corresponding neutral oils.

From the iodine absorption of the fatty acids we should not expect them to take up oxygen more readily than the neutral oil, and it seems to me that the fatty acids have something akin to a charring action on the cotton wool, that chemical act on takes place between the fatty acid and the cotton with evolution of heat, and that the rise of temperature is not entirely due to the absorption of oxygen, as we may suppose it to be in the case of neutral oil.\*

To throw some light on this point the following parallel experiments were undertaken, slag wool being substituted for cotton wool, as a substance totally unacted on by any weak acid at 100° C.

TABLE V.  
COTTON-SEED OIL ON SLAG WOOL.

Neutral Oil.	Free Fatty Acids.
Time 7 hours; temp. 103° C., max.	105° C., max.

Several more experiments would be required to settle this point, but these two experiments undoubtedly go to show that in the case of an inert body, like slag wool, neutral oil and free fatty acids act much alike.

I tried some further experiments with cotton seed oil and cotton wool, giving both the neutral oil and fatty acids a previous treatment with manganese dioxide.

Thus, 50 grms. neutral cotton-seed oil and 50 grms. fatty acid were treated with 5 grms. manganese dioxide, heated at 105° C. for one hour, spread on cotton wool, and the cotton wool, as before, placed in the water-oven.

TABLE VI.

Neutral Oil.	Free Fatty Acids.
Time 1½ hours; temp. 98° C., .....	192° C., max.
" 2½ " " 192° C., max.	" "

Again, in this case the oil and fatty acids (50 grms.) boiled 10 minutes with 5 grms. manganese dioxide.

TABLE VII.

Neutral Oil.	Free Fatty Acids.
Time 2½ hours; temp. 208° C., .....	265° C. max.
" 3 " " 225° C., max.	(Cotton wool completely charred.)

These results are in the same direction as the others, treatment with manganese dioxide accelerating the process; and I think it or some other "drier" might be used in any standard process in which the behaviour of an oil might be inferred from, say, a 2 hours' test; at the same time, the regulations as to condition of experiment would have to be very strictly laid down and adhered to if comparable results were to be expected, as I found that slight differences in the manganese dioxide treatment have a serious influence on the result.

To return to the question whether the heat evolved is due to absorption of oxygen—a drying action—or partly to that and partly to a more vigorous action of the free fatty acids on the cotton. In connection with this Lavauche found (this Journal 1886, 494) that at the ordinary temperature neutral olive oil treated with finely-divided lead and

\* The oil (originally absolutely neutral) used in experiment I., Table III., afterwards squeezed out of the cotton wool at the end of the experiment, was found to contain 10·23 per cent. of free fatty acid as oleic acid. This might point to the oil becoming acid before the heating becomes pronounced.

spread on a watch glass, in 7 days absorbed 1.7 per cent. oxygen, whilst the free fatty acids similarly treated only absorbed 0.7 per cent. in 8 days.

Again, in the case of cotton-seed oil, the neutral oil absorbed 5.9 per cent. in 2 days, the free fatty acids only 0.8 per cent.

It may be that the higher temperature at which I wrought, and this would particularly apply to the free fatty acids from cotton-seed oil, the fluidity of the acids and the state of fine division on the cotton account for my results.

Yet the results given in Tables IV. and V., particularly the latter, in my opinion point to the cotton itself playing a part in the reaction resulting in the evolution of heat.

But before anything definite can be said much work will be required. Had I had time I should have liked to determine the iodine or bromine absorptions of the neutral oils and free fatty acids before and after the experiments, also the increased acidity, if any, of the product of the neutral oil experiments.

But putting the theory of the reaction aside, it appears to me that the results have some importance as bearing on insurance risks, particularly when we consider that under the present system of rating recovered oils, practically free fatty acids are allowed to be used without any extra rate if they contain below 30 per cent. unsaponifiable matter.

It is a matter of common knowledge that the presence of unsaponifiable matter, at least when consisting of hydrocarbons, has a distinct influence in correcting the tendency of such oils as olive- and cotton-seed oil to induce heating and eventually spontaneous combustion when cotton saturated with them is heaped in a heated atmosphere. Hence I question if the insurance companies act wisely in aiming at the introduction of pure free fatty acids.

There can be no doubt that if the unsaponifiable matter consists of mineral oil it should be of very high flash point, but that can be easily ascertained by a simple and well-understood test.

That the manufacturers of certain classes of goods should prefer to work with oils containing large percentages of unsaponifiable matter, may at first appear strange, but it may be depended on that they know their own business best; and I contend that a flash-point test and a test to determine the tendency of an oil to spontaneous combustion under the conditions obtaining in use, are the points of importance from an insurance point of view. And certainly until some standard test for the latter is adopted, when the chemist is consulted, he should be required to make tests on which to base a rational opinion, and not as at present, asked merely to determine the flash point, and further the unsaponifiable matter in order that the oil in question may be classed for rating but not its safety or the reverse demonstrated.

#### DISCUSSION.

Dr. LEWKOWITZ said that little was known about the chemistry of the oxidation of oils in air, though the matter was of importance from the point of view of insurance risks. The comparative ease with which spontaneous inflammation took place on cotton waste was due doubtless largely to the great surface of oil exposed to the air favouring rapid combination. The fatty acids in the oils oxidise much more readily than glycerin, which, indeed, is little acted on. He compared in this respect oxidised oils to "boiled" oil, which contained very nearly as much glycerin as raw linseed oil.

Mr. H. R. PROCTER referred to Mr. Mackey's observation that the oils containing fatty acid when exposed to air on cotton wool developed a much higher temperature than oils which are free from fatty acid, whereas no such difference was observable when slag wool was used. This seemed to show that the cotton wool took part in the action. He asked whether an unsaponifiable mineral oil of equally high flash-point is so dangerous as an oil which can be saponified.

Mr. G. W. SLATTER said that many manufacturers would not buy oils containing more than a certain percentage of fatty acids, though this was more on account of other

properties than because of their greater liability to spontaneous inflammation. He also suggested that the value of Mr. Mackey's experiments would be greater if by aspirating a slow current of air through the oil soaked wool he approximated more to actual conditions.

Mr. PEMBERTON quoted some observations which seem to show that pure vegetable oils were more liable to spontaneous inflammation than oils containing an admixture of mineral oils. He also said that some oils, partially saponified by treatment with steam, were more easily inflammable than the same oils before steaming.

Mr. HOLBROOK said that the insurance companies had based their scale of charges on the results of a series of experiments made for them on the liability of different oils to take fire spontaneously or otherwise. They believed that the use of cotton seed oil in mills was very dangerous, and would not accept a mill known to make use of this oil.

Mr. BURRELL thought the experiments would be more valuable if oils other than cotton-seed had been more extensively employed as manufacturers did not use that oil owing to the prohibitive nature of the tariff.

It was not correct to say that the oils submitted by the tariff offices were simply tested for their flash-point and percentage of mineral oil. The insurance companies required the oils to be classified and this rendered it necessary to test for the dangerous seed-oils whenever their presence was suspected.

He thought that the use of the apparatus devised by Ordway would be preferable to a water-bath for the conduction of these and similar experiments.

The CHAIRMAN said that from the scientific point of view the investigation of the subject of the spontaneous inflammability of oils did not appear to present serious difficulties, and the most satisfactory plan both for the insurance companies and for mill owners would be doubtless to work out separately the behaviour of each oil in order to have a firm basis of ascertained fact to build upon.

Mr. MACKEY, in reply, said that it was difficult to say whether it was more dangerous to use a mineral oil whose flash point was, say, 350° F., and which was certainly not spontaneously inflammable, but which carried a fire when started very rapidly, or to use vegetable oils with a much higher flash-point (550° F. say) which were liable to spontaneous ignition. Mr. Pemberton's observations on oils which had been steamed agreed with the results of his own experiments, as the steamed oils would contain fatty acids owing to their partial saponification.

MR. R. IRVINE IN THE CHAIR.

### NEW FORM OF LAMP FOR BURNING PARAFFIN OIL WITH A SMOKELESS FLAME, FOR LABORATORY USE.

EXHIBITED BY MR. R. IRVINE.

MR. IRVINE explained that he had endeavoured to construct a lamp, producing a smokeless flame from paraffin oil, which would be adaptable as a "Bunsen" in laboratories where no supply of coal-gas was available. He had obtained some measure of success when he discovered that a lamp answering this purpose, the invention of B. A. Hjorth and Co., was in general use in Sweden and to some extent in this country for cooking purposes.

The patented apparatus which he exhibited has an air-tight reservoir F capable of containing about 2 pints of ordinary paraffin burning oil, and which can be filled at tubulure A. The burner is similar in construction to that of the well-known "showman's naphtha lamp." Directly below the burner is a small cup B, into which spirit of wine is poured. On igniting the spirit the coil of pipe E becomes red hot. By means of the small air-pump D, a few strokes of which is sufficient to compress the air in the upper portion of the reservoir, the oil is forced through the red-hot coil and becomes vaporised. The oil-vapour escapes through a small orifice in the coil and burns with a flame which closely resembles that of the Bunsen burner. The heat of this flame maintains the gasifying temperature in the "retorting" apparatus. Thus, so long as the pressure is maintained and the oil supply lasts, no further addition of spirits of wine is necessary, and the lamp continues to burn with an intense, smokeless, and odourless blue flame.

By turning the screw C, and thus relieving the air-pressure on the surface of the oil, the lamp is extinguished.

The amount of oil consumed during a period of from 20 to 30 hours costs about 1d.

MR. J. GRAY asked what pressure the reservoir of the lamp was guaranteed to stand.

THE CHAIRMAN believed that each lamp-reservoir was tested up to a pressure of 45 lbs. per square inch, but in ordinary circumstances it would be impossible for so small a pump to give a higher pressure than from 10 to 15 lbs. That pressure was amply sufficient to keep the lamp burning without again using the pump for from three to four hours.

MR. J. GRAY saw numerous applications for lamps of the kind. He asked if there was no probability of the gasifying tubes becoming choked with carbon.

THE CHAIRMAN replied that he considered the application of the principle of the lamp to be capable of great practical extension, especially for the purpose of steam-raising. In most oil-burners cold oil was forced into the furnaces by means of a great excess of steam or cold air. Thus the flame was robbed of much heat. With good oil the gasifying tube would not foul to any extent. If the tube choked it could readily be cleaned by means of a wire.

MR. BERRY inquired if there was any chance of "firing back."

THE CHAIRMAN thought not, so long as the pressure was maintained on the surface of the oil.

THE members present then took part in a discussion bearing on subjects referred to by the Chairman in his inaugural address. (This Journal, 1894, 1038—1047.)

The following gentlemen have promised papers:—

Dr. G. Archbold: "Technology of Starch."

Mr. H. Comer: "On Cresote."

Mr. E. N. Dickerson: "The relation of the U.S. Patent Laws, and Decisions thereunder, to American Chemical Industry."

Dr. H. Endemann: "Magnesia as a Waste Product, and its Uses."

Mr. E. E. Luzzwitz: "Commercial Analysis of Whale Oil."

Dr. R. C. Schupphaus:

(1.) "Evolution of Smokeless Powder."

(2.) "Chemical Nature of Celluloid."

*Meeting held at the College of Pharmacy,  
Monday, 5th November 1894.*

### CHAIRMAN'S ADDRESS.

BY ALFRED H. MASON.

GENTLEMEN,—When I yielded to the call to preside at the preliminary meeting held to consider the desirability of forming a New York Section of the Society of Chemical Industry, I did not anticipate its being more than a temporary situation, and was willing to do my utmost to accomplish the object we had in view; but owing more to the generosity of your committee than to any fitness of mine, I have been called upon to fill the position of first chairman of the Section, and I am convinced, from the interest already shown, that in the near future this Section will prove no mean part of the whole.

The formation of this Section creates a new phase in the history of the Society. There are 350 members in the United States and Canada, and we are heartily welcomed by the Council. The President in his annual address says:—

"We are pleased to add the 'Stars and Stripes' to our highly respectable old colours, and to shake hands across the ocean with the great English-speaking race, who 'shall brothers be for n' that.'"

May we not add to this, that we hope the day is not far distant when the shaking will be hand in hand, and the

Annual Meeting of the Society be held on this side of the Atlantic. In this connection the Annual Report says:—

"It is with great pleasure that the Council announces that it has acceded to the request of some of our fellow-workers in the United States to form a Section in New York. This is the first time that such a request has been preferred from abroad, and makes a new stage in the history of the Society, the importance of which cannot be too highly estimated."

We believe there is room for our Society in America. It was founded, not for the benefit of a class, but rather for the purpose of blending together the manufacturing branch on the one hand, and the abstract on the other, and that amongst English-speaking chemists. We have no wish to stand in the way of, or appear as rivals to, any other organisation, but rather as coadjutors with them. The American Chemical Society, with its sections in different parts of the country, has theoretical work to do, just the same as the Chemical Society in London has, and does it; and many members and fellows of both Societies are also members of this Society, recognising that the industrial applications of chemistry have become so numerous that the existence of a separate body to especially consider this branch is desirable. That such a want is filled by this Society, is proved by its remarkable growth.

### *Chemistry and Pharmacy.*

In the sixteenth century, that new race of alchemists, or pyrragists, as they were termed, arose, who, abandoning the search for the philosopher's stone, began to direct their energies to the discovery of chemical remedies for the various diseases of the body. "The true use of Chemistry," says Paracelsus (1493-1541), "is not to make gold, but to prepare medicines." It is not my purpose to call to your minds the various theories which followed this starting point, but it appears to me that I must have been impressed by the statement of Paracelsus, my life having been devoted to the study and practice of pharmaceutical chemistry in all its ramifications, though I have not yet discovered the way to make gold for myself. I make this, however, my apology, if such be needed, for asking your attention first of all to this branch of industrial chemistry.

We are the inheritors of the accidental success of these ancient chemists, and though we have outgrown their system, and have a truer knowledge of the workings of nature, we can get no wider field of aspiration than the health and wealth of mankind. Finding the human constitution much less refractory than that of the metals, the art of the chemist came to be regarded as almost exclusively applicable to the production of various powerful medicinal agents, and the value of his labours in dealing with inanimate nature was for a time almost forgotten. Chemical science, however, is able to provide for the wealth as well as for the health of mankind, and it is most encouraging to see in how many directions the work of this Society reflects the many-sidedness of the science.

There can be no doubt that pharmaceutical progress is chiefly to be won by the assistance of chemistry. The work done in this country is recorded in the several journals and transactions of colleges and societies devoted to the purpose, and we have a right to regard with considerable pride that work as part of the subject we are dealing with.

There are few subjects more interesting, either to the scientific or to the practical chemist, than the active principles of plants. The pharmacologist wants to know from the chemist the construction as well as the composition of the larger molecules; and until the chemist can tell him the exact manner in which such large molecules, as, for instance, morphine and strychnine, are built up, and until the pharmacologist has obtained a wider knowledge of the smaller molecules, he cannot understand the effects of the modification which can be produced in these larger molecules. At present he does not comprehend why substituting a molecule of methyl for one of hydrogen in morphine weakens its sleep-producing and pain-quelling power, whilst the subtraction of a molecule of  $\text{H}_2\text{O}$ , takes both away, and converts it into a powerful emetic; but it is to the chemist he looks to obtain

this knowledge, and with such assistance new and more powerful remedies may be constructed.

The study of the natural alkaloids has not only enriched science with a class of bodies of endless interest and opened out fields of researches of the highest promise, but has been of the greatest practical benefit to the human race. Owing to the great complexity and ready destructibility of these molecules, their synthesis, with few exceptions, appears so far to have eluded research.

Researches in this direction are of the highest theoretical interest, but whether they will ever bear fruit industrially in the production of natural alkaloids is another question. Indirectly such researches have already borne fruit in the discovery of a class of alkaloids not found in nature which possess therapeutic properties more advantageous than natural products. It is to Germany chiefly that we are indebted for these developments, because there so much skilled labour is bestowed upon, and so much encouragement given to, original research. In this country, with its abundant supply of medicinal plants, both native and acclimatised, we naturally look to the chemist for developments in this branch of our art.

The 1880 census gives 592 manufacturing druggists and chemists in this country, 112 of these in New York State, 72 in Pennsylvania. By the enterprise of these establishments pharmaceutical and chemical preparations are manufactured on an enormous scale under the most favourable circumstances, and with such excellent results that the United States takes a leading position amongst the manufacturing chemists of the world.

American pharmacists were the first to manufacture fluid extracts of standard strength, of which one minim represents one grain of the drug. These are now manufactured in many laboratories, and this system has been adopted officially in several other countries. It is not our province to enlarge upon the advantages of this class of preparation, but we may state further that America was the first country to introduce what is known as "elegant pharmacy," by which life is made more pleasant, and nauseous medicines even tempting.

The manufacture of eclectic remedies, resinoids, &c., is also of importance. In a nation noted for its dyspeptics the study of digestive ferments would naturally be one of importance. In the manufacture of pepsin America takes the lead, and there are several manufacturers who have made their reputation in this industry. Another important domestic industry is the manufacture of spread plasters and surgical dressings on scientific principles. Some years ago Colonel Shecht, of the United States army, invented a process which, by the incorporation of india-rubber with inoffensive gums in a plaster mass, produced an article which, when spread upon cloth and perforated, would stick without warming. This was a mechanical plaster, but in 1876 Seabury conceived the idea of incorporating with a rubber combination such standard medicaments as belladonna, opium, aconite, &c., and perfected an industry purely American. Other manufacturers have followed in his track, and a large home and export trade is done. It is computed that at least 20 millions of porous plasters are manufactured annually in the United States and distributed all over the world, in addition to large quantities of spread plaster distributed in rolls. In one factory alone 33,000 pounds of belladonna root, yielding 8,000 pounds alcoholic extract, was employed for this purpose in one year.

In making these plasters Para india-rubber is first soaked and steamed and then passed through spirally corrugated iron rolls under a stream of water until well cleansed. The resulting crinkle sheets are hung up to dry, and then worked to a homogeneous mass on warm, smooth calender mills. The steaming tank, washing mill, grinding calender, and some sheets of worked rubber are shown in Plate 1.

Olibanum is prepared for use by stamping and sifting: Burgundy pitch and other resinous matter, by melting and straining.

The rubber, resins, and other ingredients are worked with the extract to a uniform mass on warm calender mills. No solvent is employed, the force of iron rolls doing the entire work. When thoroughly incorporated, and of just the right temperature, the mass is spread on cloth by means of heavy calenders (Plate 2).

Plate 1.

The cloth, usually about 120 yards long by 1 yard wide, is fed through the calenders, and passing under the lower rolls is connected with a large reel behind the machine. The calenders, being gauged for the right thickness, are started, and the mass fed upon the cloth between guides. After standing a time on the reels, the material is wound up on drums, cut, and finished. Punching machines for perforating the plasters are used.

The great advantages of the rubber combination base are its remarkable keeping qualities and permanent preservation of the incorporated medication as well as lasting flexibility, a great improvement for which mankind is indebted to America.

The exhibits at the Columbian Exposition at Chicago last year show how wide a field is claimed for chemistry and for the chemical industries of this country, and yet

Plate 2.

even the most careful classification cannot include all the directions in which chemistry has found, or will find application.

Even the 23 heads, under which the abstracts of our Journal are divided, do not always include all the subjects which really belong to us, and even in those industries which are now undoubtedly within our field we find not a few branches where as yet chemistry is but imperfectly applied, and where still the empiric stage has hardly yielded to strict science; and other branches where processes really chemical are carried on without even an attempt to bring science to bear upon them. We ought not to rest content till science shall have pervaded every operation where chemical action is involved; and though this may seem to open up an over-wide field, where can we stop short of such a claim?

The census of the United States in 1880 gave 1,349 chemical establishments in operation, that in 1890 gave 1,626 such establishments. I have tabulated statistics of the production of several articles for the sake of comparison, but the report on chemicals, which will form a part of the general report of manufactures, is still in the hands of the printer and will not be available until the completion of the whole report. I, however, sent a list of articles to the Commissioner in Washington, and he courteously complied with my request as best he could; but the classification adopted in the 1890 census is not the same as that of 1880, so it is impossible to compare all the items. However, such statistics as will be published then are also tabulated.

PRODUCTION OF CHEMICALS IN THE UNITED STATES  
ELEVENTH CENSUS, 1880.—1,349 ESTABLISHMENTS IN OPERATION.

Class of Products.	Quantity.	Value.
	Lb.	Dols.
Ammonia (sulphate of) .....	16,575,988	618,485
Alum .....	39,217,725	808,165
Aniline colours .....	80,518	107,292
Anturacene .....	344,114	99,242
Borax .....	3,692,143	277,233
Bromine .....	494,890	114,752
Phosphorus .....	56,292	29,271
Stearic acid candles .....	18,363,066	2,281,609
Oleic acid soap .....	33,058,411	1,707,969
Other hard soaps .....	378,743,627	18,290,350
Soft soaps .....	34,454,100	558,280
Glycerin .....	7,117,825	961,477
Nitro-glycerin .....	3,639,722	1,830,417
Manufactured manures .....	727,453	19,921,400
Dry colours .....	67,482,415	4,088,821
White lead .....	123,477,899	8,770,699
Other salts of lead .....	11,375,466	758,689
Ground barytes .....	19,165	371,829
Zinc oxide .....	29,121,761	766,337
Acetate of lime .....	6,593,069	156,892
Potash and pearlash .....	4,516,671	232,643
Soda .....	40,259,938	866,569
Sulphur .....	1,200,000	21,600
Sulphuric acid .....	308,755,432	3,061,876
Glucose .....	151,740,400	4,551,212
Other products .....	..	44,927,101
Total value of all products .....		117,377,324

The total value of all products in the 1880 census report was 117,007,976 dols., and in the 1890 census report 137,007,976 dols. The total value of chemicals, drugs, and dyes imported in 1890 was 26,817,265.69 dols. free of duty, and 14,607,523.94 dols. dutiable. The comparison can only be made in a few instances.

Some of these, however, were produced by only a few establishments and in limited quantities, the greater portion consumed within the United States being imported; for instance, only one establishment mined and produced sulphur, yielding 1,200,000 lb., while 176,283,000 lb. were imported; three establishments produced 80,518 lb. of aniline colours, while 176,238,600 lb. were imported; one establishment produced 56,292 lb. phosphorus, valued at 29,271 dols., while the importation was valued at 78,253 dols.; three establishments produced 40,259,938 lb. of soda salts, while 360,301,309 lb. were imported; and six establishments produced 39,217,725 lb. alum, while 2,112,570 lb. were imported.

ELEVENTH CENSUS OF THE UNITED STATES.

*Statistics of Manufactures.*

STATEMENT showing QUANTITIES and VALUES of SELECTED PRODUCTS reported by ESTABLISHMENTS engaged in the MANUFACTURE OF CHEMICALS and ALLIED PRODUCTS during the CENSUS YEAR ending May 31, 1890.

Class of Products.	Quantity.	Value.
Alum .....	Lb. 93,998,008	Dols. 1,616,710

\* Establishments engaged in the manufacture of white lead, oxide of lead, and sulphuric acid, report quantities of these articles consumed as intermediate products. In such cases the quantity is included in the total quantity reported; the value of the same is not shown. The quantity of white lead manufactured in this manner was 80,603,330 lb.; of oxide of lead, 312,252 lb.; and of sulphuric acid, 581,536,200 lb.

In the eleventh census the quantity of alum produced had increased to 93,995,008 lb., whilst the total imports of alum and aluminous materials of all kinds was 6,832,025 lb. The production of potash and pearlash increased about 500,000 lb., but the value decreased materially. The production of soda and soda salts was 333,124,357 lb., against 40,257,938 lb. in 1880, whilst the imports were 364,723,196 lb., and the production of sulphuric acid was 956,449,765 lb., against 308,765,432 lb. in 1880.

Total value chemicals, drugs, dyes, &c., 1893 .....		15,768,332*40
Duties .....		4,769,213*84

All the crude materials on this list were used for the manufacture of aniline colours, cream of tartar, tartaric acid, citric acid, resublimed iodine, &c., whilst dutiable goods were required in many instances owing to the manufacture here not having met the demand. For instance, salicylic acid is manufactured in the United States, and probably demands could be met for this; but a certain foreign brand is called for. Although quinine is imported in large quantities, 3,000,000 ozs. are being made annually in this country (three factories being erected for its manufacture, but only two running). Carbonate and sulphate of ammonia are manufactured here. Sulphate of copper is manufactured and exported in large quantities. Glycerin, although imported largely, is produced here in large quantities. Phosphorus is manufactured and consumed in the manufacture of matches, &c., yet we require to import 90,000 lb. more to meet the demand. Morphine is manufactured, but, a special brand being called for, has to be imported.

#### Natural Advantages for Production.

**Coal.**—Among the materials used, fuel is an important item for chemical establishments, and, other things being equal, cheap coal will invariably draw the manufacturing chemist to its neighbourhood. The world's annual output being about 488 million tons, America stands second in the list as a contributor to this enormous output. Pennsylvania yields nearly all the anthracite, the bituminous coal being found in (1) the Triassic fields, (2) the Appalachian fields, (3) the Southern fields, (4) the Central field, (5) the Western field, (6) the Rocky Mountain field, (7) the Pacific fields.

**Coke.**—Pennsylvania is still the chief coke-producing State, contributing 65·8 per cent. of the total, and Alabama second, contributing about 12·2 per cent. In New York State during the past year, 12 hy-product ovens, on the Semet-Solvay principle, have been built at Syracuse, N.Y., and treated Pennsylvania coal. The operation of these has been highly successful. Coals, that have not been regarded as very high grade coking coals, have been used with most gratifying results. The yield of coal in coke was 84·18 per cent., including not only large coke, but "breeze" as well.

**Petroleum.**—While petroleum has been found in every State and territory, the localities in which it has been obtained in paying quantities are few. Practically, all the petroleum produced in the United States is from four districts: the Appalachian; the Limestone, or Ohio, Indiana; the Florence, of Colorado; and Southern California fields.

The world's production for 1893 was, approximately, 84,330,809 barrels (of 42 galls. each); of this, the United States produced 48,412,666 barrels, or 57 per cent.

During the year 1883 most of the illuminating oil used in the United States was produced from the limestone oil of Lima and Indiana, 1893 having marked the era of complete success in refining these oils.

**Natural Gas.**—Petroleum and natural gas have a common origin, and are both members of that wonderful series of chemical compounds known as paraffins, of which paraffin wax may be regarded as a representative of the solid portion of the series; petroleum, the liquid portion; and natural gas as the best known gaseous member. This gas is fuel of high value, and was largely utilised for industrial and domestic purposes at such great industrial centres as Pittsburg. One million cubic feet of gas are said to do the same amount of heating as about 60 tons of anthracite coal; but in Pittsburg to-day the price charged for natural gas to manufacturers is such that, ignoring the cost of plant, producer-gas can be supplied to these works

\* Including building sand, glass sand, limestone used as flux in lead-smelting, limestone in glass-making, iron ore used as flux in lead-smelting, tin ore, iridosmine, nitrate of soda, carbonate of soda, sulphate of soda, bauxite, and alum clays used by paper manufacturers.

as cheaply. In Pennsylvania natural gas first began to be used extensively as a domestic and industrial fuel.

Two hundred and eighteen companies for the production of natural gas reported to Washington, in 1893, the following numbers of producing wells owned by them. In Pennsylvania there were 841; in Indiana, 498; Ohio, 207; and these appear to be increasing. Natural gas for fuel purposes is used very largely in the western resident portion of Buffalo, and extensive additions are nearly completed for supplying a wide area on the east side. The sources of supply are the wells of Pennsylvania, Canada, and many small outlying districts east of Buffalo—a great factor in the reduction of consumption of coal in the district.

**Asphaltum.**—Deposits of asphalt are widely scattered over the United States, principally south of latitude 40°. The importations from the West Indies, North Coast of South America, and Europe, amounted to 74,774 short tons from Trinidad and 65,420 tons from Beyrout, value 21,207.44 dols. in 1893.

The commercial applications of asphalt in this country are for roadways, walks, roofs, and floors in the form of compressed asphalt and mastic, and for varnish and paints, waterproofing compositions, roofing felts, insulators, bituminous masonry, and concrete.

Professor Sadtler, of Philadelphia, has been studying the matter of asphalt paving composition, and the results of his experiments will be found in the journal "Paving and Municipal Engineering," Vol VII., September 1894. He concludes that better, stronger, and probably more durable paving composition, can be made from oil residuum.

**Ozokerite.**—In 1889, 75,000 lb. of crude ozokerite were produced, and the product of 1891 probably exceeded 300,000 lb. Petrolatum is an article largely exported.

**Sulphur.**—The total product of sulphur in 1893 was all mined by the Utah Sulphur Company at Black Rock, Utah, 105,529.00 long tons of crude sulphur, 41.00 of refined sulphur, and 721,699 tons of sulphur ore were entered for consumption during 1893.

**Pyrites.**—The quantity of pyrites mined in 1893 was 83,776 long tons, but the quantity used for acid-making was only 75,777, being less than any year since 1888. The product was entirely from Massachusetts and Virginia. An experimental enquiry by Mr. T. S. Gladding, into the reliability of the various methods of estimating sulphur in pyrites, is published in the "Scientific American," October 1894.

**Sulphuric Acid.**—The relative merits of sulphur and pyrites as raw materials for the manufacture of sulphuric acid have been considerably discussed. American writers have attributed the larger use of brimstone in this country principally to the outlay necessary to make the changes in furnaces, which manufacturers hesitated to incur.

Mr. Karl F. Stahl claims that, "besides the somewhat more complicated and more costly construction of furnaces, and the constant higher cost of labour in burning pyrites, there are other factors in favour of brimstone:—(1.) It requires less chamber space to produce the same amount of acid. (2.) Lead chambers are said to last longer with brimstone than with pyrites. (3.) The acid produced is of different quality."

The first proposition is doubtless true. In regard to the second, Mr. Stahl admits that it is difficult to get exact data, and states that while the higher temperature of the gases (and not the arsenic in the pyrites, as is claimed by some) is detrimental to the lead, this could be avoided by proper construction so as to cool the gases before entering the first chamber.

Mr. Stahl gives the following estimate for the relative cost of acids from brimstone and pyrites.

#### Cost of Chamber Acid from Brimstone.

	Dols.
2½ tons brimstone (5,600 lb.) at 21 dols. per ton.....	52.50
225 lb. nitre (= 4 per cent. of the brimstone) at 4.50 2 cents per lb.	4.50
220 lb. sulphuric acid, 60° B., at 40 cents per 100 lb. . .	0.88

Four men at 1.50 dols. (two firemen for boilers included).	6.00
Wear and tear on building, furnace, chambers, &c., 40 cents per ton chamber acid produced.	5.40
Repairs on buildings, furnace, chambers, &c., 20 cents per ton chamber acid produced.	2.70
Fuel, lights, &c. ....	2.00
Office expenses.....	5.00
Interest on capital invested.....	5.00
Product:—134 tons (2,904 lb. each) .....	83.98

One ton chamber acid, 50° B., cost 6.25 dols.

#### Cost of Chamber Acid from Pyrites.

	Dols.
5½ tons pyrites (= 12,324 lb., 37 available sulphur, at 4.00 dols.)	33.00
180 lb. nitre (= 4 per cent. of the available sulphur) at 2 cents per lb.	3.60
220 lb. of sulphuric acid, 60° B., at 40 cents per 100 lb.	1.00
Breaking of the pyrites, and removing the residue ..	1.00
Six men at 1.50 dols. (two firemen included for boilers).	9.00
Wear and tear on buildings, furnaces, chambers, &c., 50 cents per ton chamber acid produced.	5.50
Repairs on buildings, furnaces, chambers, &c., 25 cents per lb. chamber acid produced.	2.75
Fuel, light, &c. ....	2.00
Office expenses.....	5.00
Interest on capital invested.....	5.50
Product:—11 tons (2,000 lb. each) = 22,000 lb., cost ..	68.75

One ton chamber acid, 50° B., cost 6.25 dols.

From this table it will be seen that pyrites is taken as costing 6.00 dols. the long ton, and the cost of acid made from it is 3 cents more per ton than from brimstone. But the price of pyrites is too high, the average price for 1893 being 3.50 dols. per long ton, and a fair average for the past three years would not be more than 3.00 dols. per ton; and with the pyrites at 3.50 dols. per ton, the cost of acid would be 5.00 dols. instead of 6.25 dols. per ton.

With the United States almost entirely dependent upon Sicily for her supply of brimstone, there seems to be little reason why our pyrites deposits should not be made the source of supply for commercial acid, which can be made as well and cheaply in the United States as anywhere, the conditions being the same, though labour is 50 to 100 per cent. more than in foreign countries, and almost exactly 100 per cent. more than was paid 48 years ago.

Canadian competition is a matter of some importance; the Canadians manufacture more than they can use, and sell the balance in our market at an advantage which manufacturers here cannot compete with, owing to their protective rate of ½ cent per lb.

Sulphuric acid is largely manufactured in this country at different factories in the east, especially the petroleum refineries and the fertiliser factories, where they have plant for the purpose.

**Salt.**—The salt product of the United States in 1893 was as follows:—

Table salt .....	1,021,203
Pure .....	767,374
Common, fine.....	5,475,054
" coarse.....	443,498
Packets .....	95,557
Solar .....	2,110,287
Rock .....	1,884,145
Milliner .....	5,141
Agricultural.....	6,413
Total value.....	4,051,658 dols.

It is produced in Michigan, New York, Ohio, West Virginia, Louisiana, California, Utah, Nevada, Kansas, Illinois, Virginia, Pennsylvania, Texas, &c.

American salt has been so improved by new processes, which each producer holds secret, that importation of refined salt has almost ceased. Table and dairy salts are now prepared practically chemically pure, free from gypsum, calcium chloride, and magnesium salts. The elimination of these impurities has been attempted for years, but only recently accomplished at a paying cost. The value

of imported salt entered for consumption in 1893 was 705,141.07 dols., the amount of duty paid 301,972.60 dols., the quantity of salt withdrawn from warehouse for curing fish 93,937,304 lb.

**Natural Sodium Salts.**—The geographical occurrence of natural carbonate of soda in the the United States is principally confined to the arid regions of the Great Basin, especially to the Soda Lakes, at Ragtown, Nevada; Mounslake, Mono County; Owens Lake, Inyo County; California and Albert Lake, Oregon; and to the many dry deposits and incrustations in the same regions.

These lakes are for the most part residues left by the evaporation of larger bodies of water, the shore lines of which can be traced at considerable distances, sometimes several hundred feet above the present desert. This concentration has increased the proportion of their mineral salts, and sometimes this concentration reaches the crystallising point, when the sodium carbonate appears as a white incrustation on the shores of the lakes.

The production of natural carbonate of soda in 1893 amounted to about 3,100 tons, of which one-fifth was soda ash and crystal carbonate.

The Wyoming sulphate has received new attention in the last two years. In 1892, 1,670 tons of *salt cake* were shipped from the Laramie works. Improvements were being made in the works in 1893, and new plants for producing the carbonate were erected in other places in Wyoming during the year. These causes interfered with the production of both salts.

**Natural Borax.**—The waters of the soda lakes also contain small quantities of sodium borate, which the volcanic neighbourhood easily accounts for.

In various places in the arid regions of California, Nevada, and further north, even in Eastern Washington, which form the volcanic belt, there are deposits of borax and borate of lime, which have been worked more or less successfully. The origin of the soda and the lime is to be ascribed to the feldspars of the volcanic rocks, which furnished those bases for the boracic acid which was supplied by the volcanic emanations. Some springs in the volcanic belt still contain traces of boracic acid. The borates formed in this way were concentrated in lakes or ponds in the same way as the carbonates until crystallisation took place. The present bed is former lake or pond deposits of this kind.

In 1892, 12,538,196 lb. of borax was produced; in 1893, 8,699,000. The falling off in 1893 was due to the dulness of trade. The average value from 1889 to 1894 has been 7½ cents per lb. At the time of the discovery of borax in California the price was 32 cents per lb. 543,967 lb. crude borates, 11,230 lb. refined borax, and 771,775 boracic acid for potters' use, were entered for consumption from bond in 1893, paying 53,469.26 dols. duty. Over 21,000 tons of borax are used annually, about one-third of which is produced in the United States.

The Occidental Alkali Company's property consists of a dry deposit of soda, about 800 acres in extent, situated at the Douth Springs, about four miles from the Carson and Colorado R.R., at Troua Station.

The deposit varies in depth from 5 in. 15 in. 18 in., and consists of sesquicarbonate of soda with some sulphate and chloride; its average composition is as follows:—

Na <sub>2</sub> CO <sub>3</sub> .....	39
NaHCO <sub>3</sub> .....	30
Na <sub>2</sub> SO <sub>4</sub> .....	15
NaCl.....	10
Insoluble (sand, &c.).....	10
Moisture.....	5
	109

The proportions vary slightly in different portions of the deposit, some parts yielding as high as 95 per cent. of carbonate and bicarbonate. When the surface deposit is removed, it renews itself, coming up at the rate of 1 in. per annum, and is practically inexhaustible.

The process of manufacture is as follows:—

1st. The crude soda is shovelled up in win rows, being allowed to stand some time. The rains dissolve the sulphate, raising the content of carbonate and bicarbonate.

2nd. The crude soda is hauled to works, where it is thrown into shallow wooden vats. Hot water is run in, and the whole mass stirred up, making a solution of 22° to 24° Baumé as it leaves the dissolver. The major portion of sand remains in the dissolver while the solution is run into a settling vat, where it is allowed to stand until clear. It is then drawn into ground vats, 200 feet square (which are dug in a peculiar impervious volcanic mud), during spring and early summer, until a depth of 18 to 24 inches is reached. As the season advances evaporation takes place, bringing the density of the solution up to 29° Baumé, when soda is precipitated in form of sesquicarbonate, or urao. (A mixture of carbonate and bicarbonate.) The soda thus precipitated is in the form of a hard cake, from 1 in. to 6 in. thick. When the bulk is precipitated, the solution is drawn off, and the cake taken out and piled up to dry. In this form it is used in the manufacture of borax from borate of lime, the excess CO<sub>2</sub> present being valuable as a precipitant for the lime of the borate of lime.

By heating to 150° or above, the moisture and free carbonic acid are given off, leaving a normal carbonate of soda or soda ash, often as high as 97, 98, and 99 per cent. Na<sub>2</sub>CO<sub>3</sub>.

After the crop of summer soda or urao is taken up, the solution is run back into the ground vat, care being taken to keep the density below 34°. As the season advances a crop of soda, low in carbonate and bicarbonate and high in sulphate, is thrown down. The solution is then weakened down to 25° to 26° B., at which point it is kept until frost occurs, when the entire contents as carbonate and bicarbonate, together with whatever sulphate is left, is thrown down as cold-weather soda, or hydrated carbonate, leaving chloride in solution. This salt solution is then run to waste (or into a separate vat, to precipitate salt for the following season) and the crop of cold-weather soda is taken out and piled up in the open air until warm weather approaches. It is then broken down and spread upon flat forms to dry, giving an effloresced soda (or crystal-carbonate so-called) which is very much liked by soap manufacturers for crutching, and by makers of washing powders, and is quite saleable as a substitute for common sal soda.

**Columbus Borax Company, Calville, Nev.,** manufacture principally concentrated borax and also boracic acid. They produced from 1887 to July 1893 about 50 tons concentrated borax per month, and since January 1894, about 30 tons monthly. Without Chinese labour they would have to shut down, prices being unremunerative.

**Phosphate Rock** is found in Florida and South Carolina. Phosphate nodules are found in Tennessee. Phosphate rock, containing about 50 per cent. of bone phosphate, is found at Castle Hayne, North Carolina.

**Fluorspar** is produced only in one locality in the United States, near Roseclare, Illinois. The product in 1893 was 12,400 short tons, valued at 84,000 dols. In addition to its use for metallurgical purposes, fluorspar is consumed in the manufacture of glass and of hydrofluoric acid.

**Aluminium.**—Practically the aluminium in the world is now in the hands of two large concerns, one being the Pittsburgh Reduction Company, now manufacturing at New Kensington with the advantage of cheap coal in the Pittsburgh seam (costing only about one half dollar per ton delivered at the works), and using compound engines and best forms of dynamos, pumping water from the Alleghany River, with works situated on their own property in the country. They are thus in a position to generate power as cheaply as possible with steam. They, however, expect to manufacture the metal at Niagara Falls with cheaper power. They have their own works there already completed, which will be in operation as soon as the Niagara Falls Power Company have their plant completed. The other company is the Aluminium Industrie Actien Gesellschaft, manufacturing at the falls on the Rhine at Switzerland, and making several tons of aluminium per day.

**Bauxite** is an ore which furnishes more and more of the raw material from which aluminium may be manufactured, and this is procured in Georgia and Alabama. The Arkansas bauxite deposits will probably be developed in 1894 for making alum.

The purity of commercial aluminium sold by the Pittsburg Reduction Company varies from 91 to 99.75 per cent. Of the output, a small proportion was in the form of aluminium alloys, especially bronze, but a large proportion of the bronze found in commerce is made from metallic aluminium previously obtained. The greater part of the product was used as an addition to steel. Nearly all the steel makers use a small proportion of aluminium, with the result of less waste in castings. For example, the amount of waste in crop ends of steel rails is lessened profitably. Ingot aluminium also is used for the manufacture of aluminium cooking utensils and novelties, and this industry is extending satisfactorily. The remainder of the product goes out as sheet and wire for many purposes, including printing from aluminium plates instead of zinc or stone.

**Copper.**—In addition to the product of American ores in 1893, 7,723,387 lb. were produced from imported pyrites. The exports of ore and matte, 835 cwt. 40 lb.; of pigs, bars, sheet, and old metal, 138,984,128 lb. Imports of fine copper in ore, 7,256,015 lb.; regulus and black copper, 3,175,559 lb. Sulphate of copper is largely manufactured in the United States, and is used for all technical purposes, for sprinkling vineyards, &c. The production is greater than the demand for domestic use, therefore large quantities are exported.

**Lead.**—American mines produced 356,781,000 lbs. pig lead, and 3,392,502 lb. were imported.

#### Paints.—

	Tons.	Lb.
The production of White lead .....	72,172	Import 686,400
" Red lead.....	6,122	" 854,982
" Litharge.....	11,077	" 42,582
" Orange mineral ....	257	
" Zinc white.....	24,059	
" Ultramarine .....	113,647	

**Bromine** is manufactured from the mother liquors of salt works, as obtained in Western Pennsylvania, West Virginia, the Ohio, and Kanawaba Valleys. Bromide of potassium is largely manufactured for consumption in this country, and for export.

**Acetate of Lime.**—Acetate of lime and its associate product, methyl alcohol, is manufactured on a large scale. Two qualities of acetate are produced, known as "brown" and "grey," the production of the latter forming about one-fifth of the total. In 1880, 35 firms were engaged in this manufacture, producing 550 tons of acetate and 600 barrels spirit per month. The manufacture is now in the hands of a syndicate, with an invested capital of about 4,000,000 dolrs., and the output is about 2,000,000 galls. wood alcohol and 20,000 tons acetate lime per annum.

In this connection, the manufacture of acetic acid may be mentioned, also the manufacture of chloroform from acetone and ketones, a purely American industry. The probable output is 300,000 to 325,000 lb. per annum.

**Coal-Tar Products.**—In 1883 there were nine different plants employed in the manufacture of coal-tar dyes, when protection made the production remunerative, but it is not probable that so many exist now, protection having been modified and the crude material having to be imported. The principal cause for non-development is as with many other industries—

- 1st. High wages.
- 2nd. Great first cost of plant and larger annual cost of wear and tear.
- 3rd. High cost of coal-tar preparations and other chemicals and materials.
- 4th. High tax on alcohol for industrial purposes.

Aniline oil, crude and distilled liquid carbolic acid, all kinds of aniline colours, coal-tar, pitch, creosote, dead oil, benzol, toluol, solvent naphtha, nitrobenzol, naphthalene, Turkey-red oils, &c. are manufactured.

**Ammonia.**—Sulphate of ammonia is obtained in this country from the ammoniacal liquor of gasworks and the bone liquor of bone works. The production of gas-liquor has steadily decreased for the past 10 years, owing to less coal-gas being required, until the quantity now is very insignificant. The sulphate of ammonia made by bone coal manufacturers is of inferior quality, fit only for fertilising purposes, and the entire product is small. The domestic production of carbonate of ammonia is only about one half of the total consumption. Anhydrous ammonia and *Liquor ammonia*, employed in the manufacture of artificial ice and the production of cold storage, are also largely manufactured.

**Fertilisers.**—The exhaustion of the soil in the eastern, middle, and southern States, has created a large demand for manufactured manures, particularly in the cotton and tobacco-producing sections, and their manufacture has increased to such an enormous extent, that the production of fertilisers has become one of the greatest industries in the United States, particularly in those districts where mineral phosphates are produced. The raw material commonly employed in the manufacture of commercial fertilisers are bone phosphate, rock, cotton-seed meal, blood, fish, tankage, sulphate of ammonia, nitrate of soda, chloride of potassium, sulphate of potash, and kainit and such materials.

The quantity produced in 1890, from different sources, was 1,897,806 tons.

The agriculture of every State in the union is watched by bands of trained scientific men, who take special interest in the State in which they are located. By Federal Acts of 1862 and 1890 large grants of land and money are made for the support and maintenance of at least one agricultural college in every State. The Central Office of the Experiment Stations is at Washington, with Dr. H. M. Wiley at its head.

From this body is organised the Association of Official Agricultural Chemists, formed "to insure uniformity and accuracy of the methods, results, and modes of statement of analysis of the materials connected with the agricultural industry." They report upon the chemical composition and physical properties of cereals, the principles and methods of soil analyses, and the capabilities of such soils, methods of analyses of commercial fertilisers, cattle foods, and dairy products, sugar and fermented liquors, fruit juices, alcoholic beverages, &c., and also inquire into the extent and character of food adulterations, &c.

As an example of the work done in one of the States alone, Georgia, under the charge of Dr. Geo. F. Payne, State Chemist, 1,375 official analyses were made during the season 1893-4, comprising 723 brands of fertilisers sold in the territory, and representing an output of 315,612 00 tons, the increase being very considerable since the organisation of the department in 1874-5, when 110 samples were analysed, representing an output of 48,648 00 tons. The bulletins published in these departments are of great value and interest.

**Glycerin.**—In 1848 the output of glycerin manufactured in America was 15 lb., which was manufactured by Shoemaker from lead plaster; in 1850 the output had gone up to 150 lb.; in 1865 the value of nitro-glycerin as a bleaching agent became recognised, and in 1867 it was largely employed in the manufacture of dynamite.

The glycerin used for this purpose is obtained from the candle factories and soap lyes, and the estimated quantity thus obtained is 8,000,000 lb. per annum.

The demand for refined glycerin, however, increased so fast, that in 1874 there was not sufficient to meet the demand, so that supplies of crude material suitable for refining had to be imported from Europe, and in that year 576,574 lb. of crude glycerin was imported, and the demand has increased so rapidly that, in 1893, 16,440,213 lb. were imported, all used in the manufacture of refined glycerin.

**Potash.**—The manufacture of potash and pearlash has been carried on for a long time by the leaching of wood ashes, the only source of these salts in the United States. The production has decreased materially owing to the

scarcity of wood, and although there is still a demand for it, it has to a great extent been replaced by soda.

*Bichromate of Potash*, was one of the first chemical salts manufactured in this country owing to the discovery of extensive chrome ore deposits in Maryland, from which source the greater part was obtained until the discovery of ore in California. The production in 1880 was 4,000 lb.

*Prussiate of Potash* has been manufactured for 50 years. In 1843, 69,470 lb.; in 1893, 646,226 lb. of red prussiate was manufactured, the raw material being crude carbonate of potash, produced in this country from wood ashes and waste, horns, leather, scraps, &c.

*Soda*.—The production of soda according to the census report of 1880 was 40,259,938 pounds or about 10 per cent. of the quantity consumed. The total production, according to the eleventh census report, 1890, was 333,124,357 pounds. The Solvay Process Co., Syracuse, N.Y., manufacture soda ash by the Solvay or ammonia process. In addition to soda ash they produce caustic soda and bi-carbonate of soda, and recently a more concentrated form of soda crystals. They have also lately put upon the market a crown filler, for paper-makers' use, for which the demand is rapidly increasing. Their output of soda-ash represents 100,000 tons this year, of which they will probably consume one half in their own works. The total quantity of soda ash produced in this country would not exceed 67,000 tons. The quantity of bicarbonate of soda produced in 1890 is estimated at 40,000 tons; the present production is estimated at between 50,000 and 60,000 tons. The salt used by the Solvay Process Co., is obtained from the rock salt deposits just south of Syracuse, and their coal from the Pennsylvania coal-fields. The Pennsylvania Salt Manufacturing Co., Natrona, Pa., manufacture sal soda, bicarbonate of soda, caustic soda, refined sulphate of soda, sulphuric acid, sulphate of copper, caustic potash, alum, copperas, chloride of calcium, nitric and hydrochloric acids, common salt, potassium sulphate, sulphate of alumina, &c. They are also large importers of cryolite. Natrona is reported to be the only factory in the United States which utilises all its materials in the most rational manner.

*Electrolytic Alkali*.—Should success follow the working of the "Castner" process to electrolyse sodium chloride for the preparation of caustic soda and chlorine, it is probable that the manufacture will be carried on an extensive scale in this country. So far electrolytic processes have not proved a commercial success.

### *The Power of Niagara.*

As power is an important factor in manufactures, especially since the electrolytic methods are coming into use, the idea of the Cataract Construction Company, through one of its subordinate organisations, Niagara Falls Power Company, for generating cheap power will undoubtedly develop many lines of work in the future, and may be of interest.

The water surface of the Great Lakes (except Lake Ontario) is 84,000 square miles. Their water-shed covers 240,000 square miles, or more than twice the area of Great Britain and Ireland. Length of shore lines, 5,000 miles; volume of water, 6,000 cubic miles, of which Lake Superior contains a little less than one half; and rate of out-flow at Buffalo, 217,000 to 275,000 cubic feet per second. Niagara Falls are 23 miles below Lake Erie, and 14½ miles above Lake Ontario. The drop is 165 ft., and the depth of water just below the falls, 189 ft. The volume of water in the lakes is such that it has been estimated that even if no rain fell, the flow of the river would be continuous at its present rate for 100 years if the lakes could be gradually drained. Such is the never failing reservoir from which the Niagara Falls Power Company proposes to draw its supply. The company has acquired 1,600 acres of land stretching to a point five miles easterly and three miles northerly from the Falls. Of this 1,071 acres are intended to be devoted for mill sites for manufactories.

Total water power of the Falls is 7,000,000 horse-power, of which it is proposed to use 125,000 horse-power.

*The Canal*.—The main canal is protected against floating ice by having its entrance directed down stream, and by a floating boom fastened to the iron piers at its mouth. The canal is 1,300 ft. long, 100 to 130 ft. wide, and the depth of water will average 12 ft. The greatest velocity in the canal will be 4.17 ft. per second when a sufficient amount is being fed to the tributaries to produce 100,000 horse-power. From this inlet canal the water is led through steel penstocks to the turbines and is discharged into a channel at the bottom of the wheel pit, from which it flows into the main tunnel and is returned to the Niagara River at the portal just below the upper Suspension Bridge. The wheel-pit (cut into the solid rock) is 178 feet deep, 21 feet wide, and at present 140 feet long. When it is continued to its full length as planned it will provide for 10 inlets and be about 400 feet long. The tunnel is lined throughout with vitrified brick, a total of over 13,000,000 being used in the construction. Three turbines of 5,000 horse-power each are already in position, and the dynamos are nearly ready to be placed. The tunnel is 7,250 feet long, 14 to 18 feet wide, and 21 feet high. The grade is 36 feet to the mile, and the tunnel passes 200 feet under the city of Niagara Falls.

The work of construction was commenced by Rogers and Clement of New York, the contractors, October 4th, 1890.

The company has entered into contracts with the Pittsburg Reduction Co., to secure 6,000 electrical horse-power for the manufacture of aluminium, and more recently a contract for 10,000 electrical horse-power has been entered into with Carborundum Co. for the manufacture of the new abrasive material—carborundum. The hydraulic power is already applied to the works of the Niagara Falls Paper Co., who grind between 40 and 50 tons of wood pulp per day, but the mechanical and electrical equipments of the plant are not yet in readiness for distribution of power. The works of the Pittsburg Reduction Co. are, however, nearly completed, and the foundation is now being laid for the Carborundum works.

*Other manufactures*.—There are 13 establishments in the United States, manufacturing bone black, animal charcoal, and ivory black, with an invested capital of 6,000,000 dol.

It is not to be expected that I could complete the list of chemical industries in this address, but I simply give some idea of what is being done in certain directions. Such manufactures as starch, sugar, glucose, dextrine, alcohol, &c., are produced in enormous quantities in several factories. Soaps of all kinds are manufactured largely for various uses, domestic and technical, and also exported in large quantities. Some of the factories are equipped with more modern appliances than any in the world. Other industries are the distillation of essential oils and the manufacture of synthetical odours, dyes, paints, colours, varnishes, cotton seed oil, linseed oil, glue, gelatin, and even the rare earths, lanthanum, neodymium, praseodymium, zirconium, cerium, and thorium (by the Welsbach Chemical Co., Gloucester, New York), the manufacture of ceramics, building bricks, pottery, terra cotta, &c., for which we have a high reputation.

### GLASS-MAKING INDUSTRY.

In the "Engineering Magazine," March, 1893, there is a most interesting and historical article by Mr. R. M. Atwater, on the glass-making industry in America. The manufacture of glass bottles, chemical ware, window glass, polished plate glass, pressed glass and coloured glass, is described. He writes:—"The flint glass business now centres in the United States Glass Co. of Pittsburg for table ware, and the works of Whithal Tatum and Co. of New Jersey for druggists, and chemists' ware. To the same department belongs pressed glass; and although a very old process, to American glass makers is due its practical and enormous development during the last 20 years. The glass press is a finely designed machine, and by it the cost of table ware is greatly reduced and the variety of shapes infinitely increased. The moulds that produce these shapes are of great cost and variety. The art has been copied by the foreigners and the best forms of the American moulds and presses are to be found in England and Germany, and their products are a close imitation of our best lines."

The making of chemical glassware in America was a direct result of the Philadelphia Exhibition of 1876. This glass is a triple silicate of potash, soda and lime, and also contains alumina. This last gives it a dull appearance, but adds greatly to its refractory character. Up to this time, the making of chemical glassware in America has not attained the high Bohemian or German standard, though America is probably the best market in the world for chemical glassware. In the development of low cost, in making metallic aluminium, it is possible that a glass may be produced that will have the flexible character of mica with the refractory nature of the best Bohemian glass. The making of polished plate glass in America was first successfully established by Captain John B. Ford, of the Pittsburgh Plate Glass Co. His early work resulted in failure and a considerable loss of fortune, but not daunted in 1883, he put new works in operation at Creighton, Pa., which were successful from the start. The fortunate discovery of natural gas in the vicinity of the works led to a profitable and growing business, which now forms the largest plate glass works in America and produces nearly half of the total American product. Their capacity is 340 pots, producing 200 sq. ft. of polished plate glass daily. The quality is fully equal to the French standard, and foreign plate glass is now practically out of the American market.

Mr. Thomas Gaffield, of Boston, discovered the first effect of sunlight on the colour of window glass. It is, perhaps, the only American contribution to the physics of glass that has taken rank with the best European work. Mr. Gaffield based his conclusions on the results of experiments carried over a period of five years, the practical result of which was to demonstrate that the only way to obtain permanent colourless window glass was to make it from the purest materials.

Before closing, I wish to call your attention to the subject of:—

**Alcohol.**—Alcohol is the chief raw material used in the manufacture of expensive chemicals, and is taxed at about ten times its cost of production. If that part of it which is actually decomposed in the manufacturing processes were exempted from taxation, this nation would make from it chloroform, ether, &c., at as low a cost as other nations, and their use as solvents would be as much increased as that of alcohol itself. To the manufacturing chemist alcohol is as essential as iron is to other branches of industry. Untaxed alcohol would sell at from 26 to 30 cents per gallon. At present it sells at about \$2.00 per gallon. The quantity of alcohol consumed for medical and manufacturing purposes and in the arts is very large, and, as a consequence, the tax paid is enormous.

This condition of affairs may appear strange in a country where there is a law which prescribes that:

"Any manufacturer finding it necessary to use alcohol in the arts, or in any medical or other like compound, may use the same under regulations to be presented by the Secretary of the Treasury, &c., and shall be entitled to receive from the Secretary of the Treasury of the United States a rebate of tax so paid."

The fact that the Secretary of the Treasury has declined to formulate the necessary regulations before Congress meets, and that there is a general feeling that when Congress does meet the law will be annulled, is my reason for bringing this subject before your notice. I suggest, for your consideration, whether we as manufacturers can, by any united action, take means to enforce the fulfilment of the law or any modification of it such as the duty of 50 per cent. per gallon, and by such a compromise satisfy the Secretary of Treasury.

Professor H. L. Wilson, member of Congress for West Virginia, in addressing the London Chamber of Commerce in August last, said: "The manufacturing supremacy of the world must eventually pass to that people and that country which has the largest basic materials of industry and the readiest and cheapest access to them, and which brings to their development the highest intelligence, the freshest results of art, science, and invention, and the best business methods to their production and distribution. It is because we are more and more confident as each year passes in the exhaustless supply of those materials, in our

cheapness of access to them and our ease of transporting them to the markets, and in our growing control of those labour-saving appliances which the world to-day is inventing and seeking to use, that we believe that the supremacy must some day or other pass to the United States of America."

As far as chemical industries are concerned, before this can be accomplished something has to be done. Quite recently a serious depression has been hanging over the country and commerce has been almost at a standstill, caused by the want of confidence in the stability of the laws, newspaper exaggeration of the instabilities, and above all the influence of partisan politics in congress. We want cheaper real estate, cheaper cost of plant, free coal, and free alcohol, as we stand to-day; or we want absolute protection for every existing industry, every man on equal footing, no trusts, and such protection guaranteed for a series of years (say ten years) sure, so that ample provision can be made for the requirements of the people by home manufactures and industries. If this should fail, then free trade and fair trade.

America in competition with the world could hold her own and more, first providing for domestic consumption at reasonable prices and then for foreign requirements; for as the population of the world increases, the increased demand for manufactured products will follow. Nature herself provides advantageous resources in every country for the development of natural industries, and by the free exchanges of commodities all should be benefited and the common brotherhood of mankind cemented.

I am indebted to Drs. F. P. Van Dunberg, Geo. F. Payne, W. P. Sadtler, Hugo Schweitzer, and to Messrs. S. A. Knapp, Seward W. Williams, W. M. J. Gordon, F. Schoellkopf, Chas. Pfizer, and others. Also to the census officials at Washington, United States Geological Survey, statistics compiled from the mineral resources of the United States, 1893, revenue returns, 1893, and to the Journal of the Society of Chemical Industry, the Chemist and Druggist, the Oil, Paint, and Drug Reporter, Scientific American, Engineer's Magazine, &c., and I desire to acknowledge the extreme courtesy with which my enquiries have been met.

---

*Meeting held Monday, December 6th, 1894.*

---

MR. A. H. MASON IN THE CHAIR.

---

Mr. Ungerer read a paper on "Modern Perfumery," in which he mentioned the various organic substances used in this branch of chemical industry.

---

## AN APPARATUS FOR EXTRACTION.

BY CHAS. E. PARKER.

THE method of the immiscible solvents for the separation of alkaloids and other substances having proved itself a useful expedient for the purposes of proximate organic analysis, particularly pharmaceutical assaying, the frequent attention required in using the separatory funnel has created a demand for automatic apparatus for accomplishing otherwise the same result.

The contrivances of Von Ledden, Heulseboese, and Smetham, are recent inventions for the extraction of aqueous solutions with ether.

Analogous constructions to facilitate extraction with chloroform seem to have attracted less attention, though they are mentioned in Prescott's organic analysis and probably elsewhere.

The writer lays claim therefore to merely a convenient construction for applying well-known principles.

The (aqueous) solution to be extracted is floated in the extraction tube B, upon a sufficient quantity of chloroform to rise well above the side tube C at the bottom.

The flask, containing a small quantity of chloroform, being heated on the water or steam bath, the vapour rises through the bent tube A to the condenser and is returned in the liquid state through the trap tube, the solution in B, and outlet tube C, which is connected with the flask by a larger tube and a corked joint. The siphoning out of the contents of B is thus prevented. By shutting off the heat and opening this joint, a sample can readily be drawn for ascertaining the progress of the extraction.

In case an open joint at this point is such a desideratum as to counterbalance the objection to loss of solvent by evaporation, a funnel tube bent so as to form a trap may be substituted for the straight tube into which C discharges. The escape of hot vapour from the flask being thus prevented, the end of C is merely strung in position over the enlarged end of the funnel tube.

The tube B, being made from a screw-capped tubular bottle, the writer utilised the cap for its suspension by cutting away the end and attaching a copper wire hook to the threaded collar remaining.

The ascending limb of A should be jacketed with felt to prevent condensation.

## A NEW REACTION FOR THE DETECTION OF SOAP IN LUBRICANTS.

BY H. SCHWEITZER AND E. LUNGWITZ.

THE analytical chemist is very often called upon to determine the presence of soap in fats, oils, &c. Very frequently lubricants, such as mineral oils and tallow, are met in commerce to which soap has been added for the purpose of adulteration. The specifications accordingly of all the leading railroads of the United States distinctly point out that the lubricants must be free from soap. Mineral oils very often contain small quantities of soap, especially aluminium soap, which are added to make the mineral oil appear thicker and more consistent. Since the use of such adulterated products for lubrication has decided disadvantages, it is essential to have a sharp reaction by which the presence of soap, even in the minutest quantities, can be qualitatively established beyond any doubt. The methods which are at present used for this purpose do not give satisfactory results.

Our reaction is based on the fact that metaphosphoric acid is soluble in absolute alcohol or in sulphuric ether, whereas the metaphosphoric acid salts of the alkalis and alkaline earths are insoluble in these liquids. We

must add, however, that the metaphosphoric acid salt of ammonia is soluble in alcohol or sulphuric ether. But since the products to be examined are mainly lubricants which contain potash-, soda-, magnesia-, or alumina soaps, but never ammonia soap, this exception is of no importance for our new reaction. In doubtful cases, however, it will be required to test for ammonia after the well-known methods.

After these introductory remarks it is obvious that if we treat a solution of any fat, oil, or wax in sulphuric ether, benzene, or absolute alcohol with a saturated solution of metaphosphoric acid in absolute alcohol or sulphuric ether, we decompose any kind of soap present and precipitate the metaphosphoric salts from this solution.

The reaction is exceedingly sharp and absolutely reliable. But it must be remembered that some waxes and ozokerite are precipitated from their solutions in benzene by means of alcohol. In such cases we must use both the reagent and the fat in ethereal solution.

We have found that no substances which are present in coal-liver oil, fish oil, sperm oil, lanoline, except the fatty matter, give precipitates with metaphosphoric acid, and thus do not impair the value of our reaction.

To determine the accuracy of our test, we dissolved 5 drops of the substances enumerated below in 5 cc. of benzene (boiling point below 75° C.), and treated this solution with 1 cc. of a saturated solution of metaphosphoric acid in absolute alcohol. We prepare the latter reagent by shaking pulverised metaphosphoric acid with alcohol. After allowing to stand for some time, the clear liquid, representing the new reagent, is drawn off.

Simultaneously we carried out comparative tests under the same conditions with the same substances, to which we, however, added 1 cc. of a solution containing 1 gm. gelatin in 100 cc. benzene. As is well known, gelatin is the commercial article consisting of mineral oil in which 10 per cent. of alumina soap are dissolved.

The following fats and oils gave, even after 24 hours' standing, no trace of a precipitate:—

(1.) *Oils of Mineral Origin.*—Petroleum, paraffin oil, vaseline, ozokerite.

(2.) *Oils of Vegetable Origin.*—Cotton-seed oil, rapeseed oil, linseed oil, olive oil, sesame oil, peanut oil, castor oil, palm oil, Chinese tallow.

(3.) *Oils of Animal Origin.*—Lard, lard oil, tallow, stearin, oleic acid, stearic acid, neatsfoot oil, lanoline, herring's oil, fish oil, cod-liver oil, sperm oil, whale oil.

(4.) *Essential Oils, Wax.*—Rosin oil, camphor oil, spirits of turpentine, beeswax, spermaceti.

The mixtures of oil and soap, prepared as above, gave all of them characteristic precipitates.

At the same time, our reaction permits an approximate estimation of the nature of the soap present. We add to the alcoholic ethereal solution containing the precipitate of the phosphate, a solution of chloride of platinum in alcohol. In case the flocculent precipitate becomes crystalline, the presence of potassium is indicated. If the original precipitate is dissolved, then sodium, calcium, or magnesium, the platinum double salts of which are soluble in alcohol, may be present. If the original precipitate remains unchanged, aluminium or iron salts are present.

## DISCUSSION.

Dr. J. H. WAINWRIGHT asked Dr. Schweitzer what were the disadvantages of lubricants containing soap.

Mr. R. C. WOODCOCK said that if they contained a little potash or soda soap, probably that soap would contain a little free alkali. Might not that rather be an advantage than otherwise? The free fatty acids frequently met with in lubricants attacked copper bearings and zinc.

Dr. H. ENDEMANN said that a lubricant, which the vendor was anxious to introduce on the railroads, had some time ago come under his notice, which proved to be an alkaline soap in admixture with other lubricants, the soap therein being about 20 per cent. The lubricant was tried indoors, but in order to be useful had to be weighted down so as to

get it in contact with the shaft and its bearings. It was found that while the lubricant was quite good under conditions of a dry and not too low a temperature, in cold weather the soap would make the lubricant unmanageable, inasmuch as it could not be forced into the bearings. Moisture also gave rise to the formation of an emulsion. The railroads were now alive to the disadvantages of lubricants the efficiency of which was affected by moisture and low temperatures.

Mr. H. COMER asked what lubricants were in the market or used which contained soap.

Mr. VICTOR BLOEDE thought that Dr. Schweitzer did not quite do the soap question justice, in that he spoke of it purely as an adulterant. The presence of soap was a very great advantage to certain classes of lubricant oil. It increased the viscosity and enabled a higher degree of lubrication without any detriment resulting. Dr. Endemann had said that it would wash away. That applied more particularly to the true alkaline soaps, but not to alumina soap. While an excess of soap, and especially of alkaline soap, was undoubtedly added purely as an adulterant in many cases, and added no advantageous property to the lubricant at all, except to enable it to absorb water, yet that did not apply to soaps which were soluble in mineral oil. Through practical experience and many tests that he had made, he believed the viscosity and power of adherence to metal surfaces to be much increased.

Dr. H. ENDEMANN said that he had intended his remarks particularly to apply to oil to which an alkaline soap had been added.

Dr. H. SCHWEITZER said, in reply, that what Dr. Endemann had said against lubricants containing alkaline soap was confirmed by his own experience. That lubricant which consisted of paraffin oil and contained 10 per cent of alumina soap, to which Mr. Bloede had referred in his remarks, was certainly an adulterated product and was treated as such by R. Benedikt and others. Experience had shown that its use for lubrication was very disadvantageous. Firstly, the alumina soap was precipitated when it came in contact with water or steam, and the thus formed precipitate clogged the machinery. Another disadvantage was the fact that the friction was increased. Grossmann reported an instance in which the owner of a mill using water-power decided to use a consistent fat as lubricant instead of pure oil. In consequence thereof the water-power became insufficient for driving his machinery, and the mill-owner was forced to readopt his old method of lubrication.

J. E. WOODBURY, in Boston, mentioned that he used for one of the two rows of looms in a cotton-mill, under the same conditions, oil, and for the other a consistent fat. He found that that the temperature of the bearings lubricated with oil was only 4° higher than the temperature of the room, whereas the temperature on the other side was 22° higher.

An increase in friction meant an increase in the amount of fuel used, and greater wear and tear of the machinery. Granted that the viscosity of oils containing soap was much larger, and that the use of such lubricants was convenient and economical, nevertheless experience and the published literature showed that these advantages were not considered great enough to induce people to use the soap lubricants instead of pure oils.

In answer to Mr. Comer's question, there were only three kinds of lubricants with soap in the market: gelatin (paraffin and alumina soap), hot-box greases, and axle greases. The latter two products were mixtures of mineral oils with lime-soaps from vegetable or animal oils or resin soaps, at the same time frequently containing so-called fillers, such as talc, chalk, and sulphate of barytes.

## I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

### PATENTS.

*Improvements in Apparatus for Automatically Regulating the Temperature of Fluids Heated by Steam.* J. J. Royle, Manchester. Eng. Pat. 19,116, October 16, 1893.

THE invention relates to improved means for regulating the steam supply to boiling pans, storage tanks, and other steam-heated apparatus, and consists of a flexible bent metal bar having its ends fixed rigidly to convenient parts of the steam-heated apparatus, and with the centre bearing upon the stem of the balanced steam-supply valve. As the temperature rises the casing of the apparatus expands and pulls the bowed bar straight, and thereby partially closes the valve and diminishes the supply; in this way an automatic regulation of the steam supply is kept up.

—E. G. C.

*Improvements in and relating to Evaporating Apparatus.* Paul Donat de la Grée, Paris. Eng. Pat. 21,000, November 4, 1893.

THE improved apparatus is for instantaneously evaporating water, and is designed to obviate the inconvenience caused by the evaporating coil becoming filled with water when the heating is not sufficient to completely evaporate the water as fast as it enters. The invention consists of a mechanical device by means of which the variations of temperature of the evaporating coil may be caused to regulate the movements of the valve controlling the feed. The device is shown in section in the figure.

It is a tubular chamber of small internal capacity, which is fixed within the evaporating pipe or coil at some point not directly in contact with the flame of the furnace. This chamber communicates, by a side tube D, with a flexible chamber E, contained within a cylinder F, which actuates,

\* Any of these specifications may be obtained by post by remitting 8d.—the price now fixed for all specifications, postage included—to Sir Henry Reade Lack, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C.

in opposition to the spring 1, the piston G and rod H. The chambers B and E, and the tube D, are first filled with water, and then closed by screwing in the plug C. When the coil is heated, the steam within it heats the chamber B, and converts the water in the chamber partly into steam, which expands the chamber E and forces down the piston G; but if the temperature of the coil should fall too low, the steam in B will condense, and the piston G will be returned by the tension of the spring 1. By suitable connections,

ATTACHMENT FOR INSTANTANEOUS EVAPORATING APPARATUS.

the upward and downward movements of the piston-rod H may be made to close or open the valve which controls the admission of water to the coil. As, in practice, the apparatus will be adjusted so as not to completely close the valve until actual water has begun to accumulate in the coil, a relief valve is provided, in order that the pressure of the steam produced by the evaporation of this water in the closed coil, when the temperature again rises, may not become great enough to be dangerous.—L. A.

*Improvements in Mechanism for Controlling and Regulating the Discharge of Liquids from Tanks.* W. G. Strype, Dublin. Eng. Pat. 22,529, November 24, 1893.

THE inventor claims improvements in the mechanism for regulating the discharge of liquids from sewagetanks. The bottom of the tank has angular gutters, at the ends of which are sluices opening into a transverse gutter provided with a penstock valve. The shaft opening the sluices and valves, bears cams so arranged as to open every third or fourth sluice only, in addition to the penstock valve, three or four times every revolution, thus concentrating the scouring effect of the outflow upon some of the gutters. A second transverse gutter connects the further ends of the angular gutters so that liquid passes into those of the latter, which are open, from the others. A horizontal cam-shaft, turned by hand or otherwise, driving two worms and worm wheels in connection with both valve and sluices, supplies the motive power.—L. de K.

*A Means or Device for Protecting Steel Cylinders for Containing Compressed Gases from Shocks or Injury during Transit or otherwise.* W. E. Lea, Runcorn, Cheshire. Eng. Pat. 23,616, December 8, 1893.

THE patentee claims in this invention the "combination of steel cylinders or bottles used for containing compressed or liquefied or similar substance with an external protective covering of rope or other suitable material," the strands of which are wrapped round and encase the cylinder or bottle. Other suitable soft and twisted, or plaited material may be used, the object being to minimise risks of injury following a fall, blow, or shock, received by such cylinder or bottle.

—W. S.

*Improvements in Means for Utilising the Pressure in Cylinders or Reservoirs containing Compressed Gases, in the Application and Use of such Gases.* The Manchester Oxygen (Brin's Patent) Co. Lim., and W. M. Jackson, Manchester. Eng. Pat. 24,761, December 23, 1893.

FIG. 1 is a sectional elevation, and Fig. 2 a sectional plan of the apparatus, consisting of a casing *a* having an oxygen

Fig. 1.

Fig. 2.

MIXER FOR OXYHYDROGEN BURNER.

gas-inlet tube *b*, and a similar one *c* for coal gas. The oxygen gas under pressure enters the passage *b* and passes to the back of the mixing cone *f* of an injector, whereby a current of coal-gas is drawn into the chamber *e* and mixes with the oxygen as it passes through the orifice *e* into the chamber *g*. The mixed gases afterwards pass by the orifice *h* into a chamber *A* containing a sound-deadening composition, and finally escapes by the outlet *a*. Suitable plugs, *k* and *l*, are fixed in the casing *a* to allow of access for repairs and cleaning, and wire-gauze discs are placed at the back of the mixing cone and in the sound-deadening chamber *A* in order to prevent the passages being blocked by foreign matter.—E. G. C.

*Improvements in the Construction of Filtering Beds.*

T. Cosham, Newark-on-Trent. Eng. Pat. 9519, May 15, 1894.

THE combination is claimed, in filtering beds, of two or more tanks enclosed in suitable walls, and having perforated floors over "flocculent chambers" so arranged that the sewage or other matters to be operated upon and filtered, is caused to pass alternately downwards and upwards, through filtering material.

The chief claim of the inventor is, however, that in the reversal of the order of the flow by means of pumping appliances, the whole of the arrested matters may be entirely removed from the tanks without interfering with the filtering materials.—L. de K.

*Improved Refrigerating Liquid.* Martin Wanner, Yorktown, Delaware, U.S.A. Eng. Pat. 13,194, July 7, 1894.

THE inventor's object is to prevent or retard the thickening or freezing of volatile liquids, such as carbon bisulphide, used in refrigerating machines, and to regulate their rapidity of evaporation. The inventor points out that by the rapid evaporation of carbon bisulphide, for example, the liquid falls in temperature more rapidly than the walls of the containing vessel, until it at first thickens and then freezes. Thus the efficiency of the apparatus is impaired. To prevent this thickening or freezing, he mixes with the volatile liquid "oils or other liquids or fluids of as nearly as may be the same specific gravity as itself, being perfectly miscible therewith."—L. A.

*Improvements in and relating to Apparatus for Heating Liquids, Air, and other Fluids.* E. Fudicker, Elberfeld, Germany. Eng. Pat. 15,413, August 13, 1894.

IN order to more efficiently heat liquids and gases, and more particularly water for baths, a form of geyser is employed in which the liquid or gas is introduced into a central vertical pipe, provided with a rose at the top, for distributing the fluid in finely-divided streams over a corrugated and perforated spiral encircling the central tube. As the liquid flows down the spiral it meets with the hot gases from a gas burner, placed at the base of the apparatus, and thereby becomes heated: the heated fluid escapes by a suitable outlet in the base of the apparatus.—E. G. C.

*Improvements in Apparatus for Treating Powdered Materials.* J. S. Detwiler, Philadelphia, U.S.A. Eng. Pat. 17,314, September 11, 1894.

THIS invention describes an apparatus for breaking up the lumps and for drying the powdered material. It consists of a cylindrical vessel, divided into a number of superposed compartments having bottoms formed of wire gauze of a degree of fineness increasing from the top compartment downwards. In each chamber there are a number of brushes fixed to frames carried by a central vertical shaft, by the rotation of which the brushes are made to revolve and sweep the gauze bottoms of the chambers. A current of air is, at the same time, driven by a fan into the lowest compartment, and passes upwards, through the gauze bottoms, from chamber to chamber, leaving the uppermost compartment through screened openings. The material, which is fed continuously, or in small quantities at intervals, into the uppermost compartment, being dried by the current of air which rises through it, and swept downwards through the gauze partitions by the revolving brushes, gradually falls by gravity into the conical bottom of the apparatus, whence it is drawn off from time to time.—L. A.

*Improvements in Apparatus for Blending Powdered Materials.* J. S. Detwiler, Philadelphia, U.S.A. Eng. Pat. 17,315, September 11, 1894.

IN this specification three forms of apparatus are described. The first consists of a vertical cylindrical chamber, having a contracted top and outlet, and a series of inlets for air arranged around the bottom. In the centre of the cylinder

there is a vertical shaft, to which are fixed, at different heights, a number of fan blades and fingers capable of being revolved by the rotation of the shaft. The powdered material or materials which it is desired to segregate, intimately mix, and dry, are introduced into the apparatus at the bottom by means of a pipe containing a screw conveyor; the powder is then lifted by the current of air passing in at the air holes, and carried upwards among the revolving beaters, which break up the lumps and mix the material, and is finally forced out through the contracted top, and through a pipe into the settling chamber. The latter has the shape of a horizontal cylinder, and contains a screw conveyor, fixed along the bottom, which continually collects the settled powder and scrapes it towards a hole, through which it falls into casks placed to receive it; the air escapes through screened openings in the upper side of the cylinder.

The second form of apparatus is a revolving horizontal drum, having fixed blades on the inside and hollow end journals. The materials to be blended are fed into the hollow journal at one end, and are forced—by a blast of air which passes through the journal, into the drum, and out through the other end journal—into a settling chamber of the construction already described.

The third form of apparatus consists of a vertical fixed cylindrical box or chamber with flat top and bottom. The upper part of this chamber contains a vertical shaft, carrying a number of arms, which revolve between arms fixed to the walls. About half-way up, and below the revolving arms a blast of air is admitted into the chamber, and escapes through screened openings in the top. The materials, which are fed through the top of this apparatus, fall among the beaters which break up lumps and mix "and blend" the particles, by the aid of the rising current of air which also carries away moisture. The powdered mixed materials which have reached the bottom of the chamber, are drawn out thence by means of a pipe, and screw conveyor.—L. A.

*Improvements in Centrifugal Separators.* O. J. R. Ström, Stockholm, Sweden. Eng. Pat. 17,552, September 18, 1894.

IN order to effect a flow of the heavier liquid outwards in a centrifugal separating apparatus for milk and the like, a number of discs *a*, arranged in a pile within the casing of the separator in the manner shown, are corrugated in spiral

CENTRIFUGAL SEPARATOR.

lines radiating from the centre and provided with annular holes so as to form an annular chamber *c* round the central inlet pipe *b*. The liquid is poured into the central pipe *b*, and the heavier portions thereof, after penetrating through the passages formed by the plates *a*, are collected by the pipe *d*.—E. G. C.

*An Improved Method of and Apparatus for Drying Substances which are Viscous or Semi-fluid in the Hot State.* H. H. Lake, London. From R. Schicht, Bohemia. Eng. Pat. 18,214, September 25, 1894.

This invention is for a method of drying viscous or semi-fluid substances, which are liable to burn on the heating surfaces, when dried in the ordinary way. The improved method consists in heating the material, whilst under such great pressure that it cannot boil, to such a temperature that when it is allowed to flow into a vacuum vessel, the contained heat is sufficient to evaporate all the water in it. The apparatus consists of a high-pressure vessel, a heating vessel, and a low-pressure vessel, connected by pipes and valves. The material is introduced first into the high-pressure vessel, and hot air is forced in until the requisite pressure is attained; connection with the heating vessel is then opened, and also with the low-pressure vessel: the fluid then passes through a number of tubes, in the heating vessel, which are heated by steam on the outside, and is thereby raised to the necessary temperature, and it afterwards flows into the low-pressure vessel, where evaporation takes place. The latter vessel is furnished with baffle plates for distributing the fluid as it falls into the vessel, and also with steam pipes for supplying additional heat if required.—L. A.

*An Improved Method of Exhausting, and Apparatus Employed therefor.* S. H. Wright, Ganarew Manor House, County of Hereford. Eng. Pat. 19,654, October 19, 1894.

In order to create a vacuum or cause a current of air to flow through any vessel, it is connected by a side channel to a vertical downfall pipe through which water is flowing in a number of divided streams, thereby inducing a current of air. The water is divided up into streams by means of perforated plates inserted at suitable intervals in the downfall pipe.—E. G. C.

## II.—FUEL, GAS, AND LIGHT.

*The Explosive Nature of Acetylene.* L. Meyer. Ber. 1894, 27, 2764—2765.

As a general rule, mixtures of combustible gases, such as hydrogen, carbon monoxide, methane, &c., with just sufficient or a slight excess of oxygen, may be exploded without risk in an open glass cylinder, providing the latter is of uniform diameter and not constricted at the neck. Acetylene, however, forms an exception. In an experiment with this gas, the containing cylinder was shattered, even the thick foot of the jar being blown into a number of pieces. The author therefore points out the necessity for caution in dealing with explosive mixtures containing acetylene.—H. T. P.

*Experiments on Coals immersed in Water.* G. Arth. Bull. Soc. Chim. 1894, 11, 619—622.

VARIOUS kinds of coal were (a) Exposed freely to the air, (b) Immersed in water, both running and stagnant, for twelve months, and the changes produced in their composition and heat of combustion determined. Three kinds of coal were used: (1) From the Frankenholz mine in Rhenish Bavaria; (2) From Brocourt (Pas de Calais), and (3) From the mines of Aiseau-Prêle (Charleroi). The coals were broken up and sieved, the pieces being used which passed through meshes 10 mm. square, but not through meshes of 3 mm. square. Care was taken to obtain even samples. The measurements show that exposure to air or immersion in water for the length of time indicated, produces changes in composition and heat of combustion which are so small that for practical purposes they may be neglected.—T. E.

*Examination of the Products of Combustion of Coal-Gas, when burned by Argand and by Auer Burners respectively.* N. Gréhaud. Comptes rend. 1894, 119, 146.

See under XVIII. B., page 1215.

## PATENTS.

*Method of Manufacturing Artificial Fuel.* E. Kirbis, Berlin. Eng. Pat. 17,484, September 14, 1894.

THE object of this patent is to produce a fuel (for use in stoves, without stacks, &c.) which may be very easily kindled or caused to glow, and that continues glowing slowly and uniformly without evolving any smoke or smell. A scentless resin, such as tragacanth, is dissolved in water and the solution heated until it boils and is turned into a slimy mass. Into this is introduced pulverised charcoal, which has previously been twice glowd, in such proportion that the mixture of the charcoal and the resin solution contains 3 per cent. of the latter. The mass is worked through a suitable mixing machine till it looks flaky, and is then pressed into blocks and dried in a kiln. Very little air is said to be required for maintaining the combustion, and neither smoke nor smell is said to be perceptible.—L. T. T.

*Improvements in and relating to Mantles for Incandescent Gas Lights.* H. Blücher, Berlin. Eng. Pat. 18,309, September 27, 1894.

THE mantles, which have already been impregnated or treated by any of the known methods to enable them to become incandescent, are placed in a concentrated alcoholic solution of shellac (or other suitable resinous body) to which may be added either magnesium silicate, magnesium chloride, hydrated silicic acid, aluminium silicate, magnesium aluminium silicate, or potassium silicate, or any of them. The mantles are dried (ignited) in a Bunsen flame, which frees them from all organic matter. The mantles are then again preferably subjected to treatment with the alcoholic solution, and once more ignited. The mantles are thus made stronger, more durable, and more elastic. The degree of firmness and elasticity imparted may be varied by variation of the substances added to the solution.—L. T. T.

## III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*The Transport of Petroleum in Bulk.* B. Redwood. Proc. Inst. C.E., Paper 2766, 116, 1893-94. Part II.

THE author principally treats, in this paper, of the subject of the transport of petroleum, from the point of view of minimising the risks of fire and of explosion. He has therefore (1) compiled a critical and historical account of the principal accidents which have occurred with petroleum and other inflammable liquids; (2) conducted a lengthy series of experiments on the evaporation of petroleum, the formation of inflammable and explosive mixtures of vapour and air and the ignition of such mixtures, involving a comparison with the experiments of others in the same field; (3) passed in review the principles of construction of petroleum tank-steamships; (4) enumerated the precautions to be observed in the management of tank-steamships, the use of naked lights, smoking, cleaning tanks, and ventilation; and (5) exhaustively treated the whole subject of the testing of the atmosphere of tanks and other spaces for inflammable gas or vapour. This latter part of his paper contains an account of the hydrogen lamp invented by Professor Clowes and himself for the purpose.

1. *Explosions.*—Perhaps the most interesting general feature brought out by the comparison of these explosions, which has been instituted by the author, is their great

variety, both as to the circumstances leading to the explosions and as to the constituents of the explosive mixtures implicated.

Apart from the disastrous results which have attended the introduction of a naked flame into confined spaces in which ether, carbon bisulphide, and the volatile products of petroleum, or crude petroleum itself, have been allowed to evaporate, it has been found that mineral oil of a not very volatile description is liable to be present in the air in a state of extremely fine sub-division, forming what may be described as a petroleum mist or fog of a highly inflammable character. Thus refined Russian kerosene, with a flashing point of 79° F. (Abel test), brought about the first serious accident connected with the transport of petroleum in bulk, viz., that on the S.S. "Petriana," in December 1886. Here, leakage kerosene lay on the surface of water in a ballast tank and in contact with the lower surface of the partition separating the ballast-tank from the kerosene tank above. The kerosene tank was empty, and the water in the ballast tank being under some pressure, very fine spraying of kerosene took place at certain defective rivet heads. The inflammable mixture of petroleum-fog and air thus gradually formed in the kerosene tank, was unfortunately ignited by workmen carrying open lights. In an experimental imitation of these conditions a similar atmosphere was found by the author to fire at a temperature as low as 50° F. Generally, however, the mixtures exploded have been those of hydrocarbon vapour with air, those hydrocarbons which occur dissolved in crude petroleum, and which are so readily given off, being

responsible for very many of the accidents. As instances of such accidents may be specified those on board the S.S. "Solway," "Petroleum," "Noteros," &c. The "spontaneous" ignition of benzoline vapour, which occasionally occurs during the "dry cleaning" of leather, wool, silk, &c., is due, as originally pointed out by the author (the matter has since been investigated fully by Richter—this Journal, 1893, 598), to electrical discharge, the result of friction between the benzoline and the goods operated upon; wool becoming negatively, and benzoline positively electrified.

2. *Experimental Matter.*—For assistance in this part of the work, the author states that he is indebted to E. R. Blundstone. The author's experiments were principally of two kinds. In the first set of experiments he endeavoured to collect some more accurate information as to the manner in which petroleum and its products evaporate. The apparatus employed consisted of a range of six graduated tubes connected together and immersed in water contained in a large glass tank. Through the petroleum in the tubes a current of dry air was passed, while the exit tube of the system was connected with a condenser cooled by ice water. Materials operated upon were crude petroleum, benzoline (sp. gr. 0.700 at 60° F.), petroleum spirit (0.680 at 60°), gasoline (0.639 at 60°), and pentane, while the water in the tank was maintained at 40°, 60°, 80°, and 100° F. for each material. The residuary volume of liquid in the tubes, after passing air, was periodically read. The author tabulates the results in five tables, the following being that for gasoline:—

TABLE II.  
GASOLINE (Specific Gravity 0.639).

\* Tube empty before reading was taken.

NOTE.—Rapid evaporation and distillation (with condensation of liquid in exit tube) occurred in experiment at 100° F.

Besides the information as to the amount of petroleum and its products which can be carried away at various temperatures in an air current, the tables show the gradual saturation of the air current with hydrocarbon vapour and the much greater amount so vaporised at higher temperatures.

They also show the great readiness with which air will take up the major part of the hydrocarbon it is capable of carrying, complete saturation only being effected by passage through a considerable bulk of liquid.

It is considered that the conditions of these experiments, as a whole, closely imitate the prevailing conditions existing when petroleum products are pumped from one vessel to another, or otherwise agitated with air. The relative quantities evaporated are shown in the table of curves on next page.

In the author's second set of experiments he endeavoured to determine the respective volumes of a given description of petroleum required for the production, with a given volume of air, of gaseous mixtures, which, under given conditions, are (a) just inflammable, (b) violently explosive, and (c) again only inflammable.

In the case of a liquid (such as pentane) of uniform composition and of ready volatility, it is convenient to introduce gradually increasing quantities of the liquid into a known volume of air and to explode the gaseous mixtures so obtained. The author's results are embodied in a table.

When, however, the liquids under examination were partially or unequally volatile, or with diffidently volatile, it was found impossible to employ this method, and the author therefore manufactured "air-gases" from the various petroleum derivatives and from crude petroleum itself.

PETROLEUM VAPOR FLAME CAPS  
from Photographs by Messrs B Redwood and T.Horne Redwood

hydrocarbons of petroleum would, under these conditions, be less prone to escape when subjected to the action of the pump.

It is during loading and discharging that the chief risks of explosion occur with tank-ships. The tank covers should, in the case of the transport of crude oil, on no account be removed, for all necessary ingress or egress of air is otherwise provided for.

If it be necessary (as when repairs are to be carried out) to enter the tanks, they must, after the oil has been pumped out as far as possible, be filled with water, thus causing most of the residual oil to overflow. The water is then pumped out and steam injected. Next, "if the vessel is fitted with steam jet or fan ventilating appliances, these should be put in action, and soon afterwards men may be sent into the tanks to clean them down by hand with a stream of water from the pump, the operation being usually completed by drying the surfaces with sawdust." The ventilation must be continued until no vapour remains. "This may necessitate the testing of the atmosphere more than once, but whether this preliminary examination is carried out or not, the atmosphere of the oil-tanks and adjacent spaces should finally be efficiently tested by a competent expert" and a certificate stating the condition of the tank atmospheres, duly issued.

The absolute necessity of the above procedure was abundantly proved by the accident to the S.S. "Tancerville" in 1891, and it was after this accident that the inspectors for the Board of Trade made the following suggestion:—"When repairs require to be carried out in a vessel which has been carrying petroleum, there should, in our judgment, be a formal handing over of the vessel to those by whom the repairs are to be undertaken, and a certificate that the tanks and all dangerous spaces have, so far as practicable, been adequately cleansed and ventilated, and rendered free from risk of explosion or fire. If from any cause a complete certificate of this sort cannot be given, then it should be clearly notified which tanks or spaces have not been cleansed and are still dangerous." This recommendation has been now generally adopted.

**5. Testing the Atmosphere of Tanks and other Spaces.**—It was the accident to the "Tancerville," to which allusion has been made, which directed the author's special attention to this subject; for, although the cause of this accident has never been elucidated, it was at least abundantly evident that, had the tank atmosphere been properly tested for petroleum vapour, the accident would never have occurred. Prior to this accident the author had been accustomed to use the alcohol flame for testing the atmospheres, but he has since experimented with all the different instruments proposed, including the Liveing indicator (which depends upon the increased luminosity—when fire-damp, for example, is present—of a platinum wire heated to incandescence), the Ansell fire-damp indicator (depending on relative diffusion), the Pitkin and Niblett fire-damp detector (essentially two thermometers, the bulb of one of which, being coated with platinum-black, quickly heats in the presence of coal-gas), and with Heck's test (which consists in gently expelling a small syringeful of the suspected atmosphere against a minute flame, a blue flame being produced near the nozzle of the syringe when inflammable vapour is present). None of the foregoing appliances furnished sufficiently satisfactory results.

When the flame of a miner's safety lamp is much reduced in size, if fire-damp be present in the atmosphere, there appears above the flame the well-known "flame cap," caused by a conical region of the gas above the lamp flame becoming feebly luminous. This luminous region is always wider than the lamp flame, and increases in height as the percentage of hydrocarbon vapour in the atmosphere rises. The indications afforded by the miner's safety lamp in this way, are unsatisfactory for petroleum. Those similarly afforded by the large alcohol flame of the Pieler lamp are better, but infinitely more satisfactory and more sensitive are the "flame caps" of a small and almost colourless hydrogen flame. This advantage had been recognised by Pieler in 1883, and still earlier, in 1881, by Mallard and Le Chatelier, but no convenient method of practically using the hydrogen flame had been shown until Clowes

suggested the employment, for the purpose, of hydrogen stored under pressure. This investigator has, moreover, measured the "flame caps" yielded by various percentages of methane (fire-damp) in the air, and has thus placed at the disposal of the miner a portable lamp for not only detecting, but also estimating the amount of the dangerous gas he has to encounter in the atmosphere in which he works.

Meanwhile, the author has invented a lamp on somewhat similar principles, has performed similar experiments with tank atmospheres, and has, moreover, devised a set of apparatus for the collection of samples. The lamp and its accessories have now been in practical use for some time past, and so satisfactory is their use that the author is enabled without hesitation to give the "certificates," previously mentioned as having been suggested by the Board of Trade to be necessary after an examination of tank atmospheres; a result which is quite comprehensible, seeing that 0.75 vol. of pentane vapour may be readily detected in 100,000 vols. of air by the author's apparatus.

In the adjoining illustration the standard hydrogen flame burning in air, free from petroleum vapour, is shown, whilst the five other figures show the "flame caps," when 0.75, 1.5, 3, 5, and 6 vols. of pentane, respectively, are present in 100,000 vols. of air, equal to 0.144, 0.288, 0.576, 0.96, and 1.15 per cent. respectively of vapour in the air. In each case the hydrogen flame was 10 mm. high.

It has been shown by the author's experiments that the vapour of 6.65 vols. of pentane in 100,000 of air is the smallest proportion giving an inflammable atmosphere, and that this proportion must be nearly doubled to give an explosive mixture. The test is therefore a very delicate one, and it is obvious that if a tank or other space be ventilated until, with the author's apparatus, no "flame cap" is obtained, an ample margin of safety will have been provided.

The entire apparatus is shown in Fig. 1, while Fig. 2 gives sections of the lamp, and Fig. 3 sections of the sample collector. In Fig. 1, A is the lamp, B the cylinder containing hydrogen under 120 atmospheres pressure, C the collecting vessel. In Fig. 2, A is the hydrogen inlet tube with regulating valve B, and C is the hydrogen jet. D is the inlet for the atmosphere to be tested. The bore of this tube is greatly contracted, and immediately above its entrance into the chimney of the lamp there are baffles and three wire gauze discs (with not less than 781 openings to the sq. in.). By these means the rush of gas is controlled and back-ignition prevented. The chimney E fits air-tight at the base, but is capable of vertical movement on an inner tube. The chimney is partly metal (darkened inside) and partly glass, and on the window so formed, are marked horizontal lines corresponding to the various values (heights) of the "flame caps."

During observations the operator's head is enveloped in the cloth shown in Fig. 1, hydrogen is admitted to the jet at such a rate that the apex of the flame only just reaches the bottom of the window (10 mm.), and then the contents of the collecting cylinder are allowed to escape into the chimney, which they do during two minutes—a space of time quite long enough for observing the height of flame cap produced by the suspected mixture.

The collecting vessel is shown in Fig. 3, where A is the compression pump, with metallic spring piston, fitting the cylinder without the use of leather, and lubricated by plumbago. The surrounding annular space is that in which the sample (the volume of which = cu. ft. under a pressure of 30 lb. per sq. in.) is collected. E is a relief-valve, lifting at 30 lb. pressure. C is the cock connected with the pump, D a pressure-gauge, and F F brackets by which the apparatus is held down by the operator's feet.

The author states that he has recently experimented with an apparatus devised by Professor Dewar, consisting

\* This plate, which has been reproduced from a series of photographs of the actual caps, taken by the author and T. Horne Redwood, gives the true size and general appearance of the caps when viewed in the dark.

Fig. 1.

essentially of a closed cylindrical vessel (diameter, say,  $1\frac{1}{2}$  in.) with a vertical tube (length, say, 10 ft.) attached to the top, and a horizontal one (calibre, say,  $\frac{1}{10}$  in.) near the bottom of the side. A small quantity of a mobile liquid in the cylinder is forced to varying distances along the horizontal tube (which has attached to it a scale) according as the density of the gas in the vertical tube is greater or less than that of air. By increasing the length of the vertical tube or by increasing the ratio between the area of the surface of liquid in the cylinder and that exposed in the horizontal tube, Professor Dewar and the author found the sensitiveness of the instrument to be not inferior to that of the hydrogen flame for detecting small quantities of petroleum vapour in air. Unfortunately,

Fig. 2.

Fig. 3.

however, the instrument, as at present constructed, could obviously only be used on a ship in dry dock or in perfectly still water.—E. R. B.

*Terpenes in Petroleum.* R. Zoloziecki. Dingl. polyt. Jour. 293, 114—119.

CONTINUING his previous work (this Journal, 1891, 628), the author has examined the substances removed by the alkaline lye used for purifying a crude light petroleum obtained by distillation from a mixture of one-third crude Potok, and two-thirds crude Wietrno oil. The specific gravity of the crude light petroleum was 0.732, of the purified 0.736; 75 per cent. of the light petroleum distilled over below 120° C., and a further 16 per cent. below 150° C.

The lye (of which about 50 kilos. were worked up) was clear and of a yellow colour. When this lye was acidified, an oil separated out. This oil was amber yellow and was miscible in all proportions with water, forming an opalescent solution. As it probably contained alkyl-sulphuric, sulphonic, and petroleum acids and their ethereal salts, it was first distilled with a current of steam, the residue then extracted with ether, and the aqueous residue again distilled with a current of superheated steam. The final thick and tarry residue has not yet been examined. The two distillates were combined. Of the ethereal extract the non-saponifiable portion was added to the combined distillates. The small saponifiable portion of the ethereal extract yielded a mixture of petroleum acids boiling above 300° C. These high-boiling petroleum acids obtained from the low-boiling light petroleum may either be due to polymerisation or oxidation of the original petroleum acids present.

The combined distillate formed a mobile oil of pleasant ethereal odour. It absorbed bromine with a partial evolution of hydrobromic acid, showing the formation of both additive and substitution products. Fuming nitric acid formed nitro-derivatives and also oxidation products. Strong sulphuric acid dissolved a considerable part of the oil, even in the cold, and of the dissolved portion a part was precipitated on dilution of the acid with water, whilst a portion remained dissolved in the form of true sulphonic acids. Sodium caused a slow evolution of hydrogen and the formation of gelatinous compounds. Neither sodium hydrogen sulphite (bisulphite), nor phenyl-hydrazine had any action. It was thus clear that the distillate was a mixture of various hydrocarbons and oxygenated compounds. The distillate was therefore carefully fractionated. The portion boiling below 130° C. was lost. Of the remainder the four principal fractions 130°—140° C., 160°—170° C., 170°—180° C., and 210°—220° C. were treated with strong sulphuric acid. The undissolved oil (I.) was in each case then fractionated. The acid was diluted with water and the oil which then separated (II.) washed, dried, and fractionated. The aqueous acid was then neutralised with barium carbonate, the barium salt recrystallised and decomposed by heating with hydrochloric acid in closed tubes, and the oil thus formed (III.) washed, dried, and distilled.

In each case, I. (which formed about half of the fraction) was found to consist of hydrocarbons, of which a part boiled at about the boiling point of the original fraction, a part about 100° higher, and a part at a very high temperature. The lower boiling portions, from their analyses and properties, appeared to be mixtures of hydrocarbons of the  $C_nH_{2n-4}$  and  $C_nH_{2n-2}$  series, the former largely preponderating, and the higher boiling portions, polymerides of the same. Some of these hydrocarbons are almost certainly terpenes or isomerides of the terpenes.

The second products (II.) proved to be secondary or tertiary alcohols derived from the alkyl sulphates formed during sulphonation. The third products (III.) were aromatic hydrocarbons, amongst which para-ethyl toluene, and eymene were recognised. It is probable that other more condensed hydrocarbons were also present.

The lower boiling portion of I. absorbed bromine readily, and the compounds  $C_9H_{14}Br_4$  and  $C_{10}H_{16}Br_4$  were isolated. The portions of higher boiling point (polymerised) only absorbed bromine very slowly, and very soon evolved hydrobromic acid and formed resinous products. With much glacial acetic acid and little sulphuric acid these polymerides gave a green coloration. None of the constituents of I. caused any rotation of polarised light.

If these compounds really are terpenes the purification lyes from some petroleum may probably form a valuable

source for their preparation. Experiments seem to show, however, that all crude petroleum do not contain them, and apparently their absence is accompanied by absence of the petroleum acids. The presence of terpenes in petroleum would account for the tendency of the latter to resinify and to become discoloured, and for the ozonising action of some petroleum in the presence of sunlight. Their presence is no argument against the theory that petroleum are derived from animal remains by bacterial and brominising action, as terpenes have been proved to be formed during alcoholic fermentation.

The removal of the terpenes, &c. from the crude petroleum by the lye is probably due to their previous conversion into sulphonic and alkyl sulphuric acids by the treatment with strong sulphuric acid.—L. T. T.

*Quantitative Composition of the Creosotes obtained from the Wood of the Beech and from that of the Oak.* A. Béhal and E. Choay. Comptes rend. 119, 166.

THE two materials employed by the authors were the heavy oils, collected during the distillation of the tar obtained from the woods of the two trees in question, and, to secure uniformity of result, they were treated in identical apparatus and by the following method:—

The heavy oil was acidulated with hydrochloric acid, agitated with water, the liquids separated (the aqueous layer thus removing certain basic bodies occurring in the oil), the oily layer dissolved in soda-lye, a very considerable quantity of water added (necess. as concentrated solution of the alkali phenates dissolves a certain quantity of neutral substances), layers of liquid separated, alkaline solution treated with benzene, benzene separated, aqueous solution treated with a current of steam as long as distillate smells strongly. Hydrochloric acid is now added, the liberated phenols decanted, the aqueous layer agitated with benzene, the latter separated and distilled, and its phenol residue thus obtained added to the bulk.

The phenols thus separated were twice rectified, a Le Bel-Henninger fractional distillation apparatus with five bulbs being employed, and two distillates, passing over between 200° and 210° and between 210° and 220° respectively, collected.

In the case of beechwood-creosote the weights of the distillates were as 1,000 : 367 and the sp. gr. 1.085 at 17° and 1.085 at 15° respectively. The 206°—210° oak creosote distillate had sp. gr. 1.068 at 15°.

The authors have analysed these various distillates by the method they have previously described (this Journal, 1893, 618), and find as follows:—

Pure beechwood-creosote, distilling 200°—220° (obtained by mixing 1,000 parts of the 200°—210° fractions with 367 parts of 210°—220° fraction).

Monophenols .....	39.00
Guaiacol .....	19.72
Creosol and homologues .....	39.98
Loss .....	1.30
	100.00

The 200°—210° fractions yielded as follows:—

	From Beech-wood Creosote.	From Oak-Creosote.
Monophenols .....	39.00	55
Guaiacol .....	26.48	14
Creosol and homologues .....	32.14	31
Loss .....	2.38	..
	100.00	100

By comparing the two analyses of beech-creosote fractions, it will be seen that the 210°—220° fraction can contain no guaiacol.

By contrasting the oak- and beech-creosotes it will be seen that the former has the lesser density, and contains less guaiacol and more monophenols; it is the larger presence of the latter which makes it the more "caustic" of the two creosotes.

The authors have gone further, though they admit that their results now lose that precision which they declare is characteristic of the preceding work. In fractionating the monophenols the authors weighed all fractions coming over at a fixed temperature and divided up the intermediate fractions by calculation, half of each intermediate fraction being added to the phenol of highest boiling point. They consider this to be the best practical method of dealing with these fractions which are irreducible by distillation.

As an example of the difficulties of such "carrying over" phenomena, as are met with in the distillation of these creosotes, the authors mention that their 200°—210° fraction contains 5 per cent. of common phenol of boiling point about 179°, that is to say, 2.5° lower than that of the creosote containing it; while, on the other hand, it carries 35 per cent. of creosol and its homologues, of boiling point about 220°, that is to say, 10° higher than the creosote containing it. Working, however, according to their method they find, for the 200°—210° beech-creosote, as follows:—

Phenol .....	5.20
Orthocresol .....	10.40
Meta and paracresol .....	11.60
Ortho-ethylphenol .....	3.60
Metaxylenol, 1, 3, 4 .....	2.00
Metaxylenol, 1, 3, 5 .....	1.00
Phenols various .....	6.20
Guaiacol .....	25.00
Creosol and its homologues .....	35.00
	<hr/> 100.00

In conclusion the authors point out that creosote is popularly supposed to contain 60—90 per cent. of guaiacol, the remainder being creosol, with a small amount of monophenols; the above figures indicate for it a very different composition.—E. R. B.

#### *Tar of Pinus Maritima.* A. Renard. Comptes rend. 1894, 119, 165.

This tar, which is obtained, in the *landes* of South-western France, during the carbonisation of stacks of the wood of *Pinus maritima*, is met with as a thick, dark brown liquid of sp. gr. 1.054. Upon distillation it yields—

1. Water .....	3.5
2. Hydrocarbons (distilling under 300° C.) .....	12.0
3. " (between 300° and 360°) .....	45.0
4. Phenols .....	18.0
5. Pitch (containing much retene) .....	21.5
	<hr/> 100.0

The phenols are separated from their distillate by lixivation with soda—which must be used boiling to avoid emulsifying the product—and subsequent treatment with acid.

The author has isolated, by fractional distillation, operating upon 50 kilos. of the crude tar, three hydrocarbons; one of these he now describes.

It is a colourless liquid, with b.p. 171°—174°, sp. gr. 0.866 at 0°, rotation  $\alpha_D = -19.1$ , index of refraction = 1.4785, formula apparently  $C_{10}H_{16}$ , and with vapour density 4.6 (against theory, 4.7).

It absorbs oxygen more actively than turpentine does. A di-bromo additive compound ( $C_{10}H_{14}Br_2$ ), a tetrabromo derivative ( $C_{10}H_{12}Br_4$ ), and a crystalline dihydrochloride have been obtained.

With sulphuric acid much heat is evolved, and from the supernatant liquid, upon distillation, are obtained a distillate boiling about 170°, which is mostly cymene, and a very thick residue, which is a polymer of the hydrocarbon, boiling about 300°. Upon treating the 170° distillate with fuming

sulphuric acid, cymene sulphonie acid and another hydrocarbon were obtained. This latter, which is not acted upon by fuming nitric acid, nor by bromine in the cold, and has for its formula  $C_{10}H_{20}$ , is cymene hexahydride.—E. R. B.

#### *Pine Tar.* A. Renard. Comptes rend. 1894, 119, 652—654.

THE fraction of pine tar boiling at about 250°—280° C. contains a new hydrocarbon; it may be purified by treating the crude fraction with sodium, and is then obtained as a colourless liquid of sp. gr. 0.9419 at 0° C., and having a boiling point of 254°—257°. Its refractive index is 1.507. Analyses and vapour density determinations indicate that the new hydrocarbon has the formula  $C_{14}H_{22}$ . It furnishes a crystalline tetrabromo-derivative,  $C_{14}H_{18}Br_4$ , and a nitro-derivative  $C_{14}H_{21}(NO_2)$ , and gives a blue coloration when heated with sulphuric acid and alcohol, a reaction which according to Maquenne is characteristic of hydrogenised aromatic hydrocarbons. The hydrocarbon when treated with ordinary concentrated sulphuric acid, develops heat; if the solution be poured into water a sulphonic acid passes into solution, which yields an insoluble barium salt ( $C_{14}H_{21}SO_3)_2Ba$ , whilst the portion of the product insoluble in water, when steam-distilled yields a hydrocarbon,  $C_{14}H_{26}$ , boiling at 250°—253° C., which behaves as a saturated compound, and is perhaps dodecahydro-ditolyl, ( $C_7H_7$ ,  $H_6$ )<sub>2</sub>. The hydrocarbon  $C_{14}H_{22}$  may then be octahydro-ditolyl, ( $C_7H_7$ ,  $H_4$ )<sub>2</sub>. (See previous extract.)—A. R. L.

#### *New Constituents of Wood Oil.* E. Looft. Ber. 27, 1894, 1542.

THE present paper is in continuation of one published in Liebig's *Annalen*, 275, 366 (this Journal, 1893, 919). In addition to the compounds there described the author has isolated:—*Methyl pyridine* and *dimethyl pyridine* in the fractions boiling above 115° C., *butyl alcohol* (probably iso-) boiling about 115°, *pinelic ketone*,  $C_8H_{10}O$ , in the fraction boiling from 150°—160°, and an alcohol possessing the formula  $C_8H_{14}O$  in this same fraction.—T. E.

#### *Ey-products obtained in the Preparation of Butyltoluene.* A. Baur. Ber. 27, 1894, 1606.

See under XX., page 1218.

## IV.—COLOURING MATTERS AND DYES.

#### *The Technical Method of Preparing Aniline.* A. Wohl. Ber. 27, 1815—1818.

THE author makes reference to O. N. Witt's explanation of the small consumption of hydrochloric acid in the technical process of reducing nitro-compounds by means of metallic iron. According to this, the ferrous chloride formed is the real reducing agent, its action being due to its conversion into basic ferric chloride, whilst by the metallic iron it is constantly being regenerated from the latter. Witt's equations for the reduction of nitronaphthalene are as follows:—

While admitting the clearness of this explanation, and confirming the correctness of the conversion of basic ferric chloride into ferrous chloride, and the oxide  $Fe_3O_4$ , as assumed in the second equation, the author, in view of the fact of ferrous chloride being replaceable by salts ( $CaCl_2$ ,

Se.) not capable of exerting a reducing action by conversion into higher oxidation compounds, still thinks his view of the direct reducing action of metallic iron, as recently expressed (this Journal, 1894, 876), the one best expressing the reaction actually taking place.—F. M.

*Sulphur Compounds accompanying Aniline Bases, and their Colour Reactions.* A. Hantzsch and H. Freese. Ber. 27, 2329—2334.

CHEMICALLY pure aniline does not give the blue colour reaction with chloride of lime hitherto considered characteristic. The coloration obtained with aniline from coal-tar benzene is due to the presence in it of traces of a sulphur compound, probably amido-thiophene. The same rule applies to a number of other bases, and more especially to commercial para-amidophenol. Attempts to isolate the sulphur compound have as yet been fruitless, but a reliable method for its removal from aniline seems to consist in heating the latter for some time with acetone. This evidently forms a condensation product with the amidothiophene, which, on distillation of the aniline, remains behind as a resinous mass rich in sulphur. Para-amidophenol may be purified in like manner. The product crystallising from the acetone solution is distinguished from the ordinary para-amidophenol by its remaining colourless on exposure to air.—F. M.

*Tannin Orange.* C. Schoen. Bull. Soc. Ind. Mulhouse, August and September 1894, 350.

*Tannin Orange R*, a new colour manufactured by Cassella, of Frankfurt, is an azo colour, and possesses the property, rarely shown by this class of dyestuffs, of being fixed by tannin. It is obtained by the mutual reaction of para-amidobenzylidimethylamine and  $\beta$ -naphthol and has a composition expressed by the formula—

The colour is sold as a 50 per cent. paste, which gives a clear solution with distilled water; but when dissolved in calcareous water the solution rapidly becomes turbid. Its solution is precipitated by ammonia and the fixed alkalis, the precipitate being easily redissolved by acids.

As a printing colour it is fixed by tannin in presence of acetic acid. The addition of tartaric acid presents no advantage. It is not affected by sulphurous acid in steaming, and its resistance to chlorine is good. It has a medium fastness against light. It is less useful for dyeing on a tannin mordant, as the white grounds are strongly coloured. Its principal use will be in combination with Methylene blue or green, with which it gives pretty mode and grey tones.—W. E. K.

## PATENTS.

*Improvements in the Manufacture of Colouring Matters.* J. Y. Johnson, London. From "The Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 18,759, October 6, 1893.

THE soluble salts (compounds with acids) of safranine azo-naphthol bodies described in Eng. Pat. 4543 of 1891 (this Journal, 1892, 236) have been introduced into commerce under the name of Indoin blue, and afford a perfect substitute for indigo in some of its applications. It is now found that the insoluble safranine-azo-naphthol bodies can be converted into soluble basic dyes, practically equivalent to Indoin-blue, by prolonged washing with water, whereby the excess of alkali and salts is removed. For example, a 1 per cent. solution of safranine is made, taking one molecular proportion of the safranine, i.e., about 7 kilos, of safranine T (obtained by oxidation of tolylenediamine, o-toluidine, and aniline), or the equivalent quantity of another easily diazotisable safranine, and diazotised by adding a solution of 14 kilos. of sodium nitrite and 23 kilos. of 30 per cent. hydrochloric acid, the mixture being kept cool by ice. It is then run into an ice-cold solution of about 3 kilos. (one molecular proportion) of  $\alpha$ - or

$\beta$ -naphthol in 160 litres of water and 25 kilos. of caustic soda solution containing 35 per cent. NaOH. The products are washed with water until the wash-water becomes deeply coloured, and the washed paste, made up to a standard strength, is then ready for use.—T. A. L.

*The Manufacture and Production of New Compounds suited for Use in the Preparation of Diazo Compounds and their Application in the Production of Dyes.* J. A. Johnson, London. From "The Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 20,605, October 31, 1893.

THE diazo compound of  $p$ -nitraniline, when treated with an alkali at ordinary temperatures, is converted into the alkali salt of the isomeric nitrosamine. This is a tolerably stable substance, and readily crystallisable. When dissolved and mixed with sodium  $\beta$ -naphtholate and an excess of alkali it gives no colour, but if the nitrosamine salt be treated with rather more than one molecular proportion of acid, preferably in presence of a little nitrous acid, the nitrosamine is reconverted into the diazo compound, which will then combine with an alkaline solution of  $\beta$ -naphthol. Other aromatic amido compounds react in the same way, providing they contain substituting acid groups, such as one or more nitro groups, two or more halogen groups (in the one benzene ring), and with or without sulphonic acid groups. The following substituted amines have been employed: o-nitraniline, nitro- $p$ -toluidine ( $CH_3:NO_2:NH_2$  1:3:4); dichloro-aniline ( $Cl_2:NH_2$  1:4:3); 1,4-nitro-naphthylamine, dinitrobenzidine, the sulphonic and carboxylic acids of nitraniline and pteramic acid. For preparing the nitrosamine salt from  $p$ -nitraniline a 10 per cent. solution of the diazo compound from 135 kilos. of  $p$ -nitraniline is run into 8,000 kilos. of caustic soda solution containing 18 per cent. NaOH, at about 60—70° C. with vigorous stirring. On cooling, the nitrosamine salt separates in crystals, and may be purified by recrystallisation from 700 litres of hot water. In practice, it is only necessary to run the diazo solution into 18 per cent. cold caustic soda lye, taking care that the solution always remains strongly alkaline. The nitrosamine salt separates out and is filter-pressed and dried or kept as a paste. To convert it into free  $p$ -nitrophenyl nitrosamine, about 10 kilos. of the salt are dissolved in 250 litres of cold water, and decomposed with 30 kilos. of 6 per cent. hydrochloric acid. The free nitrosamine, which separates at once, is filtered off and must be used in the form of paste. The further conversion into the diazo compound is affected by adding more acid, as in the following example. About 10 kilos. of the nitrosamine salt are dissolved in 250 litres of water and this solution is run into 18 kilos. of 30 per cent. hydrochloric acid. The precipitate of the free nitrosamine disappears as it is converted into the diazo compound, and the addition of about 1 per cent. of sodium nitrite considerably accelerates the conversion. This conversion can be effected on the fibre by printing a mixture of the nitrosamine salt with certain phenols and amines, together with an excess of alkali, and gradually neutralising the alkali, either by exposure to the atmosphere or treatment with acetic acid, when the diazo compound produced immediately combines with the component present to form the colour.—T. A. L.

*The Manufacture of Colouring Matters Dyeing Blue with Mordants.* C. D. Abel, London. From "The Actien Gesellschaft für Anilin Fabrikation," Berlin, Germany. Eng. Pat. 23,311, December 4, 1893.

THE invention is based on the observation that ortho-quinones or their sulphonic acids form condensation products with alkylated  $p$ -phenylene-diamines which, when afterwards heated with sulphur and fuming sulphuric acid, yield blue colouring matters capable of forming lakes with metallic mordants, which dye fast blue shades and are especially suitable for dyeing and printing chrome mordanted wool and cotton. For example, 13.6 kilos. of dimethyl- $p$ -phenylenediamine hydrochloride are dissolved in 100 litres of water, and, while agitating, 27.6 kilos. of

the potassium salt of 1,2,3'-naphthoquinone sulphonic acid are added. The solution is kept slightly alkaline by sodium carbonate, salt is added, and the mixture slightly heated while a current of air is blown through it. The product, filtered off and dried, forms a blue powder. 25 kilos. of this intermediate product and 12 kilos. of sulphur are dissolved in 250 kilos. of 30 per cent. sulphuric anhydride. The mixture is well stirred for about 12 hours and finally gently heated until a sample dissolves in boiling water with a bright blue colour. The mixture is then poured into iced water and heated to boiling. The precipitated colouring matter is filtered off, dissolved in dilute soda, filtered again to remove sulphur, and finally precipitated with hydrochloric acid or salt. When instead of quinonemonosulphonic acids the quinones themselves are used, the same result is obtained, because sulphonation takes place in the process, and when such quinonesulphonic acids are employed as contain a sulphonic acid group in the position 4, this group is split off during the condensation.—T. A. L.

*The Manufacture or Production of Colouring Matters.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 23,392, December 5, 1893.

In Eng. Pat. 19,062A of 1891 (this Journal, 1892, 809) a process for producing dyestuffs was described, which consists in condensing tetra-alkylated diamidobenzhydrols with secondary amines, subsequently treating the so-formed leuco-products with nitrous acid, oxidising the resulting leuco-compounds containing a nitrosamine group, and finally splitting off the nitroso group. Some of these colouring matters can also be produced by the process described in Eng. Pat. 5038 of 1884 (this Journal, 1885, 279), namely, by allowing tetra-alkyl diamidobenzophenone to act, in the presence of phosphorus oxyhaloid or the like, on certain of the secondary amines. The number of secondary amines suitable for treatment by this last process is by the present patent extended, so as to include mono-methyl and mono-ethyl- $\alpha$ -naphthylamine. Benzyl- $\alpha$ -naphthylamine has already been included among them in Ger. Pat. 69,863. Analogous colouring matters are formed from *p*-alkyl-oxypheyl- $\alpha$ -naphthylamine or analogous alkyl-oxy compounds by either of the two processes above mentioned. The said *p*-alkyl-oxypheyl- $\alpha$ -naphthylamines are prepared by heating  $\alpha$ -naphthylamine with *p*-amido-alkyl-oxybenzene hydrochloride. The following is an example of the production of one of the dyestuffs. Eight kilos. of tetramethyldiamidobenzophenone are mixed with 8.1 kilos. of *p*-ethoxyphenyl- $\alpha$ -naphthylamine, and then 5 kilos. of phosphorus oxychloride added gradually, with continual stirring. After standing some time at the ordinary temperature the mixture assumes a metallic lustre and becomes crystalline. It is then heated for some time to 107°–110° C., powdered, washed with cold water, and dissolved in dilute hydrochloric acid (15 per cent. HCl). The dyestuff is precipitated from this solution by adding water. The colouring matter is easily soluble in hot water and gives greenish-blue shades on wool and on cotton mordanted with tannic acid.—T. A. L.

*The Manufacture or Production of Colouring Matters derived from Anthraquinone.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 23,585, December 7, 1893.

In Eng. Pat. 4871 of 1891 (this Journal 1892, 513) a process was described for the production of dyes by acting on certain polyhydroxyanthraquinones with atmospheric oxygen in presence of ammonia. A simpler method has now been discovered yielding similar results and of more general application. This consists in treating hydroxyanthraquinones, in presence of ammonia, with ammonium persulphate or other salt of persulphuric acid (J. Prakt. Chem. 48, 185, and this Journal 1891, 1004), using two molecules of persulphate to one of hydroxyanthraquinone. The action takes place readily in dilute aqueous solutions at a low temperature.

For example, 50 kilos. of 20 per cent. Alizarin bordeaux paste are dissolved in 500 litres of water and 100 litres of

20 per cent. ammonia. A solution of 8.5 kilos. of ammonium persulphate in 50–100 litres of water is then gradually stirred in, the mixture being kept cool by ice. The action is finished when a sample treated with acid gives a precipitate which dissolves in sulphuric acid with a cherry-red colour. The melt is then mixed with hydrochloric or sulphuric acid and the dark purple-red dyestuff filtered off and washed with water. This dyestuff differs materially from that formed by heating Alizarin bordeaux merely with ammonia (Eng. Pat. 8702, of 1891 this Journal, 1892, 514), the latter giving a blueish-red solution in sulphuric acid, whilst the pure new product dissolves in sulphuric acid with a yellowish-red colour. The new dyestuff produces on chromed wool intense greenish-blue shades retaining their colour in artificial light. As another example of the same process, the manufacture of a similar colouring matter from Alizarin blue paste is described.

The product combines with alkaline bisulphites forming compounds soluble in water. It yields beautiful greenish-blue shades on chromed wool. A table is given, showing the principal properties of nine colouring matters of the series, namely those formed from Alizarin blue, Alizarin bordeaux, Alizarin-pentaeryanine, Alizarin-hexaeryanine, hexahydroxyanthraquinone, and from the sulphonic acids of each of the last four. If the above process be carried out in the presence of sulphurous acid or a sulphite, sulphonated dyestuffs are obtained, the introduction of nitrogen ("amidation") and sulphonation thus taking place at the same time.

Sulphonated dyestuffs similar to the above may also be obtained by sulphonating the products of the action of ammonia on polyhydroxyanthraquinones with fuming sulphuric acid at 90°–100° C. The sulphonic acids yield clearer and greener shades than the unsulphonated dyes, and owing to their solubility are especially suitable for printing on wool.

The last described sulphonating process may be inverted, that is, polyhydroxyanthraquinones may first be sulphonated by the methods described in Eng. Pat. 12,715 of 1890 (this Journal, 1891, 759); Eng. Pat. 17,712 of 1890 (this Journal, 1891, 917); Eng. Pat. 12,580 of 1892 (this Journal, 1893, 596); and Eng. Pat. 8702 of 1891 (this Journal, 1892, 514), and the sulphonic acids so formed then treated with ammonia either by the process described in the last mentioned patent or by merely heating with a dilute ammonia solution at about 80° C. The isolation of the sulphonic acids of "amidated" polyhydroxyanthraquinones is best effected by acidulating the ammoniacal solution at a low temperature (to avoid decomposition and elimination of nitrogen) when the dyestuff either separates at once or on addition of salt. An example is given. The processes described in Eng. Pat. 15,246 of 1892 (this Journal, 1893, 598), and in the fifth claim of Eng. Pat. 15,325 of 1892 are hereby disclaimed.—T. A. L.

*Improved Process of Making Solid and Friable Colouring Matters from Logwood Extract and other Dye-wood Extracts.* P. R. J. Willis, London.—From W. J. Matheson, New York, U.S.A. Eng. Pat. 24,365, December 18, 1893.

The product obtained from logwood by the process claimed in Eng. Pat. 2316 of 1893 (this Journal, 1893, 598) requires the addition of a small amount of acid to the dye-bath which in certain cases is objectionable. According to the present patent, a more valuable product is obtained having a higher tinctorial value by the addition of ammonium carbonate to a hot extract of logwood of high gravity. The following is the method employed. Logwood extract of about 70° Tw. is heated to about 65° C., and thoroughly mixed with 7 per cent. of ammonium carbonate previously dissolved in as small a quantity of water as possible. The extract is poured into shallow trays and dried at about 20° C. until the mass has become spongy and a hard crust has formed. When this is the case the trays are dried at 65°–82° C., and when thoroughly dry the mass is ground. It is not affected by atmospheric moisture, but is soluble in cold or hot water, and dyes chromed wool in the same way as cured chip logwood.—T. A. L.

*The Manufacture of Colouring Matters and of Intermediate Products related to the Rhodamine Series.* J. Y. Johnson, London. From "The Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 24,543, December 20, 1893.

By treating the rhodamines derived from phthalic or succinic acids with ammonia under pressure a replacement of oxygen by the imido group (NH) takes place. This body is not a dyestuff, but on treatment with condensation agents, such as phosphorus oxychloride or pentachloride, zinc chloride, or fuming sulphuric acid, water is split off and a new rhodamine dye yielding bluer shades is produced. If the ammonia be replaced by aniline or its homologues, analogous phenyl imides are obtained, which on sulphonation give valuable acid colouring matters dyeing bright shades on animal fibres and capable of dyeing darker shades than the basic rhodamines. About 1 kilo. of tetra-ethyl phthalic rhodamine (Rhodamine B extra) is dissolved in 5 kilos. of alcohol, and the solution is saturated in the cold with ammonia. The solution thus obtained is heated in an autoclave to 180° C. for 10 hours, and, after cooling, the crystals produced are filtered off and if necessary recrystallised from alcohol. They melt at 229° C. About 5 kilos. of the rhodamine-imide so obtained are mixed with 2 kilos. of phosphorus oxychloride and heated for two hours on the water-bath. The product is then dissolved in water, filtered, and the new dyestuff salted out. The new colouring matter gives violet-red shades on wool and silk and bluish-violet shades on cotton mordanted with tannin. The following method is given for the preparation of a dyestuff by the action of aniline on rhodamine:—About 1 kilo. of tetra-ethyl phthalic rhodamine is treated with 3 kilos. of aniline under an inverted condenser for four hours. After the excess of aniline has been removed the product is purified by washing with alcohol or recrystallising, and 1 kilo. of the rhodamine-phenyl-imide so formed, is then dissolved in 5 kilos. of 100 per cent. sulphuric acid and sulphonated on the water-bath by gradually adding small quantities of fuming sulphuric acid containing 23 per cent. SO<sub>3</sub>. The sulphonation is complete when a sample is completely soluble in dilute soda solution. The melt is then poured into water, the sulphonic acid filtered off, and converted into the sodium salt. This salt is sparingly soluble in cold water, but by further sulphonation a salt more readily soluble can be obtained. This forms a red powder easily soluble in water, giving a bluish-red solution with a yellowish-red fluorescence. The dyestuff gives red fluorescent shades on wool, the dark shades being especially brilliant, and the colouring matter is said to be in a high degree fast to light.—T. A. L.

*The Production of Azo Dyestuffs Derived from  $\alpha_1, \alpha_2$  Azimido-naphthalene.* S. Pitt, Sutton, Surrey. From L. Cassella and Co., Frankfurt-on-the-Maine, Germany. Eng. Pat. 24,714, December 22, 1893.

According to Ger. Pat. 63,507, 1,1'-naphthylene diamine disulphonic acid combines with diazo compounds, and these products, according to Ger. Pat. 70,031, are converted into the corresponding azo derivatives of 1,1'-amidonaphthol disulphonic acid by treating them with mineral acids or caustic alkalis. The same effect cannot be produced by nitrous acid since this reagent produces an azimido body the substance formed having the characteristic group—

It is stated that all the azo derivatives of the mono- and di-sulphonic acids of 1,1'-naphthylene diamine show this reaction, and the colouring matters produced show a certain similarity to the corresponding azo derivatives of the 1,1'-dihydroxy-naphthalene sulphonic acids. They are

said to be easily soluble and to be very fast to light. The method employed is as follows:—27.6 kilos. of *p*-nitraniline are diazotised and combined in an acid solution with 75 kilos. of 1,1',3,3'-naphthylene diamine disulphonic acid. When the combination is complete, a solution of 23 kilos. of sodium nitrite is run in and the dye stuff which had separated goes into solution. After a short time yellowish red needles of the azimido dyestuff begin to separate and can be filtered off after a few hours. The colouring matter dyes wool magenta red from an acid bath. Similar products are obtained if the *p*-nitraniline be replaced by *o*- or *m*-nitraniline, nitrotoluidine, amidonaphthalene or nitro-naphthylamine, the shades varying from bluish red to reddish violet. Colouring matters having similar properties but rather less soluble are obtained by replacing the above naphthylene diamine disulphonic acid by the 1,1' naphthylene diamine sulphonic acid of Eng. Pat. 1613 of 1893 (this Journal, 1891, 244).—T. A. L.

*The Production of Dyestuffs from Diazo-safranines and Amidonaphthols.* S. Pitt, Sutton, Surrey. From L. Cassella and Co., Frankfurt-on-the-Maine, Germany. Eng. Pat. 24,715, December 22, 1893.

THE dyestuffs referred to, obtained by the action of diazotised safranines on certain of the amido-naphthols, are basic and dye cotton mordanted with tannin, blue-black shades. As an example of the method employed, the following details are given:—35 kilos. of safranine, C<sub>20</sub>H<sub>14</sub>N<sub>4</sub>O<sub>2</sub>, are dissolved in water and diazotised with hydrochloric acid and 7 kilos. of sodium nitrite, and the diazo compound thus produced is added to a solution of 16 kilos. of 1,2'-amidonaphthol (Ger. Pat. 69,458) in 12 kilos. of hydrochloric acid. The formation of the dyestuff is complete in a short time, and after salting out, it is filter-pressed and dried. It dissolves in water with a bluish-black colour and dyes cotton mordanted with tannin, an intense blue-black. The combination may also take place in an alkaline solution, the dyestuff so obtained only differing slightly from that obtained in acid solution. Similar dyestuffs are also produced by substituting the 1,4', 1,1', 2,2', or 1,3'-amidonaphthol for that in the example described above.—T. A. L.

*The Manufacture and Production of New Colouring Matters.* C. Dreyfus, Clayton, Manchester. Eng. Pat. 24,870, December 27, 1893.

By combining the diazo compounds of *m*- or *p*-nitraniline, of nitro-toluidines, or of nitro-xylidines with the sulphonic acids of dehydro-biotoluidine, primuline base, dehydrothio-*m* xylidine or dehydrothio- $\psi$ -cumidine, the patentee obtains colouring matters ranging from greenish yellow to orange-shades, which dye unmordanted cotton. The combinations may take place in an alkaline or acetic acid solution, and the following details are given:—13.8 kilos. of *p*-nitraniline are dissolved in 500 litres of boiling water and 100 kilos. of 34 per cent. of hydrochloric acid, and after cooling diazotised with 7 kilos. of sodium nitrite. The diazo solution is run into a solution of 34 kilos. of dehydrobiotoluidine sulphonic acid and 80 kilos. of sodium carbonate in 1,000 litres of water, and after standing 24 hours the whole is boiled up and the colouring matter salted out and filtered off.—T. A. L.

*The Manufacture or Production of Sulpho Acids of the Naphthalene Series derived from Naphthalene  $\beta_1 \beta_3$  Disulpho Acid or Naphthalene  $\beta_2 \beta_3$  Disulpho Acid.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 25,074, December 30, 1893.

THE naphthalene tetrasulphonic acid of Senhofer (Ber. 8, 1486) is a mixture of at least two isomeric acids and a mixture is also obtained, according to the method described in Ger. Pat. 40,893, in which 1 kilo. of naphthalene is heated with

5 kilos. of 10 per cent. anhydride at 160° C. In the present patent, methods are given for producing pure naphthalene tetrasulphonic acids by sulphonating 2,3'- or 3,3'-naphthalene disulphonic acid. The process consists in heating the calcium salt of the acid, previously dried at 200° C., with three times its weight of fuming sulphuric acid, containing 25 per cent. of anhydride, first of all for four hours to 90° C. At this stage a naphthalene trisulphonic acid is produced. The vessel is then closed and the temperature is raised for six hours to 260° C. The melt is dissolved in water, the excess of sulphuric acid removed by lime and after converting into the sodium salt, the solution is evaporated. Salt is then added which precipitates the sodium salt of the naphthalene tetrasulphonic acid. The tetrasulphonic acid derived from the 2,3'-naphthalene disulphonic acid when heated with caustic soda yields two new naphthol trisulphonic acids, the sodium salts of which are separated by their difference in solubility in water. If in the fusion, which in both cases is conducted under pressure, a larger quantity of soda be employed and the temperature is also higher, the tetrasulphonic acid is converted into two dihydroxy-naphthalene disulphonic acids, which are termed R and Y acids, the proportion of the two being about 3 : 7. The former acid separates in long hair-like needles and aqueous solutions of its neutral salts show a violet fluorescence. The Y acid is much more soluble and is separated by means of its potassium salt. Aqueous solutions of the neutral salts of this acid are deep yellow and show a green fluorescence.—T. A. L.

*The Manufacture or Production of Beta, Beta, Dihydroxy-naphthalene Beta, Beta, Disulphonic Acid.* H. E. Newton, London. From "The Farbentabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 25,074, December 30, 1893.

This patent describes another method for the production of 2,2',3,3'-dihydroxynaphthalenedisulphonic acid which has already been prepared according to Eng. Pat. 16,199 of 1893 (this Journal, 1894, 876), by sulphonating 2,2'-dihydroxynaphthalene. According to the present method the same product is obtained from 2,3,3',2'-naphthol trisulphonic acid by heating with caustic soda under pressure. 50 kilos. of the sodium salt of  $\beta$ -naphtholtrisulphonic acid are heated with 100 kilos. of caustic soda and 50 litres of water in an autoclave for 6—10 hours to 220°—300° C. until a sample no longer contains naphtholtrisulphonic acid which separates in needles. The melt is then mixed with acid when the acid sodium salt of the dihydroxynaphthalenedisulphonic acid separates out as a crystalline powder. Its alkaline solutions show a bluish-green fluorescence. When heated with 20 per cent. sulphuric acid to 200° C. it yields 2,2'-dihydroxynaphthalene, melting at 185° C., by means of which its constitution was determined.

—T. A. L.

## V.—TEXTILES: COTTON, WOOL, SILK, Etc.

*Artificial Production of Woollen Crape.* F. Binder. Bull. Soc. Ind. Mulhouse, June 1894, 267—268.

THE raw woven woollen crape is crabbed to remove stiffening, first, for 10 minutes in water at 25° C., and then in boiling water for 15—20 minutes. It is then dried in the drying-room (not on drums), and is given a slight stiffening with gum tragacanth. This process is applicable to rough and smooth woollen, and also to cotton crapes.—H. I.

## PATENTS.

*An Improved Method of Preventing Spontaneous Ignition of Liquid Hydrocarbons used for Cleansing and other Purposes.* M. M. F. Richter, Hamburg, Germany. Eng. Pat. 20,818, November 2, 1893.

THE object of this invention is to prevent spontaneous ignition of liquid hydrocarbons, such as benzene, toluene, naphtha, gasoline, petroleum, &c., which is caused by frictional electricity produced on rinsing woollen or silk goods in the hydrocarbon. About 2 per cent. of anhydrous magnesium oleate, which is termed "antibenzene-pyrene," is dissolved in the hydrocarbon, and this solution is said to act antielectrically.—J. J. K.

*Improvements in the Production of and in Apparatus for Producing Artificial Silk.* F. Lehner, Zurich, Switzerland. Eng. Pat. 24,003, December 13, 1893.

IMPROVEMENTS are described in the production of artificial silk according to Eng. Pat. 11,831 of 1891 (this Journal, 1892, 680) and 22,736 of 1892 (this Journal, 1893, 1024). The solutions used frequently attack the metal of which the conducting tubes are composed, and this tends to discolor the product. This defect is obviated by the use of aluminium tubes which are not attacked by the solutions.

When, in drawing the filaments, the supply is interrupted by simply closing the tap, the orifice of the outlet tube often becomes choked and cannot be cleared. To avoid this a tight-fitting rubber cap is drawn over the aperture before closing the tap; the tube does not then become choked and the supply can be restarted immediately on removing the cap, even after many days' interruption.

The drying chambers for recovery of the solvents are omitted, and the solvents are recovered by heating the filaments on spools or in hanks, in water or other liquid to distil off the alcohol and ether. It is stated that this last improvement increases the tensile strength of the fibre.

—R. B. B.

*Improvements relating to Drying and Carbonizing Apparatus for Textile and other Matters.* G. Dasse and C. Fettweis, Brussels. Eng. Pat. 23,124, December 1, 1893.

A DRYING or carbonizing machine of any kind is enclosed in a chamber provided with a special aperture close to the entrance for the material. Through this aperture by means of a ventilator, the saturated hot air is drawn, passed through a heating apparatus, and thence again into the chamber. The air at the higher temperature is capable of taking up a further quantity of moisture, and the operation may be repeated by raising the temperature of the heater. As drying proceeds, the gaseous mixture in the machine contains less and less air, and the drying is performed by superheated vapour.

For wool the process may be advantageously carried out with a drying apparatus in which the wool passes between a number of superposed endless aprons. The wool is entered at the top and passes downwards, the outlet for the saturated gas being situated above the series of aprons.

—R. B. B.

*Improvements in Means for the Production of Waterproof Ventilating Cloth.* V. Hendrichs, Hückeswagen and Berlin, Germany. Eng. Pat. 12,954, July 4, 1894.

A SOLUTION is prepared containing 2,372.5 grms. of pure alum, 550 grms. lead acetate, and 400 grms. tannin, in 20 litres of distilled water. Lead sulphate is precipitated and the supernatant liquid, containing aluminium and potassium acetates and tannin, is carefully drawn off. Cloth steeped in this solution and allowed to dry is practically waterproof, but permits the free passage of air.—R. B. B.

## VI.—DYEING, CALICO PRINTING, PAPER-STAINING, AND BLEACHING.

*The Glossing of Woollen Crapes.* Edward Kopp. Bull. Soc. Ind. Mulhouse, June 1894, 266.

The unbleached woollen fabric is stirred by hand for five minutes in a wooden trough containing a solution of zinc sulphate heated to the boil. The zinc sulphate solution (200 litres) contains 500 grms. of the sulphate per litre of water and indicates 23° B. at the boiling point. The piece after this treatment is washed in another trough for five minutes with boiling water, and afterwards in cold, until the washings no longer show an acid reaction. It is then scoured and bleached in the usual way. Each piece is then found to have taken up some 7 kilos. of zinc sulphate. The crape thus obtained resists the various operations of bleaching very well, and only slightly "yellows" on steaming.—H. I.

*Zinc Ferrocyanide as a Fixing Agent for Aniline Colours upon Aniline Black.* Ferd. Oswald. Bull. Soc. Ind. Mulhouse, June 1894, 261—265.

The author obtains by double decomposition a precipitate of an insoluble ferro- or ferri-cyanide on the fibre and finds that aniline colours on fabrics thus prepared will stand treatment in a Mather and Platt machine very well, whereas if potassium ferrocyanide be used alone, the colours obtained are not fast to soaping.

The best results were obtained with zinc ferrocyanide and on aniline black as a ground.

The fabric is padded with aniline hydrochloride, potassium chlorate, and potassium ferrocyanide, and then printed with a thickened solution consisting of the aniline colour, 5 per cent. of zinc sulphate, and 20 per cent. of magnesium acetate (which acts as a resist for the aniline black).

With Methylene blue the quantities used were as follows:—

- 500 grms. of magnesium acetate of 20° B.
- 400 grms. of dry powdered starch.

heated together and then mixed in the cold with—

- 15 grms. of Methylene blue dissolved in
- 100 grms. of acetic acid of 6° B., and
- 60 grms. of zinc sulphate.

Good results were also obtained with Magenta and Safranine, Auramine, Thioflavine, Malachite green, the different violets, Rhodamine, &c. By admixture of the above colours all shades may be produced.—H. I.

*Coloured Discharges on Aniline Black Grounds.* W. E. Kay. Bull. Soc. Ind. Mulhouse, August and September 1894, Part II., 85.

This was a communication from the author, of the firm of Walter Crum and Co. (The Thornliebank Co., Glasgow), respecting the statement in the bulletin of May 7, 1894, that M. Camille Schoen had succeeded in effecting the fixation of basic coal-tar colours as reserves under aniline black in the presence of hydroferrocyanic acid alone, without the aid of tannin. Mr. Kay claimed priority of discovery of the process (this Journal, 1893, 1027) and forwarded patterns illustrating the process. The principal constituents of Kay's reserve are acetate of soda and acetate of zinc, the latter constituent being employed for the purpose of producing insoluble ferrocyanide of zinc, which, it is said, more effectually serves to fix the basic coal-tar colours (Methylene blue, Rhodamine, &c.) used. In certain cases the reserve also contains bisulphite of soda or acetate of chrome. Thiosulphates and sulphocyanides are less suitable as reserving agents. The procedure is the ordinary one, namely, padding of the black, drying, printing the reserve, and steaming. (See also this Journal, 1893, 41, 1027; 1894, 485).—W. E. K.

*Azo Colour Resists on Steam-printed Indigo (Schlieper Method).* L. Bloch and Ch. Schwartz. Bull. Soc. Ind. Mulhouse, June 1894, 260—263.

The authors recommend the use of sulphur as a resist in steam indigo printing.

*Direct Colours.*—The best results were obtained with the following colours:—Chrysamine R (Bayer) gives a yellow, Alkaline orange G (Dahl) a lemon yellow, Eriochrome (Berlin) a rose, Benzopurpurin 1 B (Bayer) a strawberry colour, all undergoing a change in shade.

The general method of application may be given as follows:—110 grms. of colour, 330 grms. of sodium phosphate, 115 grms. of soap, 3,300 grms. of powdered starch, and 8 litres of hot distilled water, made into a paste with 2,200 grms. of precipitated sulphur. This is printed on the fabric, which is afterwards dyed as usual. The colours obtained in this way are not moderately fixed; they resist a slight soaping sufficiently well, but are attacked by the sulphur in presence of soda, giving weaker shades. Chrysamine suffers the least.

*Azo Colours produced on the Fabric.*—The procedure consists in printing the thickened diazo compound mixed with precipitated sulphur on a fabric previously padded with sodium naphtholate and glucose (which are without action on the indigo), then dipping in the indigo vat, oxidising, and washing. Resist reds, yellows, and oranges of great brilliancy and fastness may be thus produced on indigo grounds. Most of the colours are nevertheless more or less changed in shade.

Xyldine red gives an orange; Para nitramine red is destroyed. The reds obtained from cumidine and  $\beta$ -naphthylamine, and the claret from  $\alpha$ -naphthylamine, do not suffer much loss in intensity.

The red from cumidine is the most brilliant; a red of better shade is obtained from a mixture of three parts of  $\beta$ -naphthylamine and one part of cumidine. Two parts xyldine and one part of  $\beta$ -naphthylamine likewise give a good red.

The colours obtained from the diazo-chloride are somewhat dull. This may be rectified by the addition of sodium acetate (40 grms. per litre of padding) to the padding mixture.

In the association of azo-colours with direct colours and whites, it is necessary to use for the latter a stronger resist than usual, since the fabric is padded with sodium naphtholate.

To prepare the padding mixture, the glucose and sodium naphtholate are dissolved and then mixed in the cold, in order to prevent decomposition of the glucose by the soda.

For the same reason, the pieces should not be raised to too high a temperature in drying. In fact, all the precautions that are usual with diazo-colours should be taken. The addition of "oil for red" to the padding mixture produces more vivid and darker blues and a more brilliant resist.—H. I.

*The Employment of Ammoniacal Salts as Resists for Caustic Soda, Aluminate of Soda, &c.* E. Bontemps. Bull. Soc. Ind. Mulhouse, 1894, 285—286.

When, in printing, a resist is required for caustic soda, aluminate of soda, &c., it is possible to make use of an organic acid, e.g., tartaric or citric. But when these resists have to be applied on a ground of Turkey-red, or on a fabric mordanted with tannin and antimony, these acids are very unsuitable, as they, and also their sodium salts, partially dissolve the alizarin lake or the tannate of antimony.

This defect is not shared by ammonium salts, such as the nitrate, which form the best resists for these alkaline mordants. The reactions which occur are—

or—

In the latter case the metal is precipitated in the form of hydroxide, and is removed during clearing. As there is a

tendency for the resist to spread in the presence of moisture, the steam to which the fabric is exposed in the "Mather and Platt" should be well dried.

A good resist is made thus:—10,000 grms. of nitric acid at 37° B. are neutralised with 7,500 grms. ammonia (sp. gr. 0.92), and the compound poured with constant stirring on to 1,250 grms. of starch, mixed with 1,250 grms. water. The resist is then cooled and is ready for use. Care must always be taken that an excess of alkali is present to prevent the transformation of starch into glucose.—R. B. B.

*Printing Processes of the Japanese.* M. Tétaz. Bull. Soc. Ind. Mulhouse, 1894. Part II., 85.

M. Tétaz communicated to the Society an account, from personal observation, of the printing process employed by the natives of Japan. The process is based on the use of a resist paste prepared from rice, which is spread by means of a palette-knife on to a paper-stencil, and under this the tissue is placed. This reserve is successfully employed for vat blues, for which purpose the Japanese reduce the indigo by means of fermentation.—W. E. K.

*The Production of Fast Reds in Calico Prints without Mordant.* J. Dépierré. Bull. Soc. Ind. Mulhouse, 1894, 201—202.

In the Dutch East Indies the reds in the native calico prints or "batieks" are produced without the use of alumina or other metallic mordant. The fabric undergoes a lengthy preparation with oil, consisting of alternate steeping in an emulsion of sesame oil and alkali, and exposure to sun and air. This may be continued for about nine weeks. A wax resist is then applied by means of an apparatus shaped like a pipe, the bowl forming the reservoir, and the melted wax flowing from the orifice in the stem. The stem is moved about over the fabric to trace out the design, and the "batticker" is often provided with a number of these instruments, some with one orifice, others with two, three, or more.

The resist being applied, those portions of the fabric which are to be coloured are rubbed over with a paste made of 3 parts keedoe, 1 part djirack, and a sufficient quantity of water. This treatment is repeated nine times; clearing and washing with boiling water complete the production of the red.

*Keedoe* (this Journal, 1894, 940) is the powdered root-bark of *Morinda Citrifolia* or Sooranges (Schützenberger, *Traité des Matières Colorantes*, Vol. II., p. 419). The colouring matter of this root does not dye mordanted fibres in the ordinary manner. The colouring principle, morindin, gives a yellow precipitate with alum, a red precipitate with lime or baryta. Probably the lime present in the water plays the part of a mordant.

*Djirack* is an astringent product of the bark of *Symplocos fasciculata*, *S. racemosa*, and other varieties (Wardle, *Catalogue of Dyestuffs and Tannin Matters of India*, 1878).—R. B. B.

#### PATENTS.

*Process for Dyeing Textile Materials in Cops or Spools with Alizarin and other Mordant Dyes.* F. Erban, Hoechst a/Main, and L. Specht, Marienthal, Germany. Eng. Pat. 15,829, August 21, 1893.

THE insoluble mordant dyes have been hitherto considered unsuitable for cops and spools. They can, however, be applied in the form of alkaline solutions. The dyes applicable by this method are the anthracene colouring matters and other mordant dyes, such as gallein, coerulein, galloflavin, gambines, dioxine, &c., &c. The cops are impregnated with a solution of the colouring matter, together with an alkali, e.g., ammonia, sodium hydrate, carbonate, or phosphate, alkaline soap, Turkey-red oil, or an organic base (amine). The fugitive alkaline mediums have the advantage that in drying, they evaporate and leave the colouring matter insoluble on the fibre. Other substances which do not precipitate the colouring matter may be added to the dyebath, e.g., aluminate or stannate of soda, soap, &c. After impregnating the fibre the material is dried or

steamed, and then treated with an aluminium, chromium, iron, or other mordant, preferably in the form of acetate. The formation of the colour lake is completed by steaming; Washing, soaping, and clearing may increase the brightness of the dye. An example of the process is as follows:—

*To Dye Turkey-Red on Cops.*—First bath—

14 lb.  $\frac{1}{4}$  oz. Alizarin R. (20 per cent.)  
5 galls.  $\frac{1}{3}$  pints water (free from lime).  
 $2\frac{1}{2}$  pints ammonia (25 per cent.)  
 $7\frac{1}{2}$  pints Turkey-red oil (80 per cent.)

After impregnation the cops are subjected to centrifugal action and dried at 50° C., then treated with the second bath—

4.52 galls. water.  
 $5\frac{1}{2}$  pints acetate of alumina 15° Tw.  
3 pints acetate of lime 28° 4 Tw.

They are subjected to centrifugal action and steamed one hour without pressure,  $\frac{1}{2}$  hour at a pressure of one atmosphere, and  $\frac{1}{2}$  hour at a pressure of two atmospheres. After steaming, the colour can be soaped, or cleared with a mixture of soap, soda, and tin salt.—R. B. B.

*Improvements in or relating to the Clouding of Textile Materials in Dyeing.* A. J. Boulton, London. From P. V. Renard, Fontenay-s.-Bois, France. Eng. Pat. 22,498, November 23, 1893.

FLAT rings or perforated discs are held apart at fixed distances and in parallel position by suitable bracing. If the discs have a hub they are mounted on a shaft, with smaller rings interposed to keep them in position. The textile material, in the form of sheets or strips of fibres, or spun threads, is arranged in layers of as uniform thickness as possible round the periphery of the discs, and firmly bound to their edges by impermeable cords or ribbons. When the whole is immersed in the dyebath, those portions bound against the discs remain uncoloured, whilst the dye has free access to both sides of the remainder of the layer of material.—R. B. B.

*A Process for Marking Indelibly on Paper, Fabrics, and like Receptive Material.* C. F. Cross and E. J. Bevan, London. From C. Beadle, Boston, U.S.A. Eng. Pat. 6887, April 6, 1894.

THE material is moistened with water or with some other solution conducting electricity, and laid on a metal plate connected with one pole of an electric battery or generator. The other pole is connected to a metallic style or stamp. On writing with this style a current of electricity passes through the material, and an electrolytic action takes place by which portions of the metal or of the style are dissolved and deposited on the material in the form of the writing. If the deposit is not readily visible it may be treated with a suitable reagent; e.g., a deposit of copper or of iron may be developed with potassium ferrocyanide. Or, the paper may be moistened with a solution of the required reagent, or the style may be dipped in such a solution.

In some cases without solution of the metal some change is effected in the material, such that when moistened with water the marking is rendered visible. This occurs when a platinum style or stamp is used.

Paper or fabric may be marked in the same way by passing it in a moist condition between a pair of rollers, each of which is connected to one terminal of the battery.

—R. B. B.

*Improvements in Calico-printing Machinery.* M. MacPhail, Busby, Lanark. Eng. Pat. 17,885, September 20, 1894.

INSTEAD of supporting the colour-furnishing roller in bearings on its colour box, the spindle of the roller is extended, and its ends supported in bearings, capable of delicate horizontal and vertical adjustment, fixed to side brackets which are secured to the machine framing. The result is an increased steadiness and freedom from vibration of the roller.—R. B. B.

## VII.—ACIDS, ALKALIS, AND SALTS.

*Solubility of Certain Inorganic Salts in Organic Liquids.*  
S. von Lascezyński. Ber. 1894, 27, 2285–2288.

100 parts by weight of ethylic ether dissolve 0.11 part of  $\text{CuCl}_2 + 2\text{Aq}$  at 16° C.; 6.35 parts and 6.38 parts of  $\text{HgCl}_2$  at 0° and 35.5° respectively; 0.97 part of  $\text{HgI}_2$  at 36°; and 11.41 parts and 11.38 parts of  $\text{SnCl}_2 + 2\text{Aq}$  at 0° and 35.5° respectively.

100 parts by weight of ethylic acetate dissolve 0.44 part and 0.2 part of  $\text{KCNS}$  at 0° and 79° respectively; 0.08 part and 0.26 part of  $\text{COCl}_2$  at 14° and 79° respectively; 35.53 parts and 73.44 parts of  $\text{SnCl}_2 + 2\text{Aq}$  at 22° and 82° respectively; 28.92 parts and 35.98 parts of  $\text{HgCl}_2$  at 0° and 83° respectively; and 1.56 parts and 4.36 parts of  $\text{HgI}_2$  at 17.5° and 76° respectively.

100 parts by weight of acetone dissolve 2.38 parts and 1.21 parts of  $\text{KI}$  at 22° and 56° respectively; 20.75 parts of  $\text{KCNS}$  at 23°; 4.60 parts and 2.14 parts of  $\text{LiCl}$  at 0° and 58° respectively; 9.28 parts of  $\text{CoCl}_2$  at 22.5°; 17.06 parts  $\text{CoCl}_2 + 2\text{Aq}$  at 25°; 1.40 parts of  $\text{CuCl}_2$  at 56°; 8.92 parts of  $\text{CuCl}_2 + 2\text{Aq}$  at 13.5°; 98.35 parts and 126.8 parts of  $\text{HgCl}_2$  at 0° and 18° respectively; 3.36 parts and 6.07 parts of  $\text{HgI}_2$  at 18° and 58° respectively; 0.35 part of  $\text{AgNO}_3$  at 14° and 59°; 0.02 part of  $\text{PbI}_2$  at 59°; and 41.70 parts of  $\text{Bi}(\text{NO}_3)_3 + 5\text{Aq}$  at 19°.

100 parts of amyllic alcohol dissolve 0.48 part and 3.15 parts of  $\text{KCNS}$  at 13° and 133.5° respectively; 0.66 part and 9.57 parts of  $\text{HgI}_2$  at 13° and 133.5° respectively; 0.02 part of  $\text{PbI}_2$  at 135.5°; 0.54 part and 1.80 parts of  $\text{HgCl}_2$  at 15° and 84° respectively; and 0.22 parts and 1.24 parts of  $\text{HgI}_2$  at 15° and 84° respectively; 100 parts by weight of aniline dissolve 0.50 part and 1.1 parts of  $\text{PbI}_2$  at 13° and 184° respectively.

100 parts by weight of pyridine dissolve 0.26 part and 0.11 part of  $\text{KI}$  at 10° and 119° respectively; 6.75 parts and 3.21 parts of  $\text{KCNS}$  at 0° and 115° respectively; 7.78 parts and 14.26 parts of  $\text{LiCl}$  at 15° and 100° respectively; and 0.1 part and 8.6 parts of  $\text{AgI}$  at 10° and 121° respectively.—A. R. L.

*The Behaviour of Sodium Peroxide towards Alcohol.*  
J. Tafel. Ber. 27, 2297.

By pouring alcohol on sodium peroxide, about half of the latter goes into solution. This solution is strongly alkaline; on diluting with water and acidifying with sulphuric acid, it only very slightly reduces permanganate solution, showing that it contains only a trace of "active" oxygen.

The part insoluble in alcohol is a white, sandy, easily filtered powder, which differs materially from the original substance. This difference shows itself most distinctly in their behaviours respectively, when heated. Sodium peroxide may be heated to a high temperature without changing, and begins to give off oxygen only at a red heat; but this new substance liberates oxygen rapidly at a very low temperature. If heated quickly in an open tube, the oxygen is set free with explosive violence and ignition.

At a low temperature the new substance is changed into an orange yellow mass, which melts on further heating, giving off oxygen and a little water, leaving a residue which is chiefly sodium hydrate. Owing to the extreme liability of the substance to decompose at ordinary temperature, even in an atmosphere of carbon dioxide, the author had some difficulty in analysing it. The constitution he assigns to the substance is  $\text{HNaO}_2$ , and the equation showing the action of alcohol on sodium peroxide—

This new body is plainly identical with the hydrate obtained by the author by the action of alcoholic mineral acids on sodium peroxide (this Journal, 1894, 885).—H. M.

## PATENTS.

*Improvements in the Preparation of Cyanogen Compounds.*  
J. J. Hood and A. G. Salmon, London. Eng. Pat. 21,239, November 8, 1893.

As carbon bisulphide and ammonia may be caused to react to produce hydrogen sulphide and sulphocyanic acid, so the inventors find that a similar reaction takes place when carbonic acid is substituted for carbon bisulphide, the products being water and cyanic acid. The same analogy holds good with cyanides of the bases. Just, for instance, as sodium sulphocyanide heated with a reducing agent, such as zinc, gives sodium cyanide and zinc sulphide, so sodium cyanate, similarly treated, gives sodium cyanide and zinc oxide.

In applying these reactions to the production of cyanogen compounds, it is not necessary to use carbonic acid gas, for which a carbonate of the required base may be substituted, or two carbonated bases may be used. Thus, to obtain sodium cyanide, sodium carbonate or bicarbonate is incorporated with a reducing agent, as zinc, manganese, or lead, and the mixture is heated in a current of ammonia; the sodium cyanide formed is washed out from the zinc oxide, and is purified by suitable means. The reaction is thus expressed:—

As only half the base is, in this process, converted into cyanide, the reaction may advantageously be completed by passing carbonic acid over the heated mass simultaneously with the ammonia. Also, it is sometimes found better to employ zinc in conjunction with carbon, so that the former would reduce the oxy-cyanide to cyanide, and the latter in turn reduce the oxide of zinc formed, to the metallic state, thereby avoiding the action that takes place to a greater or less extent between the sodium or potassium hydrates and the zinc oxide. An oxide or carbonate of zinc, manganese, or lead, with a reducing agent, such as carbon, may be used instead of the metal.—E. S.

*Improvements in the Manufacture of Sulphocyanides, in the Recovery of By-Products, and in Apparatus therefor.*  
J. Brock, A. E. Hetherington, F. Hurter, and J. Raschen, Widnes. Eng. Pat. 21,451, November 10, 1893.

THE process consists in heating together 100 parts of carbon bisulphide, ammonia solution equal (preferably) to 45 parts of dry ammonia, and 200 parts of slaked lime, with water sufficient to admit of suitable agitation. The proportion of ammonia used, is double that required by the equation—

in order to obviate the formation of calcium sulphocarbonate.

The apparatus employed is a horizontal cast-iron or steel cylinder, jacketed for steam except at the ends, provided with an agitator, a pressure gauge, safety valve, sampling tap, a pipe for admission of the liquids, and an opening with lid for the sieved lime. In front of the short, wide pipe for receiving the lime, a plate is attached to the top and sides of the cylinder, reaching below the surface of the liquor, to prevent escape of ammonia when the lime is introduced. The top of the cylinder is connected by a pipe and valve to a cooling worm, and this to a pair of coke-charged condensers on which water or weak ammonia condensed from a former operation is sprayed. The safety valve is so arranged that in case the pressure rises too high, the escaping vapours pass to the ammonia condensers. The heating, as indicated by a permanently fixed thermometer, is carried at least to 100° C., and if the pressure is not too high, live steam may be admitted to the cylinder through a pipe provided with a back-pressure valve. When the reaction is complete, the valve admitting passage to the ammonia-condensers is opened, and live steam is passed in until any excess of ammonia is driven off and collected for future use. The charge is then transferred to a vacuum filter, and the precipitate is washed, the washings being used instead of water in the next operation.

Carbonic acid gas is forced through the filtrate, and the hydrogen sulphide set free, is collected and utilised. Or the gas may be passed through the liquor before filtration, in a suitable apparatus admitting of collection of the hydrogen sulphide in this case derived both from the soluble and insoluble calcium sulphides, and thus all the sulphur not contained in the sulphocyanide may be recovered. In either case the solution of calcium sulphocyanide obtained may be evaporated. But if it be desired to obtain the potassium or sodium salt, the solution is treated with the corresponding carbonate, and the calcium carbonate precipitated is separated. The solution of potassium or sodium sulphocyanide is then dried up or crystallised.—E. S.

*Improvements in obtaining Cyanides and Ammonia direct from the Air, or other Gases containing Nitrogen.* J. Young, Glasgow. Eng. Pat. 24,856, December 27, 1893.

Four parts of an alkali carbonate or oxide, are mixed with one part of the carbonate or oxide of an alkaline earth, and two parts of coke or charcoal, preferably paraffin coke, and the mixture is strongly heated in an iron or other suitable apparatus, through which air, or a mixture of air and a hydrocarbon gas or vapour from hydrocarbon oils or gases containing nitrogen, is passed. If the mixture is sufficiently heated to volatilise the alkali cyanide formed, the cooled gases containing the cyanide are passed through wool or cotton to retain the cyanide.

If it be desired to obtain ammonia, the heated mixture is allowed to cool a little after the cyanide is formed, and steam is then passed through the apparatus. The ammonia evolved is received in an acid to obtain an ammonium salt.—E. S.

*Improvements in or connected with the Manufacture of Bleaching Powder.* H. Gaskell, jun., Liverpool, V. C. Driffield, Widnes, A. Carey, Liverpool, and F. W. Wright, Widnes. Eng. Pat. 25,923, December 29, 1893.

THE inventors have in Eng. Pat. 1214, 1893 (this Journal, 1894, 38), described apparatus for cooling the chlorine used in the manufacture of bleaching powder, but find it desirable that it should be also dried. This is effected by connecting the successive absorption compartments to drying towers filled with coke, flints, or the like, through which, from lutes in the top, sulphuric acid is caused to trickle. The gas from one compartment enters the drying tower by a pipe near the bottom, and another pipe conveys the dried gas, first to a cooler, and then to the next absorption compartment, and so on, successively. Calcium chloride or other suitable hygroscopic substance may be used instead of sulphuric acid in drying the chlorine.—E. S.

*Improvements in or relating to the Manufacture of Chlorine.* H. Gaskell, jun., and A. Carey, Liverpool. Eng. Pat. 25,024, December 29, 1893.

IN the process for manufacturing chlorine by decomposing hydrochloric acid with air in presence of a catalytic or contact substance, the inventors add to the materials containing such substance, a substance having superior affinity for the impurities (as sulphuric and arsenic acids) contained in the acid gas. In the Deacon process for the manufacture of chlorine, in which cupric chloride is used, the substance added may be calcium chloride or magnesium chloride, which may be dissolved in the cupric solution used to impregnate the porous body serving as a vehicle. When such vehicle is burnt clay or bricks, basic material—as calcium oxide, hydrate or carbonate, or magnesia, but preferably impure calcium carbonate resulting from the manufacture of caustic soda or from the "Chance" sulphur recovery process—is used, in proportion not exceeding 7 per cent., to mix with the clay before it is burnt for the purpose stated.—E. S.

*Preventing Gases from Intermingling while passing through Liquids.* J. B. Hilliard, Glasgow. Eng. Pat. 24, January 1, 1894.

CHANNELS, preferably semi-circular in section, are placed in an inclined position in a tank containing a liquid, the lower end communicating with an entrance pipe and the higher end with an exit pipe for the gas to be passed. The channels are arranged in sets, at different elevations, and are shown with three channels to each set. As each set has a different entrance and exit, the gases travelling the higher or lower set do not mingle. The channels may be permanently fixed in the tanks, or supported by floats. The top of the tank may be inclined, so as to act as channel for one gas, while the other gases pass along other submerged channels. The invention is stated to be particularly applicable in the making of chlorine gas, "as it allows the chemist to utilise the oxygen in the atmosphere during the process without allowing the other constituents of the atmosphere to mix with and spoil or adulterate the chlorine gas."—E. S.

*Process for the Separation and Precipitation of Salts of Iron and Zinc from Solutions containing both.* A. J. Boulton, London. From E. Warzee, Brussels, Belgium. Eng. Pat. 4916, March 8, 1894.

TO a solution containing, for instance, ferric chloride, ferrous chloride, and zinc chloride, in the proportions  $\text{Fe}_2\text{Cl}_6 + \text{FeCl}_2 + 2\text{ZnCl}_2 + \text{aq.}$ , just so much of the more electro-positive metal, zinc, as corresponds to the electro-positive salt, is added. Ferrous-ferric oxide is precipitated, and the solution then contains essentially zinc chloride, contaminated, however, by a certain proportion of ferrous chloride, as is indicated by a green coloration of the liquid. Zinc in excess is then added, and the solution is boiled, whilst being subjected to a strong air-current blown into it, the process being continued for 12 to 20 hours. The green coloration then disappears, and the zinc chloride is found to be freed from iron salts. The process is represented as to its termination by the equation—

*Improvements in the Preparation and Manufacture of Hydrosulphurous Acid and Hydrosulphites.* J. Grossmann, Manchester. Eng. Pat. 16,968, August 23, 1894.

HYDROSULPHUROUS acid, or a hydrosulphite, is prepared from monosulphites or metasilphites by acting upon them in solution or suspension in water, with graduated additions of 10 per cent. sulphuric acid, followed by agitation with zinc. For example, sodium mono- or metasilphite, dissolved in sufficient water to give a solution containing from 15 to 25 per cent. of total sulphurous acid, is placed in a suitable vessel fitted with an agitator, and a pipe going to nearly the bottom of the vessel for introduction of the dilute sulphuric acid. So much acid is added, little by little, followed by gentle agitation, as may liberate from one-half to nearly all the sulphurous acid present, the temperature being kept as low as possible. When the reaction is completed, the necessary quantity of zinc or other suitable reducing agent is added with agitation. A series of tests is made to determine the proportion of sulphuric acid to be added, the final hydrosulphite being tested by Berntsen's test as modified by Rawson, or by any other suitable test. Instead of an acid, an acid salt, such as sodium hydrogen sulphate, may be used. The claim covers the use of bisulphites in the described process, as well as mono- or metasilphites or mixtures of these.—E. S.

*Improvements in Salt Evaporators.* T. Craney, Bay City, Michigan, U.S.A. Eng. Pat. 17,275, September 11, 1894.

AN upright cylindrical vessel, with ends of conical shape, is fitted with steam pipes for heating the saline liquid contained therein. The heavy crystals as they form, fall down a vertical leg, forming the lower outlet of the vessel, and from thence are removed by means of a conveyer or chute,

while the vapour formed is carried over by a goose neck, and condensed by means of water circulating in a ring pipe upon the goose neck. The condensed water is discharged by means of a pipe depending from the goose neck and dipping under water below, so as to form a water seal. Water is conveyed to the condensing ring by means of a supply pipe in connection with a centrifugal or other pump.—E. G. C.

**Improved Apparatus for the Condensation of Nitric Acid and other Vapours.** H. E. Newton, London. From E. Hart, Easton, U.S.A. Eng. Pat. 17,289, September 11, 1894.

The apparatus has a series of pipes arranged one above the other, preferably slightly inclined, in combination with a retort and receiver, whereby the vapour is divided on its path, and condensed by the cooling effect of water or other liquid sprinkled upon the pipes.

In the above drawing the vapour passes from the retort A through the pipe B into the vessel C, and thence through the vertical pipe D into the series of slightly inclined tubes E, having exit through the vertical pipe F. The supply of water through the pipe G, perforated or slotted above the condensing pipes, may be so regulated as to completely evaporate on these pipes; or there may be a surplus, carried off by the trough K and pipe k. The liquid condensed in the pipes E flows into the vessel C, and is thence conveyed by the siphon H into the receiver I, which, in the case of nitric acid, it reaches boiling hot, so that "no red oxides of nitrogen or chlorine shall be dissolved in it." The apparatus may be varied in some respects, as by arranging the tubes E horizontally, or inclined towards the pipe F, in which latter case that pipe must communicate with the vessel C. The pipes E are preferably of glass, and the vessel C and the vertical pipes of stoneware, glass, or other acid-resisting material. Although the apparatus has been described in connection with the preparation of nitric acid, it is applicable also to the condensation of other similar vapours.—E. S.

**Improvements in the Manufacture of Sodium Diborate or Borax.** J. Ascough, Birmingham. Eng. Pat. 17,556, September 15, 1894.

Caustic soda is stirred in a circular pan, to which heat is applied, with a stated proportion of water, and dissolved, when boracic acid is added by degrees, the agitation being maintained till the combination is complete; the liquid is then evaporated at 100° C. until a trial sample on being stirred while cooling is in a granular condition. The source of heat is then withdrawn, agitation being maintained in a circular direction until the mass is granulated. If the borax

is to be produced in a semi-pulverulent state, the agitation is more vigorous and longer continued. The proportions of the materials, estimated as if pure, and proportionably if impure, are caustic soda 20 parts, boric acid 62 parts, and water 120 parts. The proportion of water used is larger than is required by the equation—

in order to facilitate combination. Part of the caustic soda may be replaced, in equivalent proportion, by dry sodium carbonate, crystal sodium carbonate, or by both, and quantitative examples are given.—E. S.

## VIII.—GLASS, POTTERY, AND ENAMELS.

**R. Engelmann's Process for the Decoration of Glass.** L. Appert. Bull. Soc. d'Encouragement, 9, August 1894, 472—474.

The inventor has adapted the ordinary method used in applying colours to pottery to the case of glass. The colours are transferred from prepared paper on to the glass and are made to adhere firmly by the use of linseed oil which has become oxidised to the consistency of caoutchouc. The paper is removed by soaking for some hours in water. The principal difficulty to be overcome in the process is due to the liability of the fatty and resinous matter to spoil the surface of the colour by cracking or blistering during carbonisation. To avoid this the temperature must be raised gradually, maintained steadily, and lowered slowly. This is effected by the use of a long chamber heated by gas burners arranged at right angles to the axis of the chamber, the articles being slowly moved throughout the length of the chamber by mechanism actuated by revolving cylinders. As the articles approach the centre they are gradually exposed to higher temperatures, and as they pass the centre the temperatures decrease at the same rate. In this way glass articles of large dimensions can be decorated in colour without risk of breakage.—V. C.

## PATENTS.

**Improvements relating to the Manufacture of Pottery.** J. E. G. Méran, Paris. Eng. Pat. 24,283, December 16, 1893.

The invention consists in the employment of minerals containing magnesia as a basis for the ware, e.g., magnesite, tale, steatite, or serpentine. The material is very refractory at high temperatures, and in the porous or biscuit state is especially suitable for electrolytic purposes, being unattacked by acids. Binding material, such as clay, may have to be added to the magnesia paste, but should be in as small proportion as possible and not exceeding 10 per cent. The baking is carried out at about 1,200° C. If done at 1,800° C. a porcelain-like material, which also has industrial applications, is obtained.—V. C.

**Improvements in the Manufacture of Pottery or Earthenware.** Worcester Royal Porcelain Company, Lim., E. P. Evans, A. Rushton, and H. Hawker, Worcester. Eng. Pat. 24,682, December 22, 1893.

This process is designed as an improvement upon the old method of employing modelled pieces of clay to give the necessary impress of a design in the mould in which "ware" is to be shaped. In carrying out the invention "raised colours" mixed in the ordinary way are printed upon blocks or moulds, from which reverse moulds in plastic material are then formed. In these reversed moulds the ware is formed as usual.—V. C.

*Improvements in the Manufacture of Enamel Glass Letters and other Devices.* E. Böhm, London. Eng. Pat. 878, January 15, 1894.

THE enamel glass letters are formed by direct pressure, thereby avoiding the employment of the metallic backing, which has hitherto been generally used and which frequently becomes unfastened. Molten glass is poured into a mould of the required shape, which is made in two pieces. The mould is then heated and subjected to strong pressure, the result being that each letter is stamped out. The letter or device can then be attached to windows, sign tablets, and the like.—V. C.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

*The Effect of Stress on the Corrosion of Metals.*  
T. Andrews. Proc. Inst. C.E. 118, IV.

See under X., page 1200.

### PATENTS.

*Improved Process for Transforming Roasted Cements into Powder and in Apparatus therefor.* D. Belloe, and E. Benard, Paris. Eng. Pat. 2247, February 1, 1894.

CEMENTS which have been roasted to exactly the proper extent disintegrate rapidly, upon cooling, into a fine powder. Those parts which are insufficiently roasted disintegrate more slowly, and those which have been over-roasted do not disintegrate, but remain in lumps. In this invention the automatic disintegration is utilised, both for obtaining a fine powder composed of the properly-roasted cement, and for separating the properly-roasted cement from the remainder by "screening." If the screening be done without delay the under-burnt may subsequently be separated from the over-burnt cement by a second screening. The regular and uniform roasting of the materials is secured by the use of ovens in which combustible gases circulate through the charge, and in which the raw material, in lumps or powder, is incorporated with comminuted fuel. The subsequent cooling is allowed to proceed in a slow and regular manner.—V. C.

*Improvements in the Utilisation of Precipitated Sewage Matters for the Manufacture of Cement.* W. Bruch, Wiesbaden, Germany. Eng. Pat. 12,350, June 26, 1894.

THE precipitate obtained by the addition of lime to sewage is dried and heated to redness, when, among other things, "a basic salt of lime with hydraulic properties, is formed from the phosphoric lime, the carbonic lime, the caustic lime, and the organic substances."

The inventor claims that this compound, possessing hydraulic qualities, may be employed for preparing cement for use in the construction of subaqueous works.—L. de K.

## X.—METALLURGY.

*A Method of Treating Auriferous Ores with Bromine, with Regeneration of the Bromine Employed.* C. Lossen. Ber. 1894, 27, 2726—2727.

THE use of bromine in treating gold ores, mainly as a substitute for chlorine, has generally been abandoned after trial, on account of the loss of bromine, which amounts to at least 1.5 lb. per ton. The author proposes to regenerate the bromine electrolytically. After passing a current through a solution of potassium bromide, the resulting alkaline solution contains no free bromine, but is capable of dissolving gold. The ore, either raw or roasted, is treated with this alkaline brominated solution in a rotating cylinder until the gold is dissolved; more of the solution is added if the liquid be not still alkaline. The solution is then filtered to separate the hydroxides of iron and other metals; and the gold, which remains in solution as aurate, is reduced by passing the filtrate through vessels filled with fragments of iron and charcoal, or coke. The solution, now consisting mainly of potassium bromide, is run into troughs, where it is re-electrolysed and thus fitted for the treatment of a fresh batch of ore.—W. G. M.

*Composition of Newly-discovered and Ancient Copper from Chaldea and Egypt.* M. Berthelot. Bull. Soc. Chim. 1894, 11, 859—863.

THE author adduces the following analyses of ancient metallic objects in support of the theory that an age of pure copper preceded that of bronze, the proof of which is much obscured by the loose nomenclature adopted by antiquarians in regard to the composition of such specimens. All the objects described were much altered by exposure to salt water. No. 1 was from a small votive figure found in the foundation of a Chaldean house of the 40th century B.C. (estimated), and was almost entirely converted into oxychloride and a mixture of metallic copper and cuprous oxide; it contained no tin, and must originally have been pure copper. No. 2 was from a vase found in a tomb on the site of ancient Memphis, and is referred to the time of Seneferu of the fourth Dynasty. This also was oxidised through and partially chloridised, and gave no evidence of tin. No. 3 was from a bracelet or anklet, found in the same tomb as No. 2, but in such a position that it may have been left there by ancient depredators, and cannot therefore be accepted as evidence that bronze was known in the reign of Seneferu.

—W. G. M.

*Manganese Steel.* H. Le Chatelier. Comptes rend. 1894, 119, 272—274.

THE author recapitulates the properties of manganese steel (containing 13 per cent. Mn), which are of importance in connection with the present investigation. The alloy is non-magnetic and has the highest electrical resistance

(about 1 ohm for a wire 1 m. long and 1 mm. in diameter) of all the alloys of iron. It becomes softer on heating and quenching.

Hadfield has lately discovered the existence of an allotropic modification of this alloy, which is magnetic, this variety having been obtained by annealing the alloy at a high temperature for about 10 days. The author has defined the conditions governing this transformation. The transformation of the non-magnetic into the magnetic variety is effected by annealing it at 500—650 °C., the operation being complete in one or two hours, when the most favourable temperature (550 °C.) is adopted. To reverse the change the alloy is heated to a temperature not lower than 800 °C., and cooled rapidly enough to prevent alteration to the magnetic variety, occurring between 500 and 600 °C. Seeing, however, that the change is slow, a correspondingly moderate rate of cooling is sufficient to prevent the change. In this respect manganese steel is analogous to certain "self-hardening" steels containing chromium or tungsten, which harden on being allowed to cool spontaneously and need no quenching. The sole difference is that in the case of the last two materials, the transformation prevented by tempering, is one into an iron carbide, whilst in the case of manganese steel it is the allotropic change of the non-magnetic to the magnetic alloy which is impeded.

The following tables give the variation of the electrical resistance and the dilatation with alteration of temperature, for the two allotropic modifications of manganese steel:—

*Electrical Resistance of a Wire 1 m. in Length and 1.4 mm. in Diameter.*

Temp. °C.	15.	90.	300.	500.	635.
Resistance in ohms—					
(1.) Non-magnetic.....	1.06	1.19	1.44	1.65	..
(2.) Magnetic.....	0.88	0.99	1.27	1.50	1.70

Temp. °C.	730.	850.	965.	1020.
Resistance in ohms—				
(1.) Non-magnetic.....	..	1.88	..	1.97
(2.) Magnetic.....	1.79	..	1.93	1.97

*Longitudinal Expansion of a Rod 100 mm. in Length.*

Temp. °C.	250.	500.	680.	830.	960.	1060.
Expansion mm. (both kinds)	0.35	0.67	1.05	1.43	1.97	2.00

The two curves of electrical resistance meet at about 740° C. and become identical for higher temperatures. This temperature is that at which pure iron passes from the magnetic to the non-magnetic state. This leads to the hypothesis that manganese steel is a mechanical mixture of iron and a definite compound of iron and manganese, which would not be magnetic. The iron itself would undergo its ordinary change by rise of temperature, but the rate of change would be retarded by the presence of the compound of iron and manganese which is mixed with it. The expansion of the two modifications of manganese steel has been found to be identical, which fact excludes the possibility of a change of dimensions at the moment of transformation. Manganese steel quenched in water undergoes on annealing a contraction of 0.4 mm. on a length of 100 mm.—B. B.

*The Impurities of Commercial Aluminium.* H. Moissan. Comptes rend. 119, 1894, 12—15.

ALUMINIUM produced by electrolytic processes is always impure and variable in composition. Hitherto only two impurities have been generally recognised, namely, iron and silicon. The former has an unfavourable influence on the

physical properties of aluminium, but its presence may be avoided by due care in the choice of the raw material, crucibles, and electrodes. Silicon, being chiefly derived from the alumina employed, is more difficult to eliminate. For many applications of aluminium the presence of this impurity is of no moment; but, according to the author, its amount may be readily reduced, by fusing the metal under a layer of an alkaline fluoride. In addition to the above, the author finds that the aluminium of commerce always contains nitrogen and carbon. The former probably exists as a nitride dissolved in the excess of aluminium, the breaking strain and elongation of which it appears to reduce considerably. The nitrogen may be detected by dissolving the sample in 10 per cent. pure potash solution and passing the gases evolved into Nessler's reagent. Carbon may be separated by dissolving aluminium in hydrochloric acid, when it is left behind in the form of a maroon-coloured light powder quite free from graphite. For quantitative purposes potash is the best solvent, the residual carbon being finally estimated by combustion in the usual way. In this manner the author has obtained the following values:—0.104, 0.108, 0.080 per cent. of carbon. As regards the effect of carbon on the physical properties of aluminium, the following figures are given:—

	Limit of Elasticity.	Breaking Strain.	Elongation.
	Kilos. per Sq. mm.	Kilos. per Sq. mm.	Per Cent.
Aluminium of good quality..	..	11.1	9
The same, carburetted and cast.	..	8.6 to 9.5	3 to 5
The same, carburetted and rolled.	20	20.8	2.5
The same, carburetted, rolled, and annealed.	7.7	13.8	26.5

—H. T. P.

*Preparation of a Crystalline Carbide of Aluminium.* H. Moissan. Comptes rend. 119, 1894, 16—20.

THE electrical furnace described by the author (Comptes rend. 117, 679) may be conveniently employed. A number of carbon cells, each charged with 15—20 grms. of aluminium, are placed in the carbon tube of the furnace and submitted to the action of a current of 300 amperes at 65 volts, hydrogen being passed through the tube during the operation, and until the apparatus has become cool. The greyish fused mass formed in the cells when fractured will be found to be interspersed with brilliant yellow crystals of the new compound. Similar crystals are obtained by electrolysis a mixture of kaolin and carbon. They are best separated from unaltered aluminium by repeatedly treating the melt, 2—3 grms. at a time, with strong hydrochloric acid in a test tube kept cool by means of ice. When hydrogen is no longer disengaged, the crystals are rapidly washed with cold water, followed by alcohol, and finally ether. Thus obtained, aluminium carbide forms fine, yellow, transparent crystals, occasionally 5—6 mm. in diameter, and hexagonal in shape, having a density of 2.36, and the composition expressed by the formula  $C_3Al_4$ .

Heated to a dull red heat in an atmosphere of chlorine, the carbide is decomposed with incandescence, aluminium chloride is formed, and carbon liberated, the latter being amorphous and lamellated in character, and retaining the form of the original crystals. At temperatures above 700° C., bromine has a similar influence, whilst iodine is without action. Under the same conditions oxygen effects only a slight superficial change; but sulphur violently attacks the crystals, much heat being evolved, and aluminium sulphide and traces of carbon bisulphide produced. The carbide is completely oxidised with more or less violence when heated in contact with oxidising agents, such as potassium permanganate or bichromate, oxides of lead, &c. Potassium nitrate and chlorate, however, form exceptions. Strong acids in general have little or no action (boiling sulphuric acid is decomposed with evolution of sulphur dioxide); whilst weak acids dissolve the compound. The

most characteristic reaction, however, is that with water; methane is slowly formed in quantitative amount in accordance with the equation—

Under similar circumstances the carbides of the alkaline earths— $\text{M}''\text{C}_2$ —give off pure acetylene.—H. T. P.

*A New Method of Producing Metallic Deposits, especially adapted to the Plating of Aluminium.* C. Göttig. Ber. 1894, 27, 1824—1826.

THE difficulty in obtaining adhesive deposits of most metals upon aluminium, whether by simple immersion or by using a separate current, is well known, and appears to be dependent to some extent upon the nature and quantities of the impurities in the aluminium. The author finds that he can obtain a good deposit of certain metals by immersing the aluminium in such a solution of the metal as will not deposit by simple immersion, and rubbing the surface of the aluminium with a brush made of wires of a more electro-positive metal; and that the deposit is most rapid when the aluminium is relatively most electro-negative. Thus copper is deposited from a copper sulphate solution by rubbing the aluminium with tinfoil, but not with platinum; or tin from an ammonium stannic chloride solution by rubbing with brass wire, but not with copper. The deposit of copper may be thickened by immersing the thinly-coated aluminium in a dilute copper bath. Rubbing the copper solution on to aluminium with red-lead powder does not produce a satisfactory result, whilst with whiting a deposit is obtained instantaneously; the latter material, however, fails to give a deposit of tin from its ordinary solutions. The author intends to apply the process to other metals besides aluminium.—W. G. M.

*The Effect of Stress on the Corrosion of Metals.* T. Andrews. Proc. Inst. Civil Eng. 118, 1V.

THE author investigated the influence of stress upon the corrosion of metals, with the view of determining to what extent the alteration of rate of corrosion thus induced might account for the local attack sometimes observed in metallic structures. The metals used were wrought-iron bars and hammered shafts, and Bessemer and Siemens steel forged shafts. Soft Bessemer steel, hard Bessemer steel, Siemens steel, both soft and hard, soft and hard cast steel, and special steels, e.g., those containing Al, Ni, Cr, Si, and Cu, were also employed. The metals were in the form of bars  $3\frac{1}{2}$ — $3\frac{3}{4}$  in. in diameter or shafts  $4\frac{3}{8}$ — $5\frac{1}{2}$  in.; the plates were  $\frac{3}{16}$  in. in thickness. Full tables of the mechanical properties and chemical composition of the test pieces are given in the appendix to the paper. The method of experiment adopted, consisted in preparing ordinary test pieces, subjecting them to considerable stress in the testing machine, but not necessarily to the point of fracture, and turning from the stressed and elongated specimen, two similar pieces, one of which was from the turned-down centre of the bar where most of the stress had taken effect, and the other from the thicker end, which had been gripped in the jaws of the testing machine and had not been stressed to any considerable degree, the maximum stress being well below the yield point. The two similar pieces were placed in an electrolyte, usually a solution of common salt, and the difference of potential between them taken as a measure of their relative corrodibility. Precisely similar arrangements were used in those cases in which the stress was torsional or flexional instead of tensile.

The results of the whole of the series of experiments were nearly identical; they may be summarised thus:—

(1.) The effect of tensile stress was to cause the production of an average electromotive force of 0.016 volt between the "strained" and "unstrained" portions of the metal, the unstrained electrode being positive, and therefore considered by the author to be more corrodible.

(2.) The effect of torsional strain was to produce an average electromotive force between the electrodes of 0.018 volt, the "unstrained" metal being again electro-positive.

(3.) Flexional strain on plates gave an average of 0.012 volt in the same direction.

(4.) Flexional strain on shafts gave an average of 0.010 volt.

The author has drawn the following conclusion from his recent work on the corrosion of metals. Wrought iron, when exposed to the corrosive action of sea-water for long periods without being subjected to other causes of corrosion than such as are local, is more resistant than steel, the difference sometimes amounting to as much as 25 per cent. The more carbon present in the steel the greater the corrosion. Galvanic corrosion may be set up in metallic structures exposed to tidal flow, by reason of the local variations of the electrolyte (sea-water) in contact with them. The electromotive force existing between strained and unstrained metal in the same structure may induce local corrosion.—B. B.

*Hard Solders for Brass.* R. Schwirkus. Dingl. Polyt. J. 293, 64—67 and 89—93.

ORDINARY commercial hard solder is generally either too infusible or too brittle to be used for soldering commercial brass hammered-ware, and, as the composition of the latter is very variable, there is no solder in the market which may be safely applied indiscriminately. Exhaustive experiments have been tried with various soldering mixtures, under six heads, which are dealt with separately, as follows:—

1. *Influence on the Method of Alloying.*—The usual solder consists of copper and zinc, with or without the addition of other metals to promote fusibility. The common method of adding the zinc to the molten copper causes a loss of the former, which may amount to 25 per cent. of the zinc used, if small quantities only are being handled; and the use of brass instead of copper is scarcely an improvement. This variable loss of zinc leads to irregularity both in composition and fusibility. The method recommended by the author practically overcomes this difficulty: he heats the zinc to a temperature just above its fusing point, and then, little by little, and with constant stirring, introduces granulated copper in the form of fine grains (passing a 1.5 mm. sieve), no further quantity of copper being added until the previous addition is quite dissolved; the temperature is raised gradually as the melting point of the alloy rises. With the copper is always added one-third of its bulk of powdered sal-ammoniac, and a further quantity of the salt is introduced before pouring; for this reason the melting should be effected under a hood with a good draught to carry off the fumes. A third metal, if fusible, is added initially to the zinc (silver is introduced in the form of this strip with the copper). Brass in equivalent quantity may be substituted for copper, and is introduced in the same way; but its use is not to be recommended by reason of the incertainty of its composition. When traces of iron are to be excluded, pure materials must be used, and the stirring must be effected with wood or a clay pipe stem, the fusion being made in a non-ferruginous vessel.

2. *The Fusibility of the Solder.*—To estimate this, the author has determined the point at which the granules run together (the *flowing-point*). He places a mixture of 0.5 gm. of the solder and 0.3 gm. of powdered borax, moistened with two drops of water, in a small flat copper vessel 12 mm. in diameter, provided with a handle; the mixture is heated until the last trace of the dull white appearance of the borax is just vanishing; a too prolonged heating here causes oxidation, while insufficient heating leads to an incorrect result afterwards. The mixture is then cooled completely and placed in a constant predetermined position in a gas-blast flame maintained by regulators at a constant temperature. The exact time required to produce union of the grains is determined in half-seconds with the aid of a metronome. Five determinations were made with each mixture, and a maximum variation of 1.5 seconds in any series was held to invalidate the five trials, which were then started anew. The practical importance of a bold and rapid heating of the solder mixture is great; if heated for long to the fusing point of borax, but short of that of the solder (as by an inexperienced workman afraid

of burning his "work"), the borax runs off the corners of the solder particles, which then oxidise and may so far prevent subsequent union that the brass work to be joined is fused first. For this reason heavy work, which rapidly conducts the heat away from the intended joint, is more liable to be burnt than light work, and therefore demands the use of a more fusible solder.

3. *Estimation of Malleability.*—Tubes of brass or copper 100 mm. long by 35 mm. diameter, and 1 mm. thick, were made up from sheet metal with the solder to be tested, by means of a butt joint. One end of the tube was then carefully worked out under the hammer into a flange 7.5 mm. broad at right angles to the tube, so that the solder was submitted to a combined hammering and tensile test. If the joint gave way at once, the solder was considered non-malleable and marked 0; if the flange had turned over to an angle of 45°—60° before rupture occurred, it was marked  $\frac{1}{2}$ ; if only when brought to a right angle, it was marked 1. But if even then it remained sound, the flange was cut off, and another 10 mm. wide, was started in the same way; if this gave way at once, or between 45° and 60°, or when just complete, the solders were marked respectively 1,  $1\frac{1}{2}$ , or 2, as before. If still unbroken, the second flange was also cut off and a third was made 12.5 mm. wide; if necessary other flanges, each 2.5 mm. wider than the last, were similarly made, until at last the joint ruptured. In this way 8 degrees of malleability, corresponding to flanges from 7.5 to 25 mm. wide were obtained. Test-bars, 100 mm. long by 10 mm. diameter, were cast from the solder itself. Non-malleable solders may sometimes have to be used, but their tenacity should never be less than 2 kilos. per sq. mm. (= 1.27 tons per sq. in.).

4. *Use of Hard Solders for Various Qualities of Brass.*—Brass samples supplied by nine different makers were tried with brass and zinc, and copper and zinc solders. The flowing points of the brasses themselves were reached after from 16.8 to 23 half-seconds; and the only solders which could with safety be applied to all, were those containing 77 or less per cent. of brass (to 23 of zinc) or 46 or less per cent. of copper (to 51 of zinc), the flowing points of each of these solders being 14.8 or lower. A solder containing 51 per cent. of copper could just be used for eight of the samples, but the brass was in each case on the verge of destruction.

5. *Simultaneous Lowering of the Fusing Point and Increase in Malleability.*—By comparing Nos. 1, 2, 3, and 4 with Nos. 16, 18, 19, and 20 respectively in the annexed table, it will be seen that the substitution of silver for a small proportion of the copper is accompanied by a very marked increase both in fusibility and in malleability. Nos. 18 and 19 worked well with all the brass samples above alluded to, and No. 17 could just be used with extreme care.

6. *The Influence of an Addition of Tin upon the Malleability of the Solder.*—Nos. 26 to 32 in the table show clearly that even a small percentage of tin decreases the malleability to a greater extent than it lowers the fusing point of the solder, and the addition of this metal is not to be recommended.

In the table (page 1202) are included the results of the various tests made with alloys of the pure metals. (In the original table tests of 20 other solders made up with "brass" are included; but these are here omitted on account of the uncertainty of their composition.)

The author lays down 14 half-seconds as the high limit for the flowing point, and grade 2 (= flange of 10 mm.) as the low limit for the malleability of a generally useful solder for brass. Excluding those alloys which do not fall within these limits, it will be seen that only the solders containing silver are to be recommended for workshop use. Nos. 16 to 19 can well be used for soldering copper, but Nos. 19 to 22 are so trustworthy for all kinds of brass, and behave so well under the hammer, that the slight extra cost due to the addition of silver is more than compensated for. It is noteworthy that the silver solder, No. 23, containing 62 per cent. of the precious metal, is distinctly inferior to No. 22, containing only 12 per cent. No. 19 is especially recommended for the first soldering of brass, No. 20 for sheet and

wire, No. 21 for second solderings (on pieces which have been already soldered with a less fusible alloy) and for ordinary use, and No. 22 both for third solderings and as a substitute for fusible solders containing tin.—W. G. M.

*The Testing of Zinc Ores and Products of Manufacture.* F. Meyer. Zeits. angew. Chem. 1894, 394.

## PATENTS.

*Improvements in the Manufacture and Purification of Iron, and in Means or Apparatus employed thereon.* W. J. Chapp and S. D. Williams, Newport. Eng. Pat. 20,450, October 30, 1893.

The lime or limestone required for fluxing is introduced into the furnace in the ordinary way, but the excess required for eliminating the sulphur is blown in through the tuyères in an extremely fine state of division.

Or, the lime (or limestone) is volatilised by the electric arc, and the "calcigen" thus produced is blown into the molten metal. Liquid fuel is also blown in when required. A specially-constructed revolving tuyère, carrying radial arms with channels or blades, and shaped screw or propeller fashion, dips into a trough or container holding the supply of pulverised lime. It is thus scooped up and delivered at an orifice, where it meets the blast and is carried into the furnace.

The furnace is lined with a flux of borax and chloride of sodium, or with bauxite, clay, silicate of soda, or potash, or a suitable mixture of these, thus setting up a hard, firm, glazed surface.—J. H. C.

*Improvements in Coating Iron, Steel, or other Metallic Plates with Tin, Terne, and other Mixtures.* F. Watkins, Llanelly. Eng. Pat. 23,048, December 1, 1893.

The plates having been "pickled," are passed through hard paraffin or ozokerite, or a mixture of the two, then into the tin, terne, or other metallic bath, and finally through palm-oil or palm-oil mixture.—J. H. C.

*Process for the Elimination and Recovery of Arsenic from Copper Precipitates.* E. G. N. North, Rio Tinto, Spain. Eng. Pat. 23,770, December 9, 1893.

AFTER being washed and dried, the precipitate is heated to a temperature somewhat below redness, in a closed muffle, which is provided with a small outlet-pipe for the escape of arsenical fumes. Stirring is effected without allowing air to enter, by means of a poker, working through a hole in a small sliding plate let into the sliding door. The arsenic is condensed in separate chambers, and removed at intervals.—J. H. C.

*The Manufacture of Ferro-Boron.* C. J. L. Lettler, Shetfield. Eng. Pat. 24,230, December 16, 1893.

FERRO-BORON is obtained by mixing boric acid and any suitable ore or artificial oxidised compound of iron in the requisite proportions, and heating them in a crucible or furnace, from which the resulting borate of iron may be poured. The borate of iron thus produced, or a natural borate such as *Lagonite*, is then mixed with carbonaceous matter and again strongly heated, thus producing ferro-boron or boron-iron containing from 2 per cent. to 20 per cent. of boron.—J. H. C.

\* Note by Abstractor.—The numbers are quoted as for Cu + Zn + Sn in Nos. 26—32; but this appears to be a misprint for Brass + Zn + Sn.

*Processes of and Converters for Smelting and Refining Ores.* C. M. Allen, Butte City, Montana, U.S.A. Eng. Pat. 8586, May 1, 1894.

The raw materials are reduced to a molten condition in a suitable converter, which is so mounted, on trunnions or otherwise, that it can be tipped for drawing off any required quantity from the contents, and then restored to its original position for further charging with a suitable quantity of fresh material, and so on. The converter is water-jacketed, and the blast is usually introduced through one of the trunnions. The dust and fume are collected in separate chambers, and returned to the converter at suitable intervals.

—J. H. C.

## XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

*The Scientific and Technical Electrochemistry of the Present and Future.* W. Ostwald. Zeits. f. Electro-technik u. Electrochem. 1894, 122—125.

The author, in this address, discusses some problems, to-day of speculative scientific interest only, but which may in the near future be of technical and manufacturing importance.

The great waste of energy in the steam engine, owing to the very great loss of heat between the fireplace and the boiler and again between the boiler and the engine, is first mentioned. It is pointed out that of the energy of the coals consumed, only about 10 per cent. is realised in the form of mechanical work in the very best cases. Gas-engines may remedy this to some extent, but the author looks to the electrical transformation of the energy of the fuel. In this connection he points out that attempts at direct union of coal and atmospheric oxygen must fail. He illustrates his argument by an experiment with a divided cell containing zinc and platinum plates in potassium sulphate; no permanent current is set up till acid is added to the liquid, and this acid, which is to act on the zinc, must be added to the compartment in which the zinc is not, for electrochemical reasons set forth in the paper. He then indicates the coal-cell of the future, containing coal in the one part, the oxidising material in the other (which must be atmospheric oxygen or something easily obtained from this), and containing possibly an electrolyte for purposes of conduction, which must undergo no permanent change.

Secondary batteries are then referred to, and the author points out that as the energy in an accumulator is proportional to the quantity of electricity and the E.M.F., and as the former depends on the electrochemical equivalent of the material employed, attempts should be made to utilise in accumulators a metal of low equivalent, in order to economise bulk and weight.

Here also he points out that the ordinary distinction between primary and secondary reactions in electrolysis is to a great extent arbitrary and meaningless, for the E.M.F. needed for electrolysis is always that agreeing with the actual products, not that calculated for the imaginary ions, which are supposed afterwards to form the actual products by "secondary actions." He distinguishes between the electrolytes which aid in conveying the current and those which are separated at the poles; the current strength will depend on the resistance, to which all the substances present contribute, according to their mass or concentration and their ionic speeds, but the polarisation at the electrodes is conditioned only by what deposits there.—J. H. D.

*Darriens' Theory of the Lead Secondary Battery, and the Life of Lead Accumulator Plates.* P. Schöpp. Zeits. f. elektrotech. u. elektrochem. 1894, 294—298.

The experiments of Darriens, as described in his *Essai de Théorie Chimique sur les Accumulateurs au Plomb* (Bull. de la Soc. Internat. des Electriciens, 1892), render the generally accepted sulphating theory of Gladstone and Tribe untenable; the apparent confirmation of their theory that lead sulphate is formed upon both plates by normal discharge, which is afforded by the agreement of calculated and observed E.M.F., being purely accidental. If the positive\* plate be removed from a cell which has just been fully charged, and be plunged into water, the presence of persulphuric acid may be proved. The proportion of this acid present in the liquid increases with the strength of the sulphuric acid, being almost *nil* in a 5 per cent. solution; and it rapidly diminishes when the charged accumulator is left at rest. A determination of the persulphuric acid from a freshly charged plate, effected by measuring the oxygen produced on dilution with water, showed it to be equivalent to that given by 0.15 ampère-hour per kilo. of plate. The active material of the charged positive plate was not affected by nitric acid, indicating the absence of oxides of lead lower than  $PbO_2$ , whilst after washing and drying *in vacuo* it evolved 31 per cent. of chlorine from hydrochloric acid (pure  $PbO_2$  gives 29.7 per cent.); when partially dried it smelt strongly of ozone. The E.M.F. of a charged positive plate, purified from persulphuric acid by washing with water, when opposed to a normally charged negative plate, was 1.92 volt, whilst a plate filled with chemically prepared peroxide gave 1.88 volt.

After normal discharge (stopping when the E.M.F. falls to 1.8 volt), the positive plate is partly soluble in ammonium acetate solution, and therefore contains lead oxide and sulphate; mixed with hydrochloric acid it evolved from 18 to 24 per cent. of chlorine. The quantity of sulphate found by boiling a portion of the well-washed material with sodium hydroxide and precipitating with barium chloride, is given in the following table, from which it will be seen to be small, and quite disproportionate to the ampère-hours of discharge.

Expt.	After Charging.		After Discharge.		Formed.		Ampère-hours.	$PbSO_4$ corresponding to Amp.-Hrs.
	$PbO$ .	$PbSO_4$ .	$PbO$ .	$PbSO_4$ .	$PbO$ .	$PbSO_4$ .		
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.		Per Cent.
1	2.33	3.60	8.72	4.41	6.39	9.81	86	21.12
2	0.21	0.47	6.97	4.40	6.76	3.93	114	28.00
3	0.40	0.90	8.40	2.18	8.00	1.28	120	29.47
4	2.44	0.95	10.92	4.01	8.48	3.06	121	29.71
5	1.47	0.19	6.65	1.16	5.18	0.97	76	18.66

Hydrometric determinations of the strength of the electrolyte before and after discharge, confirm the results of these experiments and show the sulphating to be confined to one plate. This is contrary to Kohlrausch's experience; but

\* Throughout this abstract the plate on which peroxide is formed during charging is termed the *positive*, and that on which lead is reduced the *negative* plate. And for sake of brevity either plate is said to be "charged" or "discharged" when it has been taken from a cell which has been charged or discharged.

Darriens discharged his cells rapidly, and then at once made his determinations, because a slower discharge or a period of rest subsequently would allow the sulphating to take place by chemical action. But the sulphate formation, even on the negative plate, is due to secondary reactions:—A negative plate, after discharging 58 amp.-hrs. with an average E.M.F. of 1.80 volts, contained only a trace of sulphate; but the sponge, when heated before the blow-pipe, suddenly glowed, and on cooling was shown to be a mixture of litharge and lead globules, and thus behaved as lead sub-oxide would. If sub-oxide were the first product of discharge it would quickly react with sulphuric acid to form lead sulphate and metallic lead, so that the sulphating would be proportional to the current, and might at first be ascribed to direct electrolytic action. The presence of lead molecules side by side with those of the sulphate accounts for the rapidity of the action of charge and discharge, which is so inexplicable by the old theory, when the insolubility and low conductivity of lead sulphate are considered. On long standing after discharge, especially if left short-circuited, the admixed spongy lead itself becomes sulphated, and then the cells cannot be again charged; this is confirmed by the fact that the plates lose "capacity" when exposed freely to air:—A plate, normally giving 320 amp.-hrs. afforded only 32 amp.-hrs. after a month's free exposure to the air.

The rationale of charge and discharge appears to be as follows:—On charging, persulphuric acid, formed at the positive electrode, there converts lead oxides and sulphate into peroxide, and, when this conversion is complete, is broken up into sulphuric acid and oxygen, the escape of which gas marks the completion of charging; whilst on the negative plate lead sulphate is reduced to spongy lead, and finally hydrogen is evolved after a small proportion has been occluded by the sponge. Then, on discharging, the occluded hydrogen is oxidised in the one plate, and the persulphuric acid is reduced in the other, thus accounting for the initially high E.M.F. of the cell; next a part of the spongy lead of the negative plate is converted into sub-oxide, which reacts with the electrolyte to give lead and lead sulphate. Meanwhile the peroxide on the positive plate is reduced to a lower oxide, which in time is partly transformed into sulphate; spontaneous discharge ("local action") of the positive plate, owing to the presence of  $PbO_2$ ,  $PbO$ , and  $H_2SO_4$ , may result in the complete sulphating of the plate, as it only ceases when all peroxide has been reduced. The E.M.F. on first discharging, due to the oxidation of nascent hydrogen and decomposition of persulphuric acid, is theoretically 2.07 volts ( $+34.5 + 13.2 = 47.7$  kilo.-calories), but by applying Helmholtz' correction it approximates to that observed, viz., 2.24 volt; subsequently it is 1.9 volts. In making thermal calculations it must be remembered that the published heats of formation of lead salts refer to dense, not spongy, lead; and these two substances give with a peroxide plate in dilute sulphuric acid 1.6 and 1.93 volts respectively; chemically prepared lead sponge behaves precisely like that formed on the negative plate, and both may perhaps be considered a true allotropic modification of the metal.

The complete sulphating of the negative plate on continued short-circuiting may be explained by the electrolysis of persulphuric acid, which continues so long as any peroxide exists on the positive plate. But it should be noted that solid lead sheet exposed to a solution of potassium persulphate is gradually covered with a film of oxide, whilst if in contact with platinum wire, it will be encrusted with white lead sulphate in less than a day. It is the action of persulphuric acid on massive lead which causes the often observed rapid destruction of the lead plates; and as the production of this acid is essential to the action of the battery, it may be said that every lead accumulator inevitably carries within it the means for its own destruction; nevertheless circulation of the liquid, even while the battery is at rest, may possibly prolong the life and increase the capacity of the cell.—W. G. M.

*The Electromotive Force of Alloys in a Voltaic Cell.*  
A. P. Laurie. Proc. Chem. Soc. 1894 [142], 173.

THIS paper contains the results of determinations of the electromotive force of 16 of the 19 alloys alluded to in Matthiessen's paper on the conductivity of alloys (*Phil. Trans.* 150). The results obtained confirm Matthiessen's conclusion that only one compound, the tin-gold alloy, exists among the 16, which are:—

Bismuth-tin, bismuth-lead, bismuth-gold, bismuth-silver, gold-silver, antimony-lead, cadmium-zinc, antimony-tin, lead-gold, lead-silver, lead-tin, lead-zinc, lead-cadmium, cadmium-tin.

In some cases the addition of a metal to the alloy results in displacement. Thus mercury decomposes the gold-tin compound, and zinc, added to a copper-tin alloy, appears to replace the tin.

*The Electrolysis of Copper Sulphate.* A. Chassy. Comptes rend. 1894, 119, 271—272.

ON electrolysing a hot solution of copper sulphate a violet-red deposit of cuprous oxide is frequently obtained. At 100° C., with a current density of  $\frac{1}{100}$  ampère per sq. cm., a saturated solution of copper sulphate gives on a platinum electrode a deposit which, when examined under the microscope, is seen to consist of bright red crystals in the form of cubes or octahedra. The deposit is not always uniform, for, if the temperature of the electrolyte be lowered some of the crystals have the yellowish-red colour of copper, their proportion increasing with diminishing temperature. At 40° C. only a few isolated red crystals are obtained, the bulk of the deposit being metallic copper. Raising the current density and diminishing the concentration of the electrolyte have the same effect as decreasing its temperature. In order to obtain red crystals the electrolyte must be nearly neutral. Removal of oxygen by previous ebullition of the liquid does not prevent the formation of the red crystals, which upon analysis are found to be cuprous oxide, thus ranking as artificial cuprite.

A comparison was made between the weight of the deposit thus obtained and that of one of copper thrown down in a voltmeter in series with the first. The deposit of cuprous oxide was always greater in quantity than corresponded with the weight of the copper thrown down in the second voltmeter (calculated into  $Cu_2O$ ). The relation to be expected is expressed by the ratio 1:1.12, whereas that actually obtained was 1:1.35, when the conditions were favourable to the production of cuprous oxide. If a plate of copper of the same dimensions as the platinum electrode be kept in the cell for the whole period during which electrolysis is proceeding, it suffers an oxidation so slight as to be negligible compared with that of the deposit on the platinum plate. The loss of weight of the anode of a voltmeter used hot is smaller than the increase of weight of the cathode. It is obvious that measurement of current by means of a voltmeter containing a warm solution of copper sulphate is inaccurate; a slight error exists even when the solution is feebly acid and when the current density is fairly high, but the inaccuracy becomes of moment when the solution is neutral and the current density small.

—B. B.

*The Electro-Nickeling of Metallic Surfaces.* Dingl. Polyt. J. 293, 69—70.

THE following baths (most of them well known) have all given good results, but require careful handling:—

1. 8 kilos. nickel ammonium sulphate in 100 litres of water, made slightly alkaline with ammonia, and then weakly acidified with citric acid.

2. 5 parts nickel sulphate neutralised with ammonia, 3.75 ammonium tartrate, and 0.025 gallotannic acid per 100 of water. This gives a homogeneous white and smooth reguline deposit, even when of great thickness.

3. 2.75 nickel acetate, 2.5 calcium acetate, and 100 of water, afterwards mixed with 0.7 part of acetic acid (sp. gr. = 1.017) and filtered. (Potts' formula.)

4. 5 nickel ammonium sulphate, 2 ammonium sulphate, 0.5 citric acid, and 100 of water. Boil and filter.

5. 8 nickel ammonium sulphate, 1 ammonium chloride in 100 of water, with or without the addition of 0.5 part barium oxalate.

6. 6 nickel ammonium sulphate, 3.5 ammonium chloride, and 2.5 ammonium sulphate per 100 of water.

7. 5 nickel ammonium sulphate, 1 ammonium sulphate, and 100 of water. Specially suitable for cast iron.

8. 5 nickel ammonium sulphate, 2.5 boric acid, 100 water.

Powell has found that the addition of not more than 1 to 8 grms. per litre of benzoic acid or of a benzoate to a suitable nickel bath produces a good and pure deposit. Baths containing boric acid, such as are commonly employed, give a good deposit upon smooth surfaces, but refuse to cover cavities or hollows; this difficulty may be removed by the addition of sodium chloride to the bath. Such a bath may be made by dissolving 5 kilos. nickel ammonium sulphate in 100 litres of water, adding 2.5 (or 1.25) kilos. of boric acid and 1.25 kilos. of sodium chloride, boiling, acidifying with citric acid, neutralising with ammonia, and filtering.

So also nickel chloride with boric acid in the proportion of 5 : 2 or 2 : 1 gives a good bath, but it is not suitable for depositing upon iron or steel, as all baths containing chlorine are apt to cause rusting of these metals. The use of citric, benzoic, tartaric, or other weak acids is to be recommended for them, except upon the score of expense. —W. G. M.

*Klein's Method of Compressing and Shaping Electrolytically Deposited Metals.* G. Langheim. Zeits. f. Electrochem. u. Electrochem. 1894, 161—165.

THE object of the apparatus here described is the electrolytic production of articles (such as candlesticks or stair-rails) the shape of which is that of surfaces of revolution round a central straight axis, and the longitudinal section of which may have any profile. The cathodes are built up on central "cores" which consist of strong rods or tubes, coated with a layer of easily fusible substance; these, if tubes, are stopped at the ends by caps, and in any case are provided with short axles at the ends. A core is covered with (for example) clay, and is then worked to the right shape by being rolled on a plate the surface of which is cut in parallel ridges and hollows of the required form; it is then baked and finished by being again rolled under pressure on the plate, guides being used to ensure the right motion. Its surface having been rendered conducting, it is placed in a bath of the electrolyte, on a glass or porcelain plate of the same shape as that on which it was formed, confronted with an anode also shaped to correspond to it, and rolled back and forth during the whole time of the deposition, more or less pressure being applied to it according to circumstances. A number of objects of the same or of different shapes can be worked at the same time; and the paper gives diagrams illustrating various forms of apparatus, in which the cathodes are arranged side by side on the horizontal or inclined plate, and pressure and motion applied by means of a framework laid over them, provided with slots open below in which the axles work, or in which the motion is guided by wheels rolling against the sides of the trough, while pressure is got by elastic pressure-rollers working against the top or against upper ledges. In other forms the plate is a vertical cylinder with horizontal corrugations, round which the cathodes roll continuously as they rotate round a central vertical axis; or a flat plate with circular corrugations, on which the cathodes, radially disposed round a central axis, roll like the spokes of a wheel. Metal can thus be deposited on both the inside and outside of an annular cathode, and is obtained in an exceedingly tough and resisting state; whilst by substituting polishing arrangements for the shaped "matrix-plates," the same apparatus can be used for silver or nickel plating. The author points out the advantage of Klein's process over Elmore's, in that so much more work can be done in the same space and with the same amount of electrolytic fluid, and that not only cylindrical articles, but objects of

any profile, can be produced. He suggests the manufacture of boiler tubes as one of the large uses to which the method may shortly be put. J. T. D.

## PATENTS.

*Improvements in Voltage Batteries.* J. A. S. Gregg, New Rochelle, U.S.A. Eng. Pat. 20,975, November 4, 1893.

THE apparatus described is for automatically supplying a cell with fresh liquor at the rate required by the use of the cell and in a continuous manner.

The cell is provided with a water-tight cover, through which a wide vertical tube passes to the bottom. A second tube passes just through the cover and is bent to act as an overflow. Above the wide tube is mounted a reservoir, mouth downwards, the mouth being fitted with a short length of pipe and a stopcock. The end of this pipe dips just below the level of the liquor in the wide tube. During use the spent liquor, being of lower density, collects at the top and flows away by the overflow pipe. The level falls in the wide tube, and bubbles of air enter the short pipe and pass into the reservoir, a corresponding quantity of fresh liquor flowing from the latter into the wide tube. The reservoir can be raised or lowered so as to regulate the point at which feeding shall go on. The short pipe from the reservoir has the end which enters the wide tube, cut off obliquely.—E. T.

*Improvements in Electrolytic Apparatus.* W. H. Caldwell, Cambridge. Eng. Pat. 21,531, November 13, 1893.

THESE improvements relate to a diaphragm for use in electrolytic tanks. This diaphragm is made up of the loose crystals of the salt which is being decomposed. A vertical wall of these crystals is maintained by horizontally placed strips of glass, porcelain, or other suitable material, arranged vertically one above the other, from the bottom of the tank to the surface of the solution, after the manner of the laths of a Venetian blind. Apparatus is shown for the electrolysis of sodium chloride solution, narrow spaces being left between the screens for the electrodes.—J. C. R.

*Improvements relating to the Electrolytic Preparation of Oxygen and the Halogens, and to the Simultaneous Production of Electrodes.* A. Cohn, Berlin, Germany. Eng. Pat. 23,478, December 6, 1893.

THE inventor proposes to make use of the hydrogen set free in the electrolytic production of oxygen and the halogens, by employing a cathode capable of absorbing it. The compound electrode thus produced is employed in the generation of current in primary or secondary batteries. "Negative accumulator plates work advantageously as cathodes. These absorb the evolved hydrogen, as in their usual accumulator charge, until they reach a saturation limit, which is indicated by a violent ebullition of free hydrogen."

Batteries are formed with this hydrogen-charged lead, representing the zinc, and copper, separated by a diaphragm, in sulphate of copper, as in the Daniel's cell. Single fluid batteries are constructed with negatives of carbon or copper in dilute sulphuric acid. Polarisation is prevented by constant circulation of the electrolyte, or by blowing air through it. Cells thus set up can be employed as generators of electric current for a further electrolysis, in order to produce oxygen or halogens thereby.—J. C. R.

*Improvements in Process and Apparatus for Electrolytical Decomposition of Alkali Salts.* A. Sinding-Larsen. Christiania, Norway. Eng. Pat. 13,499, July 12, 1894. (Under International Convention, December 12, 1893.)

This invention relates to apparatus in which mercury is employed as a cathode for transporting the metallic constituent separated from the salt in solution under treatment. Chloride of sodium is the example given. The characteristic feature of the process is the use of an amalgamated metal body (tinned iron for example), having a greater part of its surface exposed to the solvent agent, a part of its surface in contact with mercury serving as a cathode, and being moved in such a manner that the amalgam in the cathode is pushed through the solvent in the form of a thin layer adhering to the surface of the moving body.

The illustrations show metal discs or drums mounted on shafts journaled vertically and horizontally across, or in tanks divided by non-porous walls extending into the mercury. These discs or drums dip into the mercury. In one case the mercury is contained in a bowl perforated at the bottom, by the rotation of which the mercury is continually carried up centrifugally and falls back again over a flanged edge, re-entering the bowl by the perforations. The anode chamber walls dip into the mercury in the centre of the bowl. The outer portions of the bowl are in the tank containing the solvent liquor.

In another description it is proposed to separate the mercury from the anode by the electrolyte under pressure forced in between them, the mercury normally resting on the anode, but a piece of thin cloth may be inserted between them. Methods, electrical and otherwise, are explained for rendering the apparatus automatic.—J. C. R.

*Improvements in the Manufacture of Carbon for Electric Lighting and other Electrical Purposes.* R. Niewerth, Berlin, Germany. Eng. Pat. 24,081, December 14, 1893.

THE inventor claims the heating of carbons after moulding, by means of an electric current in place of baking. During this heating the carbon is supported in a holding sleeve of non-conducting material to prevent warping. Ammonious earths, magnesia, and other metalliferous compounds, which are added to the mixture before moulding, are reduced when the carbon is subsequently raised to a "red heat." Carbons thus prepared have less resistance and more illuminating power when used in arc lamps, as the metal, burning simultaneously with the carbon, gives a very great illuminating effect.—J. C. R.

*Improvements in Apparatus for Electrolytic Purposes.* H. Guthrie, Manchester. Eng. Pat. 21,276, December 16, 1893.

THE inventor describes apparatus for the decomposition of brine by electrolysis. Electrodes of sheet or flat material are placed between frames carrying porous partitions. These are arranged in series to form electrode compartments, the whole being screwed up together, filter press fashion, to form tight joints, in a containing tank for the electrolyte. Suitable feed and exit ducts or passages for the products are fully detailed and shown.—J. C. R.

*A New or Improved Preparation of Active Material for Electric Accumulators.* C. K. Mills, London. From C. J. Barbier, Lyons, France. Eng. Pat. 24,353, December 18, 1893.

THESE improvements relate to the preparation of active material for electric accumulators. Lead or an alloy in a liquid state is projected upon a rapidly revolving wheel, provided with floats or blades, which acts by shocks upon the molten metal and produces particles of peculiar texture. This wheel is fixed on a shaft or spindle journaled in a tank containing water, the sides of which are kept wet by a perforated water-coil. By projecting the lead from the wheel on to solid metallic or other surface, to which is given movement of variable speed, agglomerates are formed, the metal being partially soldered to it. In this agglomerated

condition it is applied to form negative plates without supports. In the finely divided condition, the material produced is applied as a paste, or under pressure in proportion to the porosity required.—J. C. R.

*Improvements in Electrode Plates for Secondary Batteries.* Dr. A. Lehmann, Berlin, Germany. Eng. Pat. 24,389, December 19, 1893.

A LEAD plate is so corrugated as to present the appearance of a series of gutters of semicircular section placed one above the other, with their axes horizontal. The top gutter is turned round its axis apparently 30° or 40° degrees to the right: its right-hand horizontal edge is the right-hand edge of the second gutter, which, running below it, is inclined towards the left: the left-hand edge of this is the left-hand edge of the third gutter, which is turned towards the right: and so on to the bottom of the plate. The active material is placed in these gutters, and is locked in place independently of the action of gravity, by passing into numerous perforations made in the metal. If any material should fall out of these perforations, it will fall into the gutter below.—E. T.

*A New or Improved Electrical Accumulator Plate.* C. K. Mills, London. From C. J. Barbier, Lyons, France. Eng. Pat. 24,442, December 19, 1893.

A NEW accumulator plate in which the active material is enclosed in a flat box of lead or lead alloy, the flat sides of which are perforated and provided on the interior with pins or projections passing through the active material, and extending to within a short distance of the opposite side.—E. T.

*Improvements in Primary Voltaic Batteries.* W. Walker, jun., Birmingham. F. R. Wilkins, Handsworth, and J. Lones, Smethwick. Eng. Pat. 616, January 11, 1894. Improvements on Eng. Pats. 23,007 of 1892 and 10,942 of 1893.

(THIS Journal, 1893, 1042; 1894, 529.) The porous pot, containing a zinc cylinder, is placed in a perforated vessel of earthenware, the annular space between them being packed with carbon granules, fine next the porous pot and coarser next the perforated outer vessel. Carbon electrodes make contact with these granules, which are thus kept continually moist by the leakage from the porous pot, and are yet bathed in air. It is the air which acts as depolarizer. Caustic potash or caustic soda are preferred as electrolytes. The cell, of course, stands in a tray, to collect the liquor flowing from the porous pot. A perforated metal cylinder is in some cases placed between the porous pot and the earthenware vessel, to make contact with the carbon granules, in place of the carbon electrodes.—E. T.

*Improvements in Electrical Accumulators or Storage Batteries.* D. Young, London. From the Hess Storage Battery Company, Springfield, U.S.A. Eng. Pat. 16,425, August 28, 1894.

THE electrode preferred by the patentees consists of a plate of active material clamped between two perforated lead sheets. The perforations and the spaces between the separate electrodes are filled with quartz, sand, or some such non-conductor, the separate grains of which are held together by some adhesive material like india-rubber or shellac, such material not being allowed to fill the interstices. The parts of the lead sheets not immediately in contact with the active material are varnished or otherwise protected.

The use of quartz sand or similar material, treated as above, is claimed for cells of any type, as well as for the one described.—E. T.

*Improvements in Secondary or Storage Batteries.* C. Rindon, Toronto, Canada. Eng. Pat. 18,288, September 22, 1894.

EACH electrode consists of a number of plates or strips of metal laid horizontally, and separated by layers of active

material. The side-edges of the strips are turned up or down, to keep all in position horizontally. Clamping-plates of insulating material are placed at top and bottom, and are furnished with side lugs, through which bolts pass to bind the whole together. Each bolt is provided with a springy washer—made, for example, of india-rubber—which, while constantly exercising pressure, allows for expansion of the electrode. At one end the metal strips are continued beyond the active material and bent upwards; they are united above the surface of the electrolyte by a saddle-piece carrying a terminal.—E. T.

*Improvements in and connected with Carbons for Electric Lamps, or for other Purposes.* E. G. Acheson, Monongahela, U.S.A. Eng. Pat. 18,339, September 27, 1894.

For arc lamps, the inventor uses rods made of pure carbon to which has been added about 10 per cent. of carbide of silicon; or the core of an ordinary carbon may be made of carbide of silicon.

For incandescent lamps, the carbide is suspended in the oil-bath used for building up the carbons, and gets bound up in the carbon deposited from the oil on the filament; or other methods may be employed to construct a filament containing carbide of silicon.

The inventor claims that the above additions to the pure carbon have the effect of increasing the number of light-waves produced at a given temperature.—E. T.

## XII.—FATS, OILS, AND SOAP MANUFACTURE.

*The Clarification of Oils.* Chem. and Druggist.  
November 24, 1894, 740.

MANY methods have been tried, some of which are very slow. In the *Corps Gras Industr.* cellulose and asbestos are especially recommended, filters similar to those used for beer, being used. The best results are said to be obtained by first clarifying by means of decantation, and finally filtering through cellulose.

*The Extraction of the Free Acids of Beeswax.* T. Marie.  
Comptes rend. 1894, 119, 428—431.

THE free acids characteristically present in beeswax, were considered by Brodie to be a chemical individual to which he assigned the name cerotic acid,  $C_{26}H_{52}O_2$  (melting point  $78^\circ\text{C}.$ ). Schalfew in 1875 showed that this substance was a mixture, containing a small quantity of an acid (melting point  $91^\circ\text{C}.$ ) of the formula  $C_{34}H_{68}O_2$ ; the more recent values of Nafzger for the same acid are melting point  $90^\circ\text{C}.$  and formula  $C_{30}H_{60}O_2$  or  $C_{31}H_{62}O_2$ . The author has endeavoured to supplement existing knowledge on this subject by working on large quantities of beeswax and submitting the products to various methods of fractionation, and has found that fractional solution in boiling methyl alcohol yields the best results, always provided that it be applied to mixtures of acids free from substances of alien character. In the case of beeswax, however, boiling alcohol dissolves certain hydrocarbons, fatty products and colouring matters which may be present, and also myricin in addition to these. (The last-named substance is almost insoluble in alcohol *per se*, but is taken into solution by the wax acids). The separation of the first two impurities is effected by taking advantage of the solubility of fatty and colouring matters in cold alcohol, and of the ease with which the hydrocarbons can be extracted from the salts of the wax acids. Myricin is removed by heating the crude wax acids with potash lime (containing half its weight of caustic potash), whereby it is saponified and the alcohols thus liberated oxidised and fixed as the corresponding acids. The

acids thus formed are found by the author to be identical with the free acids of the wax. The application of the foregoing method is made in the following way.—The wax is extracted with boiling alcohol, the bulk of which is distilled off. The residue is cooled and pressed to remove colouring and fatty matter. The cake of wax thus obtained is washed with boiling water, decolourised by charcoal and filtered. It is then heated with potash lime until hydrogen ceases to be evolved; the mass is powdered and boiled with a large quantity of water. The solution is saturated with dilute hydrochloric acid, the wax acids, in the presence of soluble calcium salts, being completely transformed into insoluble calcium salts, which are precipitated. These are washed, dried, and extracted by boiling alcohol and light petroleum (to dissolve impurities). The acids are recovered from the purified calcium salts and after the removal of a little palmitic acid, derived from the decomposition of the myricin, are found to fuse at  $79-80^\circ\text{C}.$  The mixed acids are gently heated with 30 times their weight of methyl alcohol, and filtered at  $60^\circ\text{C}.$ ; the filtrate, on cooling, deposits cerotic acid. The process is repeated until the fusing point falls to  $76^\circ$ ; a single recrystallisation of the product in ethyl alcohol, raises the fusing point to  $77.5^\circ\text{C}.$  This acid appears to be pure cerotic acid, several dry methods of fractionation having failed to prove it non-homogeneous. The crude acid on the other hand contains 30—40 per cent. of acids similar to cerotic acid.—B. B.

*The Behaviour of the Alkaline Salts of Fatty Acids and of Soaps in the Presence of Water.* I. and II. F. Kraff and A. Stern. Ber. 27, 1747—1761.

AN historical and critical account of the various theories of the action of soap and of the decomposition by water of the alkaline salts of the fatty acids of which it is composed. Chevreul's researches, the results of which were published in 1823 (*Recherches chimiques sur les corps gras d'origine animale*) still remain the most important ones on this subject. His views regarding the behaviour of the alkaline salts of the solid fatty acids and of oleic acid, when dissolved in a large amount of water, although now generally abandoned in favour of those of Rotondi and others must, according to the authors' investigations, still be accepted as correct. According to Chevreul a solution of normal potassium stearate in 20 parts of boiling water gives on dilution with 1,000 parts more of hot water and subsequent cooling a precipitate of an acid stearate, potassium hydrate and only an almost imperceptible trace of stearic acid remaining in solution. Potassium oleate, on the other hand, shows far greater stability, and in order to effect its decomposition it is necessary to use a very large quantity of water and to expose the solution to a low temperature for a considerable time. Chevreul made use of this difference in the behaviour of the stearates (and margarates) and oleates for the separation of the respective acids. An acid potassium oleate (bioleate) was obtained by the same investigator by the combination of weighed quantities of oleic acid and caustic potash, as an almost insoluble substance. Rotondi (1883) assumes that the soaps are split up by water into basic and acid salts, the former being readily soluble in hot and cold water. His experiments were made with a solution of purified Marseilles soap. Subjecting this to dialysis he obtained besides the insoluble acid salt, an alkaline solution, in which, after evaporation on the water-bath, he estimated the amount of sodium, and, overlooking the fact that the supposed alkaline soap consisted of nothing but a mixture of free alkali and sodium oleate, he arrived at his erroneous conclusions. Basic alkaline salts of the fatty acids and of oleic acid have never yet been obtained. The authors likewise did not succeed in preparing them. Thus, by dissolving equal parts of elaidic acid and caustic soda in hot alcohol, and pressing and drying the crystals *in vacuo* which separated on cooling from the filtered solution, it was found that only normal (neutral) sodium elaidate had been formed. A further proof of the non-existence of basic soaps is the fact that from highly alkaline soap solutions only neutral soap is precipitated by the addition of common

salt. This has long been recognised by practical soap-makers, and was verified by the authors by accurate experiments.

For the study of the hydrolysis of soap the authors used pure sodium palmitate. It was found that about 900 parts of water are required to separate all the palmitic acid as acid sodium palmitate,  $C_{15}H_{31}O_2Na$ ,  $C_{15}H_{31}O_2$ , and that by reducing the quantity of water less acid palmitates of varying composition can be obtained. The dilute hot solution of sodium palmitate or stearate shows the remarkable property of possessing a strongly alkaline reaction, and at the same time containing minute globules of free fatty acid in suspension. By extraction of the hot solution with toluene, the fatty acid can be obtained in a state of perfect purity. Formation of the acid salt takes place on cooling the solution, by the combination of the acid set free with the neutral salt remaining undecomposed in solution. The filtrate from the acid salt never became strikingly turbid by the addition of a mineral acid, and therefore could not contain a basic salt, but consisted simply of a solution of alkali. It seems probable that not only the free alkali but also the finely suspended free fatty acid plays a definite part in the washing process with hot soap solutions. The difference in the action of water on neutral sodium oleate as compared with sodium palmitate and stearate is shown clearly by the fact that 200 parts of hot water are necessary to produce even a faintly turbid solution of sodium oleate. This turbidity is scarcely increased in a solution of 1:900, and immediately disappears on addition of a small quantity of alkali. The acid sodium oleate behaves in a different manner, being immediately split up by an excess of cold water, with separation of minute globules of free oleic acid, causing a turbid solution. Sodium elaidate closely resembles sodium stearate in its behaviour in dilute aqueous solutions.

Regarding the cleansing action of soap the authors point out that its emulsifying capacity for greasy substances, and the important part which this plays, was fully recognised by Chevreul, Berzelius (1828), and Persoz (1846), whilst more recently purely chemical theories of its action held the field. By more recent research the truth of Chevreul's theory has become fully established.—F. M.

*Action of Hydrogen Sodium Sulphite and Sulphurous Acid on Oleic and Erucic Acids.* M., C., and Alex. Saytzeff. *J. Prakt. Chem.* 50, 1894, 73—80.

DESIRING to extend the field of research opened up by the investigations of Strecker and Messel and others on the direct union of unsaturated carbon compounds with bi-sulphites of the alkalis, the authors experimented on oleic and erucic acids, but with results differing from those obtained by their predecessors with such bodies as fumaric acid, acrolein, &c.

On gradually heating oleic acid with an equal bulk of  $NaHSO_3$  solution (saturated in the cold) in sealed tubes up to  $180^\circ C.$ , the liquid separated when cooled into a crystalloid fatty layer, a watery liquor containing  $H_2SO_4$  and free sulphur. The fat, after repeated recrystallisation and purification by alcohol and ether, was found to be identical in composition with oleic acid, and from observation of its melting and congealing points, behaviour in combination with alkalis and silver, oxidation by potassium permanganate, and results when tested by an alcoholic solution of iodine in presence of  $HgBr_2$ , was considered to be elaidic acid, which view was confirmed on comparison with this acid prepared by the action of nitrous acid on oleic acid.

In order to determine whether the transformation was attributable to the action of the hydrogen sodium sulphite itself or to the sulphur dioxide evolved therefrom at the high temperature, the experiment was repeated separately with neutral sulphite of sodium and with a solution of  $SO_2$  saturated in the cold. In the former case no detectable amount of elaidic acid was produced, even with a temperature of  $200^\circ C.$  and over, but with the  $SO_2$  solution (kept at  $200^\circ C.$  for 24 hours) the same phenomena were observed as in the original experiment and the resulting fat exhibited

on purification all the characteristics of elaidic acid. The amount of this acid produced was increased when a larger initial volume of  $SO_2$  solution was employed.

Erucic acid yielded brassic acid on being treated with hydrogen sodium sulphite or sulphurous acid under the same conditions as the oleic acid, and the brassic acid thus obtained corresponded in all particulars with the same acid prepared by the action of nitrous acid on erucic acid. Almond oil also yielded elaidic acid on exposure to the same treatment, and in addition the oil underwent saponification with formation of fatty acids and glycerol.—C. S.

*A Simple Viscosimeter.* M. Wendriner. *Zeits. angew. Chem.* 1894, 545.

See under XXIII., page 1220.

## PATENTS.

*Improvements in Bleaching, Sweetening, and Purifying Oils and Fats.* F. B. Aspinall, R. W. Hoar, and G. H. Wise, Hull. Eng. Pat. 18,767, October 6, 1893.

THE application of an electric current is claimed for this purpose. A tank divided into two parts by a porous partition is used. In one compartment a carbon electrode is placed in a solution of salt at  $8^\circ T.$ , and in the other compartment a copper electrode, with a mixture of equal parts of oil and salt solution. A continuous electric current is then generated by a dynamo, the oil and salt solution being agitated by mechanical means at the same time. The treatment of oils and fats by means of the light and heat generated by incandescent electric lamps immersed in the oil is also claimed.—J. J. K.

*Process of Distilling Glycerin and similar Liquids, and of Treating the Residue Obtained after Distilling Glycerin.* J. Van Ruynebeke, New York, U.S.A. Eng. Pat. 24,556, December 20, 1893.

THE first part of this invention consists in the use of a closed vessel, containing an expansion coil of larger diameter than that of the steampipe from the boiler, for the purpose of allowing the steam to be expanded in the coil, and reheated at the same time by steam outside the coil, supplied by the same boiler. This reheated steam at a temperature of  $300^\circ F.$  is then blown into the still containing the crude glycerin or glycerin residues, which is also heated by a steam coil. A high vacuum is maintained in the still during the distillation.

The second part of the invention consists in treating the "foots" left in the still, with sulphuric or hydrochloric acid, to decompose the sodium salts of the non-volatile organic acids, separating the precipitate formed, then volatilising the acetic acid, and distilling off the glycerin from the residual liquid in the manner described above.

—J. J. K.

*An Improved Soap.* H. J. W. Taylor, Scarborough. Eng. Pat. 25,001, December 29, 1893.

THE alleged improvement consists in the admixture of about one part of chocolate, cocoa, or the extracts thereof with three parts of ordinary soap, whereby it is claimed that a soft and pleasing effect is produced on the skin.—J. J. K.

*Improvements Relating to the Manufacture of Soaps.* J. O. Klimsch, Vienna. Eng. Pat. 15,228, August 9, 1894.

THIS relates to the production of a hard resia soap. 100 kilos. of resin and 120 kilos. of sodium carbonate are mixed and ground to a powder, and the mixture is moistened with a binding agent, such as alcohol, benzene, glycerin, starch, glue, or other material, and pressed into tablets or bars. This soap is said to be soluble in cold water.—J. J. K.

### XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, Etc.

#### (A).—PIGMENTS, PAINTS.

##### PATENTS.

*Improvements in Washing Blue.* K. Ammann, Lenzburg, Switzerland. Eng. Pat. 17,630, September 17, 1894.

THREE hundred parts of ultramarine in fine powder are mixed with 150 of powdered and warmed glucose and five parts of sodium thiosulphate (hypo-sulphite), perfume being added if desired. It is claimed that this device renders spotting of the goods impossible, and that the balls may be repeatedly used until they are completely consumed without suffering any decomposition and without the appearance of fungoid growths.—F. H. L.

*An Improvement in and relating to Compounds for Destroying or Removing Old Paints.* E. Tessen, Rostock, Germany. Eng. Pat. 17,544, September 14, 1894.

It is claimed for this composition, that it will remove old paint or lacquer from wooden surfaces completely, in a short time without injuring the wood itself. This is effected by introducing into the substance a quantity of "unsaponified" paraffin oil, "said oil having the property of filling the pores of the wood, and of protecting thereby the fibres of the latter." 30 kilos. of linseed oil are saponified with 20 of caustic potash, 100 of paraffin added, and the mixture stirred into 50 of slaked lime. When homogeneous, 500 kilos. of caustic soda, 200 of potash, 200 of chalk, and 25 of starch or flour are mixed with it, and the whole is ready for use.

—F. H. L.

#### (B).—RESINS, VARNISHES.

##### PATENTS.

*Improvements in Varnish.* R. G. Bennett, London. Eng. Pat. 19,115, October 11, 1893.

LINSEED oil is mixed with half its weight of water and 2 per cent. of sulphuric acid and an electric current passed through the liquid which is kept in the form of an emulsion by means of a stream of air or ozonised air, one or more of the electrodes being made in the form of a revolving disc to assist in the agitation. Sodium peroxide in small quantities may be added to hasten the oxidation, but in the latter case, care must be taken to avoid fire. Gum or resin varnishes in oil or turpentine may be prepared in a similar manner after the addition of 10 per cent. of water.—F. H. L.

*New or Improved Manufacture of Varnish, or of a Substance for Use in Making Varnish.* L. L. B. Meyer, Hamburg, Germany. Eng. Pat. 9883, May 21, 1894.

FAT-TAR, a kind of pitch which remains in the still after the dry distillation of fatty acids, is heated for a few minutes to 500° C. with 5 or 6 per cent. of litharge, and 5 or 4 per cent. of lead peroxide. When cold it is dissolved in a mineral "oil" such as benzene, and diluted to a proper varnish strength with turpentine or other diluent.—F. H. L.

#### (C).—INDIA-RUBBER, &c.

##### PATENT.

*A New Elastic Material or Manufacture, composed chiefly of Gutta Percha, India-Rubber, or other Analogous Substance, and the Application of the Same to various Useful Purposes.* E. M. Desprez, Paris. Eng. Pat. 23,028, November 30, 1893.

THIS invention consists primarily in the manufacture of a strong or tough elastic material by taking gutta-percha, &c. in the form of a sheet and covering it on one or both sides

with a more or less close-meshed fabric or wire gauze, the whole being agglomerated by simple pressure under heat. With the gutta-percha may be incorporated saw dust and zinc oxide for various purposes, and the material may finally be cut up into strips. Its chief value lies in the ease with which it can be moulded by heat into any shape, the curvature being retained when cold.—F. H. L.

### XIV.—TANNING, LEATHER, GLUE, AND SIZE.

*The Estimation of the Sugar Content of Tanning Materials, Tanning Extracts, Tanning Liquor and Weighted Leather.* A. Schroeder, A. Bartel, and W. Schmitz-Dumont. Dingl. Polyt. J. 1894, 293, 234.

See under XXIII., page 1227.

##### PATENTS.

*Improvements in the Treatment of and Improved Products from the Seed of the Locust Bean.* J. Pearson, Liverpool, and F. H. Taunton, Waterloo, Lancaster. Eng. Pat. 20,368, October 28, 1893.

THE kernel of the locust bean consists of two equal parts, which are secured together by a considerable thickness of matter different, as regards its construction, from that of the halves forming the kernel. If this "division" substance, which includes the germ, be removed from the kernel, the products made from the bean will keep for a much longer time than would otherwise be the case. The bean is accordingly decorticated, cracked, and cleansed to remove this division substance: it is then heated in water, milk, or other suitable liquid (3 or 4 gallons per pound of seed), for 5 or 6 hours with occasional stirring. The decoction is strained and the liquid extract concentrated, when it becomes useful as a lubricant or sizing material; if it be poured upon a hot plate a dry cake is obtained, and may be substituted for gelatin, isinglass, glue, &c. The solid matter strained from the extract is boiled with water until it becomes a firm jelly; this is suitable as a basis for soap, or as a toilet requisite, or as a gelatinous substance to be used in cookery.

The necessary machinery consists of rollers or grinding tools, such as emery wheels, designed to excoriate the division substance from the surface of the half bean.

—A. G. B.

*Improvements in Machines for Removing Stiff Water or Waste Hairs from Pelts.* L. Werner, New York, U.S.A. Eng. Pat. 17,710, September 18, 1894.

VARIOUS machines have been made for removing the stiff water or waste hairs from pelts, notably one which separates the soft fur from the water hairs by a blast of air, so that the shearing mechanism can remove the water hairs without damaging the fur. In the present modification the pelt is fed intermittently over the edge of a plate where the fur is turned aside by a brush, and the water hairs made to stand erect on the sharp edge of the plate; a metallic conductor, heated to redness by an electric current, is then brought in contact with these hairs so as to burn them away. The appropriate mechanism is described and depicted in the specification.—A. G. B.

## XV.—MANURES, Etc.

*The Valuation of Artificial Manures.* E. Henfeldt.  
Zeits. angew. Chem. 1894, 383.  
See under XXIII., page 1224.

*Estimation of Phosphoric Acid by the Citrate Method.*  
F. Glaser. Zeits. angew. Chem. 1894, 543.  
See under XXIII., page 1225.

*The Agricultural Value of certain Natural Phosphates.*  
G. Paturel. Comptes rend. 119, 1894, 119—122.

THE fertilising power of mineral (fossil) phosphates varies considerably, although so far as richness in phosphoric acid is concerned, there may be little difference between good and indifferent samples. In order to throw light on the matter, the author, starting with the idea that the assimilation of phosphoric acid is due to the solvent action of acids contained in the roots of plants and in the soil, has investigated the solubility of two different samples of phosphate in solutions of organic acids (citric and acetic acids). From the results it is concluded that the solubility of natural phosphates depends almost entirely on the amount of chalk (calcareous gangue) associated with the mineral; large quantities of chalk, by reason of its neutralising action on the acids of the soil, &c., having the effect of almost completely preventing solution. It is to this fact that the comparative inutility of certain phosphates (for instance, the granular phosphate from the Somme district, which contains much chalk) must be ascribed. Determinations of the commercial value of mineral phosphates should not, therefore, be based solely on their richness in  $P_2O_5$ ; account must be taken of the chalk present, and a reduction, proportionate to its amount, made in the price.—H. T. P.

## XVI.—SUGAR, STARCH, GUM, Etc.

*Losses by Concentrating Beetroot Juice.* Degener.  
Deutsch Zuckerind. 1894, 19, 1210.

DESTRUCTION of sugar occurs during the boiling process, and indeed principally by the protracted contact of the liquor with heated surfaces; the compounds formed in this way are of a dextrin-like nature, but their properties are as yet unknown. Their presence in technical products renders uncertain the analytical results obtained by the application of the raffinose formula (inversion method), but besides this, since they may be melassigenic at high temperatures and concentrations, a fresh difficulty is introduced in the calculation of the losses.—A. R. L.

*Decomposition of Sugar during Evaporation.* Strohm.  
Oesterr. Zeit. Zuckerind. 1894, 23, 456.

THE author again directs attention to this important question. Herzfeld has observed that the losses in practice (for example, in the boiling of heavy massecuites) are much greater than were those in his own laboratory experiments, in which much lower concentrations were dealt with. Claassen's values are perhaps also too low.—A. R. L.

*Purification of Beetroot Juice.* Bouvier. Sucr. indigène, 1894, 43, 724.

THE author explains the advantages arising from completely freeing the raw juice from albuminous matters and pulp, and recommends defecating the juice at a temperature of 80° C. with dry lime, which presents advantages.—A. R. L.

*Diffusion in Vacuo according to Heckmann's Process.*  
Mügge. Zeits. Zuckerind. 1894, 44, 596.

THE author has obtained good results with this process. He points out, however, that it was patented as long ago as 1867. Beauvais and Vier have also found that the process yields good practical results.—A. R. L.

*Purification of Beetroot Juice.* Sucr. indigène, 1894, 44, 2.

THE method advocated here is to treat the juice in the cold with dry lime, to saturate with carbonic acid in closed centrifugal machines either at a high or low temperature, and finally to remove the last traces of lime in pans.  
—A. R. L.

*Estimation of the Quantity of Crystalline Sugar contained in Massecuites.* Vivien. Sucr. indigène, 1894, 44, 234.

THE author effects this by systematic washing of the massecuites with saturated chloride. The percentage of water in the resulting white sugar is estimated, and this deducted, together with double its amount of sugar.—A. R. L.

*Yield of Sugar from Massecuite.* Claassen. Deutsch Zuckerind. 1894, 19, 956.

THE author shows conclusively that the yield of sugar is augmented much more rapidly when the purity of the massecuite is increased than when the amount of drainage syrup is diminished, and it is not, therefore, as a rule, to be recommended to allow the quotients of the drainage syrups to fall below 70—73, which can with certainty be accomplished by means of crystallisation in motion.—A. R. L.

*Grey Colour of Raw Beetroot Sugars.* Drenckmann.  
Zeit. Zuckerind. 1894, 44, 632.

THE grey colour and sensitiveness towards light of many massecuites and raw sugars met with during the last campaign is, among other causes, to be attributed to the presence of citric acid or citrate of iron. Citric acid and its amide were found frequently in large quantities in the products manufactured during the present year.—A. R. L.

*Valuation of Raw Sugars and After-products on the Basis of their Content of Crystalline Sugar.* Karcz. Oesterr. Zeits. Zuckerind. 1894, 23, 557.

THE so-called "Rendement" gives no idea of the real yield of refined sugar obtained in practice, because the latter does not depend upon such illusory values, but (other things being equal) it depends upon the amount of crystalline sugar contained in the raw sugar and upon the purity of the syrup which drains from it. By the aid of the author's glycerin process the amount of crystalline sugar may be determined, and from this the yield can be calculated.

A refinery, for example, worked 330,000 metre-centners of raw sugar of Pol. 95·3, water 1·8, ash 1·25, and organic matter 1·65 per cent., having thus a "Rendement" of 89·05. The percentage of crystalline sugar was, however, only 87·85, besides which the sugar contained 12·15 per cent. of syrup having a purity of 71·96. The known loss of sugar in the refinery was 0·69 per cent., due to decomposition by boiling, and 0·21 per cent. by washing, making a total of 0·90 per cent. on 100 parts of sugar or 0·61 + 0·19 = 0·80 per cent. on 87·85 parts of sugar. The remaining syrup comprised 12·15 + 0·61 = 12·76 per cent. of 67·96 purity, yielding according to experience 1·95 per cent. of after-product containing 1·56 per cent. crystalline sugar. The calculated yield is therefore 87·85 - 0·80 + 1·56 = 88·61 or 0·44 per cent. below the "Rendement." In reality the yield amounted to 286,950 metre-centners or 86·159 per cent. of white sugar, and 9,726 metre-centners of after-product containing 2·490 of crystalline sugar,

making a total of 88.649 per cent., thus 0.039 per cent. above the calculated; this difference would probably vanish when the after-product was manufactured into refined sugar.

—A. R. L.

*Inversion of Sugar by Glycerol.* Bordt. Zeits. Zuckerind. 1894, **44**, 701.

THE author shows that Donath's observations (this Journal, 1894, 823) are erroneous and that aqueous solutions of saccharose are more easily inverted when heated alone at 130° C. than in presence of glycerol.—A. R. L.

*Remarks on the Alcoholic Extraction of Beetroots.* Wiskirchen. Zeits. Zuckerind. 1894, **44**, 700.

#### PATENTS.

*Process for Purifying and Decolourising Saccharine Juices and Sugar Solutions.* C. Steffen, Vienna, Austria. Eng. Pat. 20,397, October 28, 1893.

THE patentee claims a process for obtaining decolourised and purified sugar solutions by treatment of the juices of

beetroot and cane-sugar manufacture after they have been defecated in the usual way, and in some cases saturated with carbonic acid, freed from defecation scum, and cooled below 60° C. (preferably, however, between 30 and 40° C., or lower) with sulphurous acid. He also claims the application of the same process to medium and thick juices of any concentration as well as to all syrups of the sugar manufacture; furthermore, the repeated application of the process to sugar solutions which have been partially decolourised, as also to the *chareux* or fine liquors of refineries. The sulphurous acid is employed in sufficient quantity so that the colouring and other non-saccharine matter are as much as possible made to form sulphite or acid sulphite compounds, being thereafter precipitated together with the acid in excess, by the action of suitable quantities of lime (or of baryta, strontia, alumina, &c.). The resulting neutral or slightly alkaline liquors being freed from the precipitates and, if desired, subsequently filtered through small quantities of animal charcoal, in order to obtain a still higher degree of decolourisation and purification.—A. R. L.

*An Elastic Composition for Moulds.* E. Hérisse, London. Eng. Pat. 5440, March 15, 1894.

FOUR parts of gelatin are softened in water, melted by heat, and added to one part of glucose previously dissolved in sufficient water to give it the consistency of "boiled sugar." The mixture is well stirred, allowed to set, again melted to remove air bubbles, and poured into suitable matrices. When cold, it is stained orange, by being dipped in a five per cent. solution of potassium permanganate, and after drying it is ready for employment as a flexible mould for casting articles of confectionery.—F. H. L.

*Improved Process for the Treatment of the Juice of Sugar Canes.* H. H. Leigh, London. From G. Cambray, Paris, France. Eng. Pat. 11,812, August 2, 1894.

THIS process consists in the subjection of cane juices to a double treatment with sulphurous acid (SO<sub>2</sub>), as follows:—The juice, after treatment with lime, is fed into tanks, where it is saturated to such an extent, either hot or cold, with sulphurous acid (SO<sub>2</sub>) that it allows the separation from it of the precipitates, either by decantation or by filtration under pressure. The clear juice is then again treated with sulphurous acid, until it is neutral or slightly acid, after which it is filtered through any type of mechanical filter. A perfectly colourless highly pure liquor is thereby obtained.

—A. R. L.

#### XVII.—BREWING, WINES, SPIRITS, Etc.

*Behaviour of Various Sugars towards Pure Yeast Cultures.* E. Fischer and H. Thierfelder. Ber. 1894, **27**, 2031—2037.

THE older experiments on the fermentability of various sugars were carried out with ordinary brewery yeast. A description of the results obtained by operating in this manner is to be found in the paper of Stone and Tollens (Liebig's Annalen, **249**, 257). According to the observations of these chemists, glucose, fruit sugar and galactose are completely fermentable; arabinose is, however, unfermentable. Sorbose is also stated to ferment but slowly and incompletely with ordinary yeast. The investigations of Hansen have shown that the yeasts formerly employed in the industry are mixtures which, by systematic cultivation are separable into a large number of sharply-defined varieties. The behaviour of a number of pure cultivations of yeast towards glucose, saccharose, maltose, and milk sugar has been studied by Hansen himself (see Jørgensen, Mikroorganismen der Gährungsindustrie, page 131). According to his observations, we have to do with three different classes of Saccharomycetes, of which the members

of the first and most numerous, ferment glucose, saccharose, and maltose. In this class are included *Saccharomyces cerevisia*, I.; *S. Pastorianus*, I., II., and III.; and *S. Ellipsoides*, I. and II. The second class embraces the class whose members ferment glucose and saccharose but not maltose (*S. Marxianus*, *S. Ludwigii*, and *S. Eriguns*). The third class is represented by a single species (*S. Membranifolius*), which, strangely enough, does not exhibit the phenomenon of alcoholic fermentation. Milk sugar is not affected by any of the above-mentioned *Saccharomyces*.

*S. apiculatus* ferments glucose, d-mannose, and d-fructose (Chemer, Zeits. Biol. 29, 525), but not galactose (Voit, *ibid.* 29, 149), saccharose, milk sugar, and maltose (Hansen, Anthor. Zeit. physiol. Chem. 12, 563). Finally, Daclaux (Annal. Institut. Pasteur, 1, 573), Adametz (Centralbl. Bact. und Paras. 5, 116), Grolenfeld (Fortschr. d. Mediz. 1889, 121), Byerinck (Centralbl. Bact. und Paras. 6, 44), and Kayser (Annal. Inst. Pasteur, 1891, 395), have described some yeasts which ferment milk sugar.

The authors have investigated the action of 12 different yeasts on various sugars, including some of the synthetical sugars and glucosides obtained by Fischer. In order to economise the material, the experiments were carried out on a small scale, making use of the flask which is shown in the cut in its actual size. The flask *a*, having a capacity of about 1 cc., is closed with a wadding stopper, sterilised, and about two-thirds filled with a mixture of equal parts of a 20 per cent. aqueous sugar solution and yeast extract. The latter is prepared by boiling well washed and pressed pure yeast with four parts of water, and, after repeatedly filtering the extract so obtained, adding a small quantity of citric acid thereto. To the carefully sterilised liquid about 0.013 gm. of the pure yeast cultivated on beer-wort gelatin is then added by means of a platinum wire furnished with a loop, observing the usual precautions; the tube *b*, which is filled to the mark *c* with baryta water and also sterilised, is then inserted, the joint being rendered gas-tight by smearing the inner portion with vaseline and melting paraffin round the outer portion. The apparatus so charged is allowed to remain 3—10 days in an incubator, the temperature being

maintained at 24°—28° C. In all cases when the sugar is unfermentable, and even when no sugar is present beyond

that contained in the yeast extract, the surface of the baryta water is covered with a thin layer of barium carbonate. If, however, the carbohydrate be fermentable, the baryta water not only becomes turbid, but the whole of the barium is precipitated as carbonate, and finally no reduction by Fehling's solution takes place by the liquid which contained the sugar in solution. In cases in which the material is not directly fermentable, but only so after hydrolysis, such as with the glucosides, and where, on this account, fermentation proceeds slowly, and probably with a limited quantity of yeast is never complete, the amount of evolved carbonic anhydride is always sufficient to indicate whether fermentation has or has not taken place.

The results obtained are shown in the following table:—

	d-Mannose.	d-Fructose.	d-Glucose.	d-Talose.	L-Mannose.	L-Glucose.	Sorbose.	L-Arabinose.	Rhamnose.	α-Glucoheptose.	α-Glucooctose.	Saccharose.	Maltose.	Milk Sugar.	Methyl Glucoside. <sup>c</sup>	Ethyl Glucoside. <sup>c</sup>	Glucose Resorcinol.	Glucose Pyrogallol.	Glucose Ethyl Mercaptal.

Milk sugar yeast . .	++	+++	+	..	..	..	..	..	..	..	..	+++	..	+++	..				

Explanation of the table:—

.. denotes that the solution no longer reduces Fehling's solution at the end of eight days; thus fermentation was complete.

++ denotes a very slight reduction after eight days; thus almost complete fermentation.

+++ denotes distinct reduction after eight days, but undoubted fermentation.

.. denotes no fermentation.

<sup>1</sup> Obtained from C. E. Hansen.

<sup>2</sup> This was Töberg yeast, or yeast No. 10 (see Irmsch. Wochensh. Brauw. 1891, No. 39—46); P. Lindner, *ibid.* 1893, 692; 1894, 381.

<sup>3</sup> This is described in the literature as yeast No. 128, variety 2 (see Zeit. Spiritusind. 1892, 361).

<sup>4</sup> Obtained from B. Yerinck.

<sup>5</sup> This yeast has not yet been morphologically defined.

The test after complete fermentation was omitted in these cases, as the detection of the glucoside, which only reduces Fehling's solution after hydrolysis, is rendered difficult by the presence of yeast glycogen.

<sup>6</sup> After 11 days the sugar had all disappeared.

These experiments, so far as they are a repetition of the results of others, confirm all the older observations with the exception of that of Stone and Tollens, who found that sorbose was fermentable, although incompletely so—a result which must have been due to the presence of foreign organisms in the yeast. Sorbose is unaffected by pure yeast.

The authors then discuss the bearing of these results on the configurations of the various sugars.

It is shown, furthermore, that it is possible to ferment away, by means of *S. Pastorianus* L., the whole of the glucose from mixtures of that sugar with *D*-mannose, the latter remaining unattacked by the yeast at the end of three months.—A. R. L.

#### Maltol. J. Brand. Ber. 27, 806–810.

An aqueous solution of the so-called "crystal malt" gives a similar reaction to salicylic acid with ferric chloride, leading in the past to the erroneous conclusion that beers made from this class of malt contained salicylic acid. On carefully heating crystal malt in a test-tube the whole of the substance which gives this reaction is volatilised, and hence it is that patent black malts do not give this coloration with ferric chloride. By treating the aqueous extract of crystal malt with ether it was obtained as needle-shaped crystals, melting at 148–150° C., and soluble in water. It yields no coloration with Millon's reagent—a reaction which differentiates it from salicylic acid. The author prepared it in large quantity from the steam issuing from the roasting cylinders employed in the manufacture of "coffee-malt." By this method it was obtained as large, shining, yellowish leaflets which were odourless, and had a melting point of 159° C. They were very soluble in hot water, in chloroform, and in acetic acid. Analysis showed its formula was  $C_6H_8O_3$ . It shows some phenol characteristics, gives some but not all the aldehydic reactions, and is not a true acid, so that the author concludes it is derived from a sugar by the abstraction of water, and gives the following as the formula of "maltol":—

Maltol is thus of great interest, as it is allied to cincol and its derivatives, and also to the terpenes.—J. G. W.

#### Employment of Selected Yeasts in Wine Production. Charles Fabre. Comptes rend. 119, 1894, 373–375.

The author carried out experiments during 1891–93 in order to find to what extent the character of wine from a given must, may be altered or improved by the use of selected yeasts. The musts used in the laboratory had been previously heated to 70° C., and were sown with selected yeasts obtained from the Institut de la Claire. For instance, must from Cabernet-Sauvignon was sown with yeast from Margaux; Sauterne must with *Sémillon* yeast; and Vongont must with yeast from Pineau noir.

The results obtained show that the same must behaves differently with different yeasts, in spite of the sterilisation of the must at 70° C., but the flavour of a wine, although depending partly on the yeasts used, also largely depends on the composition of the must. Experiments were conducted on the large scale, using 3 hectols. of must, and the following conclusions are to be drawn therefrom:—

(1.) A selected yeast will not yield a fine wine with every must.

(2.) The must used should be obtained from grapes which were grown in and were well acclimatised to the district from which the selected yeasts used were obtained.—T. A. G.

#### Phenomena accompanying the Dialysis of the Cells of Beer Yeast. E. Ommus. Comptes rend. 1894, 119, 179–180.

If a solution of sugar in boiled water be separated from an aqueous yeast extract by means of a membrane of parchment paper, the sugar is found to be inverted after 15–20 minutes. No cells can, however, be discerned under the microscope, but only some microzymes; and it is only after two or three hours that a few isolated yeast cells make their appearance. A solution of sugar freely exposed to the air was found to undergo no alteration during this period. In order to completely exclude air, the author placed a sugar solution in a small metallic cup, the orifice of which was covered with parchment paper held in position by a metallic band. The solution was boiled and the whole treated with beer yeast. On the following day the sugar was inverted, and small isolated cells could be discerned in the liquid.

These experiments show that beer yeast secretes a dialysable substance, and that the inversion of sugar precedes the appearance of new cells. The medium is at first modified by the enzyme, and only after this process does it become nutritive for whatever can give birth to the cells.—A. R. L.

#### Yeast Gum. E. Salkowski. Ber. 27, 925–926.

The author considers that his formula for this body,  $C_{12}H_{22}O_{11}$ , is more probably correct than Hesseland's,  $C_{12}H_{20}O_{10}$ , as the products of its hydrolysis were found by Hesseland to be *D*-mannose and a little dextrose, which renders it probable that his preparation was not homogeneous.—J. G. W.

#### The Power in Ferments of becoming Inured to the Action of Antiseptics, and the Influence of the Inurement upon their Chemical Work. J. Filron. Comptes rend. 119, 169.

In his preceding work the author showed that the inurement of brewer's yeast to the antiseptic action of fluorine compounds, brings about a manifest change in the chemical work effected by these organisms of the yeast; such change, indeed, that the secondary fermentation, which consists in the formation of glycerol and succinic acid from the sugar, diminishes, gradually and proportionally, according as the yeast has become more or less accustomed or inured to fluorine antiseptics; so that after a sufficiently lengthy inurement, its chemical work consists almost exclusively in the transformation of sugar into alcohol and carbon dioxide.

The author has now extended his work to the cases of the lactic acid and butyric acid ferments, and to that of *mycoderma aceti* (acetic acid ferment).

In the first place the author established—by inoculating with pure cultures of the lactic and butyric ferments, sterilised malt infusions, to which varying quantities of hydrofluoric acid had been added—that 25 and 12 mgrms. of hydrofluoric acid per 100 grms. of infusion were respectively sufficient to arrest the lactic and butyric fermentations.

He then proceeded to inure the organisms to the hydrofluoric acid by a series of cultures, in which the amount of hydrofluoric acid present was gradually increased until the organisms were able to withstand the antiseptic (inhibitory) influence of 30 mgrms. of hydrofluoric acid in 100 grms. of malt infusion.

In such infusions the ferments produced 1.5 grms. of lactic acid and 0.86 grm. of butyric acid per 100 grms. of infusion—quantities which are approximately equal to those which, with like environment, but with absence of hydrofluoric acid, are produced by the respective ferments. Microscopic examinations showed that, just as was the case with yeast, less than the normal amount of new cells had been formed; so that, in the presence of hydrofluoric acid, though their powers of increase had been curtailed, the fermenting power of the cells had proportionally increased.

In ordinary lactic and butyric fermentations, just as in alcoholic fermentation, secondary products are undoubtedly

formed, and that this is so may be proved by estimation of the sugar before and after fermentation; the acid formed being found not to account for the whole of the sugar which has disappeared. Little, however, is as yet known about these secondary products of the lactic and butyric fermentations.

With the *mycoderma aceti* fermentation the change in the character of the chemical work accomplished is much more strongly marked. Here the author employed a mixture containing in 100 parts, 6 parts of alcohol, 1 of acetic acid, and 5 of a sterilised malt infusion, the specific gravity of which was 7° B. In the presence of 50 mgrms. of hydrofluoric acid, such a mixture, after being inoculated with the acetic ferment, developed no mycelium, nor was there increase in the amount of acetic acid; in control experiments, where the antiseptic was absent, the development of the *mycoderma* was quite regular; the production of acid normal.

A series of cultures was now undertaken with increasing quantities of hydrofluoric acid present, and it was noted that as the increment (power of resistance to the antiseptic) of the fungus increased, so proportionally the oxidation approached that represented by the equation—

A series of determinations of the alcohol and acetic acid, in liquids which had been submitted to acidification during three days, gave the following figures per 100 grms. of liquid:—

HF Present.	C <sub>2</sub> H <sub>5</sub> HO Remaining.	CH <sub>3</sub> .COOH Formed.
0·0	1·55	4·32
0·025	1·75	3·27
0·050	1·95	1·31
0·120	1·40	0·12

So that, as against the disappearance of 100 parts of alcohol, there is an appearance of acetic acid of 97·08 parts (HF present = 0), of 76·94 parts (HF = 0·025), of 32·34 parts (HF = 0·05), and of 2·62 parts (HF = 0·120) respectively.

In conclusion the author states that the study of the increment of ferments to antiseptics has a very special interest from the point of view of bacteriological pathology; he suggests that perhaps certain pathogenic ferments may lose some of their virulence under an antiseptic treatment by fluorine compounds, and he further states that he has already commenced work in this direction.—E. R. B.

#### PATENTS.

*Improved Manufacture or Production of Extracts from Malted Grain.* F. Faulkner, Birmingham, and J. E. J. Johnson, Old Ford. Eng. Pat. 23,846, December 11, 1893.

The patentees claim the invention of certain fluid extracts from malted grain denoted respectively:—*Digestive malt extract*, *saccharine malt extract*, and *amide yeast food*.

In the manufacture of so-called *digestive malt extract* one quarter of malt may be heated at 110° F. for 50 minutes with, say, 108 gallons of water. The extract so obtained is separated from the draff or grain, and the liquid concentrated *in vacuo* at a temperature not exceeding 118° F. until it has the consistency of about a 14-lb. syrup, or 14 lb. to the gallon. This extract is suitable for medicinal purposes, and also for use in breweries and distilleries as a nutritive material for yeast.

*Saccharine malt extract* is prepared by mixing the primary or partially extracted draff from the last-mentioned operation, with about 15 or 20 per cent. of fresh crushed malt, and adding the mixture to water in the proportion of about one quarter of mixed draff and fresh malt to about 72 galls. of water at about 110° F., maintaining the mash at this temperature for about 50 minutes, and finally raising it to 150—160° F. for 10—15 minutes. The liquor filtered from the draff is then concentrated to a 14-lb. syrup, and thus forms an extract practically equivalent to entire malt extract existing in a brewery wort, but without the enzymes.

*Amide yeast food* is manufactured from the draff left in the second operation (manufacture of saccharine malt extract) by extracting about one quarter of it under pressure with, say, 90 galls. of water at a temperature of 250° F. for 2—3 hours. The filtered liquor is then concentrated as in the other cases, the finished product being specially suitable for brewery operations.—A. R. L.

*Improvements in Drying Brewers' and Distillers' Grains and the like, and in the Means or Apparatus employed therein.* H. Fielder, South Hampstead and the Dailuaine-Glenlivet Distillery, Limited, Carroo, Strathspey, N.B. Eng. Pat. 24,949, December 28, 1893.

THE patentees claim the combination or arrangement and use, for drying distillers' grains and the like, of apparatus comprising a series of communicating tortuous unjacketed chambers, through which the material to be dried is caused to travel by means of scoops radially flanged on one side thereof, carried on rotary shafts suitably mounted and driven. Through the drying chambers mentioned heated air is caused to pass in the earlier sections of the chambers against, or alternately with and against, the flow of the material, and in the later sections, where the final drying is effected, *with* the flow of the material. There are also claimed, means for heating the drying air by tubes below the drying chambers, which tubes effect direct transmission of heat thereto, as well as by communication to the interiors thereof. Furthermore, the combination or arrangement and use of apparatus for drying brewers' or distillers' grains and the like, whereby the amount of inlet of hot air to each section of the chambers can be separately regulated, and the direction of the currents of air and of the flow of the material is alternately the same and in opposite directions. Access to the material is facilitated by removable covers, and increased surface is exposed to the heat of radiation of the air-heating tubes.—A. R. L.

*Improvements in the Treatment of Yeast.* G. G. Cave, Penny Stratford, Bucks. Eng. Pat. 2889, February 9, 1894.

THIS specification relates to a process whereby yeast may be preserved, it is said, for any length of time in an inert state without its vitality being destroyed. The washed yeast is mixed with finely pulverised malted grain, which has been roasted, in the proportion of five parts of yeast to six parts of malt, after which the dough is dried by the action of heat. The grain used is preferably barley, but may also be rye, oats, maize, &c., which, after being malted in the usual way, is roasted or carbonised in a manner similar to that adopted in the case of coffee beans, and subsequently ground to an almost impalpable powder.—A. R. L.

# XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY AND WATER PURIFICATION, DISINFECTANTS.

## (A.) CHEMISTRY OF FOODS.

### PATENTS.

*Improved Manufacture and Production of Extracts from Malted Grain.* F. Faulkner, Birmingham, and J. E. J. Johnson, Old Ford. Eng. Pat. 23,816, December 11, 1893.

See under XVII., page 1214.

*Improvements in Food Preparations for Man and Animals.* H. P. Madsen, London. Eng. Pat. 1772, January 26, 1894.

THIS is an extension of previous patents (this Journal, 1886, 675). For food for man 150 parts of blood mixed with 600 parts of water are boiled while well stirred; when boiling, sufficient vinegar is added to "cause extraction of the albumen, the fibrin, and the alkaline and other salts." After sifting, the parts remaining on the sieve are mixed with condiments and made into a dough, which is fashioned into biscuits and baked at 200°–300° F.

A number of recipes, in which the above blood-substance is mixed with other foodstuffs to make food suitable for diverse animals, is given. A drink for man is made by mixing "albumin fibrin and the salts obtained from blood" with water, flavouring with cinnamon, orange juice, pineapple juice, cardamom, and sugar, boiling and filtering.

—A. G. B.

*Improvements in Apparatus for Use in the Sterilisation of Materials in Bottles, Jars, or other Vessels.* A. Hüssener, Gelsenkirchen, Germany. Eng. Pat. 4178, February 27, 1894.

THE inventor claims the hermetical sealing of vessels, in which foods have been sterilised, by means of the pressure of the outer air. The vessels are placed on a base plate and suitable covers are held down on their mouths by spiral springs. The apparatus is immersed in water up to the necks of the vessels and heated. This causes the central spring to lengthen and lessen the pressure, so as to allow the heated air to escape from the vessels. On removing the source of heat, the pressure is again increased, and when the vessel is cold, the external pressure of the air is sufficient to keep the covers in position.—L. de K.

*Improvements in the Manufacture of Feeding Cakes Suitable for Human or Animal Use.* A. W. Rehnström, Målhammer, Rekarne, Sweden. Eng. Pat. 5373, March 14, 1894.

SKIMMED milk is more or less concentrated and mixed with residues obtained in expressing vegetable oils, or with meal or bran of cereals, maize, rice, peas, vetches, brewers' grains, beet-pulp, reindeer-moss, or oil-seeds; the mass is made into cakes and baked. The most concentrated foods will contain the milk substance evaporated to dryness, and the proportion added will vary with the requirements of the animal in respect of nitrogen.—A. G. B.

*Improvements in Pasteurising Apparatus for Milk, Cream, or the like.* W. Paaseh, Horsens, Denmark. Eng. Pat. 18,143, September 24, 1894.

THE apparatus consists of a pasteurising vessel immersed in a steam-bath, and containing a rotatory agitator which, by centrifugal action, shall raise the milk to a higher level than that of influx. The agitator mentioned is mounted so

as to rotate on a vertical axle, and it is furnished with broad blades or pallets, so that in the agitating, centrifugal force is communicated to the milk, and the latter whilst rotating, is thus raised above the level of the vat, without producing foam or froth.—A. G. B.

## (B.)—SANITARY CHEMISTRY.

*Examination of the Products of Combustion of Coal Gas when Burned by Argand and by Auer Burners respectively.* N. Crochant. Comptes rend 119, 146.

THE author has minutely examined the products of combustion for carbon monoxide in the two cases, both chemically and physiologically.

The chemical examination consisted in passing the products of combustion, first carefully freed from carbon dioxide, over red oxide of copper and then through baryta water.

In the physiological examination a dog was caused to breathe the products of combustion for half an hour; samples of its blood were analysed for combustible gas before and after breathing the products of coal-gas combustion.

The results obtained were as follows.—For the Argand burner, by the chemical process, 1.2 cc. of  $\text{CO}_2$  from 73 litres of the products of combustion, equal to a trace of  $\text{CO}$ , say,  $\frac{1}{75,000}$ ; by the physiological process, nil. For the Auer burner, "which gives so white and dazzling a light," they were very different. Here 60 litres of combustion products gave 23.2 cc. of  $\text{CO}_2$ , equal to 23.2 cc. of  $\text{CO}$  or of formene, or a mixture of these two substances—say  $\frac{1}{23.2}$  of the volume of the products of combustion. By the physiological method 100 cc. of blood yielded 1.3 cc. of  $\text{CO}$ , equal to  $\frac{1}{1300}$  of the air inspired.

It is pointed out that these results are most interesting from a hygienic point of view; the products of combustion of lighting gas should be carefully avoided, especially those emitted by the Auer burner.—E. R. B.

*Attempts to Estimate Sulphur Compounds in the Atmosphere.* W. H. Oates. Proc. Chem. Soc. 1894 [113], 218.

See under XXIII., page 1222.

### PATENTS.

*Improvements in connection with the Precipitation of Sewage and Polluted Waters, and in Precipitation Tanks, and in Filtering Apparatus, and in Filter Beds for the Purification of Sewage and Polluted Waters.* F. P. Candy, London. Eng. Pat. 19,560, October 18, 1893.

THE sewage first passes through a settling-tank to remove heavy matter, and then, after mixing with the precipitant or deodoriser, through the inventor's improved mixing-tank. The latter is furnished with variously arranged partitions bearing flanges so placed as to cause as much disturbance of the liquid as possible. The sewage should flow at such a rate that any sediment is carried through. The improvement claimed in the filter-tank is that the bed can easily be cleaned by an upward flow of water of small pressure without disturbing the filtering material. This is accomplished as follows:—On an iron plate with large perforations rests a non-corroding sheet with smaller holes, and on this is placed a sheet of copper gauze. The three plates are fastened to a flange on the side of the tank, so that all liquid must pass through the holes. Resting on the gauze is a coarse layer of iron ore, above which comes a layer of coarse sand, and on the top is a layer of coal or coke granules. The difference between their specific gravities keeps the layers in their proper positions when being cleaned. The large openings of the lowest plate may be provided with automatic valves, on the principle of a ball-cock, to prevent any return of the sewage.—L. de K.

*Improvements in Mechanism for Controlling and Regulating the Discharge of Liquids from Tanks.* W. G. Strype, Dublin. Eng. Pat. 22,529, November 24, 1893.

See under L, page 1180.

*Improvements in the Precipitation of Compositions adapted for Use in the Treatment of Sewage and Foul Waters.* H. B. Sharp and J. B. Petrie, both of Smithy Bridge, Lancaster. Eng. Pat. 25,049, December 30, 1893.

Poor iron-ore largely, if not mainly composed of alumina, is reduced to a very fine powder and then thoroughly mixed up with water. Hydrochloric and sulphuric acids are next added and the mixture boiled with constant stirring until the solution is so concentrated that on cooling it will set in blocks or masses. At this stage the contents of the boiling-pot is run into suitable moulds.

The inventors claim that this preparation is superior to either sulphate of iron or sulphate of aluminium when applied to the disinfecting of sewage.—L. de K.

*Improvements in and connected with Iron Compounds for Use in Precipitating Sewage, Purifying Waste Liquors, Colouring, and the like Purposes.* I. Levinstein, Manchester. Eng. Pat. 1415, January 23, 1894.

SUITABLE bisulphates and oxides of iron, especially ferric oxide, are heated together to about 300° C. with stirring, until quite dry, water having been previously added to promote the reaction. The preferred materials and proportions are equal parts of sodium acid sulphate and ferric oxide, with one-fourth part water. It is defined that the term "bisulphate" "is intended to cover and include sulphates having an additional molecular proportion of sulphuric acid mixed therewith or added thereto." The compound, obtained as described, containing per salts of iron, is used for the purposes stated in the title.—E. S.

*Improvements in or relating to the Recovery of Sediment from Clarifiers.* O. Schmidt, Berlin, Germany. Eng. Pat. 2051, January 30, 1894.

These improvements are included in a process for the separation of sediment in a thick and semi-fluid state from water in clarifying apparatus, with a siphon-vessel or deep well, so arranged that the sediment in the mud-collector is removed by an exchangeable pump working in the collector itself and driven from above, whilst at the same time it is prevented from accumulating and consolidating itself on the walls of the mud-collector, by the use of an agitator rotating round the axis of the pump.—L. de K.

*An Improved Continuous Apparatus for the Sterilisation of Water or other Liquid by Ebullition.* E. Herscher, Paris, France. Eng. Pat. 16,938, September 5, 1894.

The apparatus consists essentially of a reservoir in which a constant level is maintained by a ball-cock. The water passes thence through a valve, which is only opened when the water in the boiler reaches 100°, into the outer part of the condenser, and from there, part passes to the boiler and another part flows away through a waste-pipe. From the boiler, water and steam pass through a pipe, which is above the level of the reservoir into the inner part of the condenser. The boiler contains a system of bells and inverted bells to keep the water for some time at boiling point before allowing it to pass into the condenser, and the high-level pipe ensures the temperature, whilst the steam-worked valve prevents loss of water when the apparatus is not in use.

—L. de K.

## (C).—DISINFECTANTS.

### PATENTS.

*An Improved Anti-fouling Composition for the Prevention of Marine Growth in or on Wood or Iron.* R. Hingston and J. P. Wernegreen, Brisbane, Queensland. Eng. Pat. 17,662, September 17, 1894.

SIXTY-NINE pounds of purple oxide of iron are ground into 3 gallons of boiled linseed oil, and, in succession, 10 lb. of "patent driers," 5 lb. of mercuric chloride in fine powder, and 1 lb. of mercuric oxide are added and the whole well mixed in a wooden or iron vessel.—F. H. L.

## XIX.—PAPER, PASTEBOARD, Etc.

### PATENTS.

*Improvements in the Manufacture of Cellulose Pulp.* J. Y. Johnson, London. From P. Sobège, Paris, France. Eng. Pat. 24,503, December 20, 1893.

THE inventor claims the addition of tannic acid to the cellulose intended for sizing with gelatin, and the employment of celluloses containing tannin, either in a natural state or in the state of tan, for making pulp for the production of paper or card, in which the gelatin is rendered insoluble, inaptesible, and very slightly liable to swell and soften by the action of damp.—J. C. C.

*Improved Process for Making Paper Pulp Boards or Paper in Imitation of the Grain, Knots, or Burls of Natural Woods.* W. N. Cornell, Brownville, New York, U.S.A. Eng. Pat. 13,790, July 17, 1894.

THIS process consists in winding convolutionally on a paper machine a pulp board of less than the desired thickness; then in adding to the partially finished pulp board a separate piece or pieces of pulp of greater density, or drier, or of a darker colour than the pulp board; then finishing by winding to the required thickness, whereby the pieces of pulp cause the pulp board to slip and wrinkle on the forming roll; finally in removing the board from the machine, drying, and sandpapering it. An article is produced, which is said to be similar in appearance to natural wood.—J. C. C.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

*The Emetics.* Paul Adam. Bull. Soc. Chim. 1894, 11, 597—602.

IN the emetics (of which tartar emetic is the type) the antimonyl (SbO), arsenyl (AsO), "or boryl (BO)" groups are generally regarded as being substituted in the carboxyl group of the organic acid. The author brings forward various facts in support of the view, originally put forward by Jungfleisch in 1883, that the substitution really takes place in the alcoholic or phenolic hydroxyl.—T. E.

*The Alkaloids of Corydalis Cava.* Corybulbine. J. J. Dobbie and A. Lander. *Proc. Chem. Soc.* 1894 [143], 217.

This alkaloid is obtained from the commercial corydaline supplied by Schuchardt of Grlitz, by either of the following methods:—

1. The crude material is dissolved in hydrochloric acid, and the solution mixed with excess of soda, which throws down the corydaline only. The filtrate is then saturated with carbon dioxide, when the corybulbine separates out.

2. The crude corydaline is repeatedly exhausted with hot alcohol, which dissolves out the greater part of the corydaline. The residue is dissolved in a large quantity of boiling alcohol, from which the corybulbine separates on cooling as an exceedingly fine crystalline powder. It is purified by conversion into the hydrochloride, which, after repeated recrystallisation from water, is decomposed by ammonia.

Corybulbine is nearly insoluble in water, soluble with difficulty in methyl and in ethyl alcohol, and insoluble, or nearly so, in ether. It dissolves readily in carbon bisulphide, chloroform, and hot benzene. It is also soluble in solutions of the caustic alkalis. An alcoholic solution of the alkaloid rapidly reduces a warm solution of silver nitrate. When heated, corybulbine softens at 210°, but does not melt till 238°–240°. A solution of the alkaloid in chloroform is dextro-rotatory.

Corybulbine has the formula  $C_{21}H_{25}NO_4$ . The hydrochloride,  $C_{21}H_{25}NO_4 \cdot HCl$ , is obtained in clusters of prismatic needles by dissolving the alkaloid in hot dilute hydrochloric acid. This salt is remarkable for the difficulty with which it dissolves in water.

The acid sulphate,  $C_{21}H_{25}NO_4 \cdot H_2SO_4$ , is prepared in the same manner as the hydrochloride. It dissolves with difficulty in hot water, from which it slowly separates on cooling, in long prismatic crystals.

*Corydaline. Part IV.* By J. J. Dobbie and A. Lander. *Proc. Chem. Soc.* 1894 [143], 218.

It is probable that corydaline is an alkaloid of the same type as papaverine, narcotine, and hydrastine, containing an isoquinoline and a benzene nucleus, but of simpler constitution than these alkaloids, inasmuch as the two nuclei appear to be united directly to one another and not through an intervening carbon-atom.

*Alkaloids of the Bark of the Pomegranate Root.* G. Cianaicari and P. Silber. *Ber.* 1894, 27, 2850–2861.

THE paper deals with the alkaloid "*Norgranatoline*" previously obtained by the authors by the reduction of granatoline with phosphorus and hydriodic acid (this *Journal*, 1894, 417). This product forms small white needles, melting between 50 and 60°C., which absorb carbon dioxide very readily from the air. So greedily does this absorption take place that the melting point could not be determined. Distilled over zinc-dust,  $\alpha$ -propyl pyridine is formed, a decomposition corresponding to one in which  $\alpha$ -ethyl pyridine is formed from norhydratropidine.

Granatoline, upon oxidation with an alkaline potassium permanganate solution, forms *Norgranatoline* under similar conditions to the formation of trepigenine from tropine. The properties and some derivatives of this new base are described. Distilled over zinc-dust, pyridine is obtained. The paper concludes with remarks on the probable constitutional formula of granatoline and its relation to tropine, of which it is the next higher homologue.

The group of bases obtained by the authors from Granatoline are now:—

Granatoline.....	$C_{17}H_{19}ON \cdot CH_3$
Granatoline.....	$C_{17}H_{19}OH \cdot N \cdot CH_3$
Granatoline.....	$C_{17}H_{19}N \cdot CH_3$
Granatoline.....	$C_{17}H_{19}N \cdot CH_3$
Norgranatoline.....	$C_{15}H_{17}(OH)N \cdot H$
Norgranatoline.....	$C_{15}H_{17}N \cdot H$
Norgranatoline.....	$C_{15}H_{17}N \cdot H$

Norgranatoline is isomeric with A. W. Hofmann's Coniceine.—C. A. K.

*Piceol. A Glyceride obtained from the Root of the Pine.* *Pharm. Ztg.* 1894, 39, 119, 120.

THIRTY hopped pine twigs are boiled for a short time with water. From a grams of solid material, the particles of twigs, filtered off, and digested for an hour in ether. The extract is poured into a beaker, successively with 10 cc. of benzene and lead acetate, and the precipitate produced by the addition of concentrated sulphuric acid. The resulting solid is exactly neutralised with sodium carbonate. The solid is then again subjected to a similar weight to one third of the original weight in ether, which is exhausted by repeated extraction. The ether extract is then distilled off, and the residue is taken up in alcohol, again evaporated to expel the last traces of acetone, and finally dissolved in a small quantity of warm absolute alcohol. The liquid is then set to a pasty mass, which is washed by suction with a solution of alcohol camphoraceous residues are thus removed and dissolved in boiling absolute alcohol or water. The solid mass, on cooling, deposits crystals of *piceol*. The yield is about 10 per cent.

*Piceol*,  $C_{10}H_{16}O_2$ , crystallises from water with one molecule of water of crystallisation, anhydrous from alcohol, and in either case forms a very fine, needle-shaped, transparent, of boiling water, for cold water, 500 of cold water, 100 of boiling absolute alcohol. It possesses a bitter flavour. *Piceol* is dextro-rotatory,  $\alpha_D^{20} = +84$  in  $CHCl_3$ , and  $+78$  in alcohol solution. Anhydrous *piceol* melts at 104°C.

*Reactions.*—A small fragment of *piceol* dissolved in strong sulphuric acid imparts a coloration of a reddish-brown tint. This fact serves to distinguish it from *pinic acid*, which yields a violet coloration. *Piceol* is not precipitated by tannin or basic lead acetate, but with the addition of lead acetate a precipitate of the compound  $C_{10}H_{16}O_2 \cdot Pb(OAc)_2$  is obtained. Under the influence of emulsion of lime acids, *piceol* is split up into glucose and *pinic acid*.

*Piceol* melts at 109°C. It is soluble in 100 parts of cold, or 14 of boiling water. From the latter it separates, on cooling, in oily drops which gradually become crystalline. With ferric chloride, its solution yields a violet coloration. *Piceol* appears to be a monatomic phenol and forms crystalline compounds with caustic alkalis, acetic and benzoic acids, &c.

—H. T. P.

*Conine Alkaloids.* R. Wolfenstein. *Ber.* 27, 2611–2615.

A SAMPLE of Merck's pure conine, boiling at 165–169°C., showed an unusually high rotatory power, which was found to be owing to the presence of methyl conine. The latter was isolated from the mother-liquor left after separation of the crystals of conine bitartrate from a solution of 135.5 grms. conine and 160 grms. tartaric acid in 450 grms. of water. By treatment of the mother-liquor with caustic potash, separation of the conine as nitro-compound from the resulting mixture of bases (by addition of potassium nitrite to the aqueous solution of their hydrochlorides) and subsequent supersaturation of the remaining solution with caustic alkali, pure methyl conine was obtained. This proved to be identical with *n*-methyl conine obtained synthetically and showing a specific rotation of  $-81.33$  and boiling point of 173–174°C. Pure conine, prepared from the crystallised bitartrate boils at 165.7–165.9°C. (759 mm.), and has a specific rotation of  $-15.6$ . Merck's conine contains about 95 per cent. of pure dextro-conine and 5 per cent. of *n*-methyl conine.—F. M.

*The Technical Preparation of Conine from the Alkaloids accompanying it.* A. Linhorn and R. Willstätter. *Ber.* 1894, 27, 1523.

THE alkaloids are boiled with a solution of sulphuric or hydrochloric acid in methyl alcohol, whereby they are converted into their mother-substance, the methyl ester of econine. This is then converted, by the introduction of a benzoyl group, into cocaine.—T. E.

*Note on the Paper of Einhorn and Willstätter on the Technical Preparation of Cocaine.* C. Liebermann. Ber. 27, 1894, 2051.

THE author denies that the process described by Einhorn and Willstätter (see foregoing abstract) is any improvement on or materially differs from the process described by Giesel and himself. (This Journal, 1889, 131.)—T. E.

*Physiological Action of Compounds of the Cocaine Series.* P. Ehrlich and A. Einhorn. Ber. 1894, 27, 1870—1873.

THE investigations of Filehne, Ehrlich, and Poulsson have shown that neither benzoylcegonine, ecgonine methyl ester, nor ecgonine have any anæsthetic action, whilst these substances are about 20 times less toxic than cocaine.

MacLagan first observed in 1857 that the alkaloid from *Erythroxylon coca* produced a sensation of numbness when placed on the tongue; von Anrep found in 1879 that cocaine has the property of a local anæsthetic, but this property was first made use of in medical practice by Koller (Wiener. med. Woch., 1884, 1276). Knapp (New York Med. Rec., 1884) and Zieminski (Inaug.-Diss., Dorpat, 1884) observed the mydriatic action of cocaine.

Ehrlich (Deutsch. med. Woch. 1890, No. 32) discovered that cocaine produced an extraordinary increase in the volume of the liver and exerted a specific decrease on the cells of that organ; these phenomena are not exhibited by *ecgonine*, *ecgonine ester*, and *benzoylcegonine*. Falek (Inaug. Diss., Kiel, 1886) had already observed that the homologues of cocaine—*esters of benzoylcegonine* containing a higher alkyl group in the place of methyl—have a like physiological action. Derivatives containing other *acidyl* groups in the place of benzoyl, such as *isatropyl*, *cinnamyl*, *phthalyl*, *phenylacetyl*, &c., act in the same manner on the liver as cocaine, but with the exception of the *phenylacetyl* derivative, none of them are anæsthetics, and the anæsthetic property of this is much weaker than in the cocaine. It is worthy of note that both Poulsson and Ehrlich agree that the anæsthetic action of *R-cocaine* is more rapid than that of (ordinary) *L-cocaine*.

The *orthochloro* and *meta-nitro*-derivatives of *L* and *R*-cocaine have only slight anæsthetic action, but exhibit the typical physiological action on the liver; whilst the *metamido* derivatives exhibit neither actions. The *meta-hydroxy* derivatives occupy as far as their physiological properties are concerned, a position intermediate between the *nitro*- and *amido*-cocaines. The *acetyl* and *benzoyl* derivatives of the *meta-amido*-cocaines are not anæsthetics but act on the liver, whilst the cocaine urethanes obtained by the action of ethyl chlorocarbonate on *R*- and *L*-amidococaine are much more powerful anæsthetics than cocaine, exert the characteristic action on the liver, and are highly toxic. Since *metabenzenesulphamido-R-cocaine* and *R-cocaine-urea* have no anæsthetic action, the physiological inactivity of the *amidococaines* cannot be due to the neutralising (basic) effect of the *amido* group.

The colouring matters *R*-cocaine-azodimethylaniline hydrochloride, and *R*-cocaine-azo- $\alpha$ -naphthylamine hydrochloride produce slight anæsthesia but exert no action on the liver.

The *norcocaines* are more powerfully anæsthetic than the *cocaines* themselves and act on the liver, but are far more poisonous.

Cocaine methiodide exhibits neither anæsthetic properties nor action on the liver.

Besides the benzoylated alkaloids examined by Filehne (Berl. Klin. Woch., 1887, 107), benzoylmorphine, benzoylhydrocotarine, benzoylquinine, benzoyleinchonine, &c., it may be mentioned that *ethoxycaffeine*, *eugenolacetamide*, *orthonitrophenyl- $\beta$ -hydroxypropionic ester*, *benzoylquinoyl- $\beta$ -lactic ester* and other substances, an account of which will be given later, are more or less anæsthetics.—A. R. L.

*By-products obtained in the Preparation of Butyltoluene.* A. Baur. Ber. 27, 1894, 1606—1609.

IN the preparation of butyltoluene, the parent hydrocarbon of artificial musk, by the method already described (this Journal, 1891, 1024), the crude reaction product contains the following other hydrocarbons:—

The fraction boiling at 160°—180° C. contains butylbenzene, and, inasmuch as pure toluene was made use of, a conversion of the latter hydrocarbon into benzene must have taken place under the influence of aluminium chloride, as Friedel and Crafts have already observed. It is interesting to note that the author shows in another paper (Ber. 27, 1610) that the *nitro*-derivatives of butylbenzene do not possess the odour of musk.

A conversion of toluene into xylene must also have taken place in the above-mentioned synthesis (*loc. cit.*), for the fraction boiling at 190°—220°, which consists chiefly of butyltoluene, contains also *butylxylene* boiling at 202°.

The fraction boiling at 220°—250° consists of *dibutylbenzene* melting at 76°, and *dibutyltoluene*, an oily hydrocarbon, boiling at 240°—245°. When *dibutylbenzene* is warmed with a mixture of nitric and sulphuric acids, *dinitrobutylbenzene*,  $C_{11}H_{16}(NO_2)_2$ , is obtained; it crystallises from alcohol in white needles, has a faint odour of musk, and melts at 167°—168°. *Dibutyltoluene*, on nitration, yields the trinitro derivative,  $C_{11}H_{14}(NO_2)_3$ , which melts at 152°—153°, and has a faint odour of musk.—A. R. L.

## PATENTS.

*Improvements in the Manufacture of Aromatic Sulphuryl Derivatives of Protocatechuic Aldehyde and their Conversion into Vanillin.* Sidney Pitt. From the Chem. Fabrik auf Aetien vorm. E. Schering, Berlin. Eng. Pat. 24,177, December 15, 1893.

PROTOCATECHUIC aldehyde is treated with benzene (or toluene) sulphonic chloride and caustic soda or other alkali, under conditions which are more fully described in the patent. Considerable quantities of *p*-benzene sulpho-protocatechuic aldehyde and smaller quantities of the *meta* compound are formed, the reaction being similar to that given below (See patent following). The *para* compound is methylated, and the benzene sulphonic acid group then split off by boiling with potash, vanillin being formed.

—T. E.

*Improvements in the Manufacture of Vanillin.* Sidney Pitt. From the Chem. Fabrik auf Aetien vorm. E. Schering, Berlin. Eng. Pat. 24,178, December 15, 1893.

THE claim is for the manufacture of vanillin from protocatechuic aldehyde,  $C_6H_3(CO\cdot H)(OH)_2$  1.3.4, by transforming a mono-metallic salt of the aldehyde into the *p*-benzyl ether by the action of benzyl chloride, methylating this ether, and then separating the vanillin. The following equations will make the reactions clear:—

—T. E.

*The Preparation of a Crystalline Polymeric Base, suitable for Medical Use, from Amido-Acetic Aldehyde.* S. Pitt. From The Chem. Fabrik auf Aetien vorm. E. Schering, Berlin. Eng. Pat. 24,179, December 15, 1893.

EMIL FISCHER has recently shown that amido acetal is converted into a salt of amido-acetic aldehyde by the action of a strong acid. On standing at the ordinary temperature this salt passes over into a polymeric. The substance is made as follows:—Amido-acetal is mixed with hydrobromic acid (sp. gr. 1.49), and after standing for 5 hours at the ordinary temperature the mixture is evaporated *in vacuo* at

a temperature not exceeding 60° C. The syrup obtained is allowed to stand at 25° C. until it crystallises. The crystals are the hydrobromide of the new base and possess the composition  $C_{10}H_{10}N_2O_2(HBr)_2$ . The free base is very soluble in water, has an alkaline reaction, and is not altered by boiling with alkalis or with Fehling's solution. It is intended for therapeutical use.—T. E.

**Manufacture of Ethers of the Alcohols contained in Natural Essences and of their corresponding Alcohols.** M. Otto and A. Verley, Paris. Eng. Pat. 18,509, September 29, 1894.

CERTAIN natural essences contain isomeric alcohols of the formula  $C_{10}H_{18}O$ , mixed with terpenes, camphenes, &c. To prepare the ethers of these alcohols the patentees treat the essence, in presence of some neutral solvent, with an acid or alcoholic chloride, and sodium. The reaction which occurs is—

where R is any acid or alcohol radical. The ether is separated from other bodies by fractional distillation. The alcohols may be obtained by saponifying the ethers. Several ethers of the above-mentioned alcohols, obtained from the essence of geranium are described; they possess delicate and agreeable odours, and can be used in perfumery.—T. E.

## XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

### PATENTS.

**Method and Apparatus for Timing Photographic Development.** A. Watkins, Hereford. Eng. Pat. 23,894, December 12, 1893.

As a result of numerous experiments the inventor has ascertained that the total length of time of development required to bring a correctly exposed plate to a given density, is generally a definite multiple of the time which elapses between the pouring on of the developer and the first appearance of the image. Also that the multiplying factor is always the same for a particular make of plate, but varies slightly with different makes, and also with different kinds of developers. If, therefore, the time between the pouring on of the developer and the appearance of the image be determined, this time forms a reliable basis to determine the total time required for leaving the plate in the particular developer, as it makes correct allowance for variations in temperature, or in amount of bromide or alkali. Two instruments are described for these timing operations; one is similar to a double-cased hour glass (sand-glass) with two orifices, the lower orifice being capable of alteration in size by means of a regulating screw-plug. Thus, relative variations in the time which the same amount of sand will take in falling through the two orifices may be observed at will. On pouring on the developer the instrument is placed with the sand-chamber uppermost and on the appearance of the image is reversed, the development being finished when the sand has finished running back. The second instrument described is of the nature of a clock.—J. C. C.

**Improvements in producing Photographic Prints.** J. Packham, Croydon. Eng. Pat. 24,963, December 28, 1893.

For the production of warm or pleasantly-tinted photographic prints, platinum prints are treated in a bath of tannin, catechu, &c., either alone or along with deoxidising agents. If after this bath the high lights are degraded, the print is further subjected to the action of a soap- or acid-bath. Several different methods and modifications of this process are described.—J. C. C.

**Improvements relating to the Development of Photographic Pictures.** M. Andresen, Berlin, Germany. Eng. Pat. 25,002, December 29, 1893.

THE inventor claims the following naphthalene derivatives as photographic developers—

1.  $\alpha$ -amido- $\beta$ -naphthol- $\alpha$ -mono-sulphonic acid. 2.  $\alpha$ -amido- $\beta$ -naphthol- $\alpha$ - $\beta$ -disulphonic acid, prepared by the action of sulphurous acid on the nitroso compound of the  $\beta$ -naphthol monosulphonic acid of Schaefer. This acid is obtained as fine white crystalline needles, easily soluble in water, insoluble in alcohol, and sparingly soluble in concentrated hydrochloric acid. The alkaline salts are very soluble in water, and their solution turns brown after exposure for some time to air. The acid solution turns yellow on the addition of ferric chloride. 3.  $\alpha$ -amido- $\beta$ -naphthol- $\alpha$ - $\beta$ -disulphonic acid, prepared by the action of sulphurous acid on the nitroso compound of the  $\beta$ -naphthol- $\beta$ -mono-sulphonic acid. The properties of this body are similar to those described above. 4.  $\alpha$ -amido- $\beta$ -naphthol- $\beta$ -carbo- $\alpha$ -sulphonic acid, prepared by the action of sulphurous acid on the nitroso compound of the  $\beta$ -oxy-naphthol acid having the melting-point 216° C. The properties of this body are, again, similar to those described, with the exception that the acid is sparingly soluble in water.—J. C. C.

## XXII.—EXPLOSIVES, MATCHES, Etc.

### PATENTS.

**An Improved Manufacture of Explosives.** Hans Ritter von Dahmen, Castrop, Westphalia. Eng. Pat. 23,579, December 7, 1893.

ANTHRACENE (eight parts) is melted in a steam-bath and mixed with a powdered mixture of ammonium nitrate (45 parts) and potassium nitrate (44 parts), which salts have previously been melted together at 150° C. About three parts of potassium chlorate are preferably added to the final mixture. Other proportions may be used, larger quantities of ammonium nitrate increases the bursting force. The explosive does not ignite by blows, friction, or heat.—T. E.

**A New Explosive.** H. Boyd, Calcutta. Eng. Pat. 24,425, December 19, 1893.

THE patentee claims the use, in the manufacture of explosives, of oxide of iron which "has passed through the retorts at gasworks, and become impregnated with sulphurous and chemical gases," along with other substances, viz., potassium nitrate, powdered kerosene shale, commercial sulphur, wood dust, and barium nitrate.

A number of valuable properties are attributed to this explosive; among others, that it cannot be exploded by concussion or friction, nor does it explode in the open air. It generates very little smoke or fumes, and is not affected by keeping or by climatic changes. The composition mentioned is oxide of iron, four parts by weight; nitrate of potash, four parts by weight; powdered kerosene shale, three parts by weight; commercial sulphur, two parts by weight; wood dust, two parts by weight; barium nitrate, one part by weight.—T. E.

**Improvements in Explosives.** H. Maxim, New York. Eng. Pat. 18,682, October 2, 1894.

THE object of the invention is to provide a fulminating compound for detonating large masses of high explosives, and which can be thrown from ordnance in considerable quantities with safety. For this purpose nitro-glycerin is thickened with pyroxylin to the consistency of raw rubber. This is done by employing about 75 to 85 per cent. of nitro-glycerin in admixture with 15 to 25 per cent. of pyroxylin, according to the stiffness or elasticity of the compound that may be desired. To facilitate the above

admixture, usually a sufficient quantity of a solvent of the pyroxylin in conjunction with the nitroglycerin, to make the mixture sufficiently pasty to admit of the mixture therewith of a desired quantity of fulminate of mercury. The solvent preferred for the pyroxylin is acetone. With the pasty mass fulminate of mercury is now mixed, to the extent of about 75 to 85 per cent. of the entire compound. The compound can be made less sensitive to shocks by giving it a porous consistency, in agitating it with air while it is still in a syrupy condition. The nitro-glycerin, especially in this latter case, may be omitted. In some cases it is desirable to add a deterring medium, such as nitrobenzene or some suitable gum.—T. E.

*Improvements in the Process of Nitrating Cellulose.*  
Robert Charles Schippaus, Brooklyn, U.S.A. Eng.  
Pat. 18,683, October 2, 1891.

THE improvements consist in adding sulphuric anhydride and nitric acid to the acid bath which has been weakened by acting on the cellulose, and thereby restoring it to its original strength. Water is formed by the action of nitric acid on cellulose, the sulphuric anhydride added converts this water into sulphuric acid; the nitric acid added makes up for that which has combined with the cellulose.—T. E.

## XXIII.—ANALYTICAL CHEMISTRY.

### APPARATUS, ETC.

*An Aluminium Drying-Oven.* L. Meyer. Ber. 1894, 27, 2769—2770.

ON account of its high conductivity and comparative permeability in air, aluminium is a very suitable material for the construction of drying-ovens. It possesses over copper the advantage, that the film of oxide formed remains very thin and does not scale off. The author has designed a very convenient form of air-bath, the details of which are

shown in the accompanying drawing. The oven is surrounded throughout (door included) by a double casing through which circulate the products of combustion derived from two perforated tube burners, one at each side of the apparatus, and so arranged that their distance from the bath may be regulated. Two interchangeable sets of burners are provided, the tubes of one set having six, of the other 22 gas outlets each. Using either the small or large burners, according to requirements, it is stated that any temperature between 70 and 330° C., may readily be obtained and kept absolutely constant for any length of time, providing, of course, that a gas-pressure regulator be employed.—H. T. P.

*A New Apparatus for Shaking Bottles.* C. Maull. Ber. 1894, 27, 1732.

THE apparatus, which is shown in the figure, is said to have the advantage that it can be set in motion by a small

Rabe's turbine, worked by water and consuming 12 litres per minute, and will shake bottles containing as much as 500 cc. Larger instruments are also made.—T. E.

*A Simple Viscosimeter.* M. Wendrin. Zeits. angew. Chem. 1894, 545—547.

THE apparatus shown in the cut consists of a pipette of 50 cc. capacity, the lower end of which is drawn

out to a cylindrical point as shown in *a*: the stem has two marks upon it at *b* and *c*. The pipette is held in position within a cylindrical tube by means of caoutchouc stoppers, and this tube is supported vertically by a clamp. Water is

passed through the cylindrical tube from a reservoir R; it may be raised to any desired temperature by the Bunsen's lamp. A thermometer placed through the upper caoutchouc stopper serves to register the temperature of the water passing through the cylindrical tube.

The liquid of which it is required to determine the viscosity is sucked into the pipette somewhat above the mark *c*, and after being adjusted to this mark at a known temperature, the time is noted that elapses while the liquid drops out until it reaches the lower mark *b*. The oily liquid collected in a beaker may be weighed and its specific gravity deduced from this; the estimation of acidity may also be made in the same quantity.—A. R. L.

*Determination of Vapour Density, and a Process for Exhausting without an Air or Water-Air Pump.* C. Schall. J. prakt. Chem. 50, 1894, 87—88.

THE vessel K (Fig. 1), in which the sodium carbonate is decomposed (this Journal, 1892, 370), is now fused on to

Fig. 1.

the apparatus, the acid being slowly run in—and preferably at not less than 300–400 mm. pressure—through a funnel tube, fitted with a tap, and fused on to the soda vessel. The tube containing the substance under examination is held by a hooked wire *a*, and is released on turning this round by means of the bowed handle.

In the absence of a pump for exhausting, the apparatus in Fig. 2 may be employed. This consists of a tin bottle,

Fig. 2.

A, such as is often used for chemical preparations, which is fitted with a Bunsen valve, B (made of air pump tubing, and slightly increased on the outer edge), and connected with the density apparatus. The air is expelled from A through *c* by boiling water, *c* being closed by sliding a pinchcock from *a* at the moment when the lamp is removed from A. As the vessel cools, which can be accelerated by laying a cloth on A, and afterwards immersing the latter in cold water, the mercury in the density apparatus quickly rises. With a capacity for A of 2½ litres, and of 100–110 cc. for the density apparatus, an attenuation of between 60 and 70 mm. of mercury is soon produced, and this is in most cases sufficient. By repeating the operation (or, less preferably, using a larger vessel) the attenuation can be increased in a manner readily calculable. The vessel A may also be of glass, but in that case the operation of cooling must be carried on more gradually. The soda vessel and the substance tube are weighed together, and, by pouring the soda into the vessel until the required weight is approximated, and then making up exactly by the aid of the rider, the three weighings can be performed almost as quickly as the customary two.—C. S.

*A New Apparatus for the Valuation of Manganese Ores, Estimating Carbon Dioxide, &c.* A. C. Christomanos. Ber. 27, 2748.

THIS is a modification of the well-known Bunsen's apparatus. The carbon dioxide is generated in an Erlenmeyer flask, A, of 55–60 cm. capacity, and about 4½ cm. wide at the bottom, B being the acid vessel, of about 25 cm. capacity, and C the absorption tube, of about 16 mm. diameter, fitted with a bulb of about the same capacity as the

tube, to prevent the sulphuric acid being drawn into the flask A. Sulphuric acid is used for absorption in preference to calcium chloride. B and C are closed by glass Geissler taps, and there is also a tap at *c*, to regulate the supply of acid into A.

The method adopted is as follows:—The substance is first weighed out into the flask A. The vessel B is filled up to the tap *a* with dilute hydrochloric acid, sp. gr. = 1.085, obtained by diluting strong fuming acid with an equal volume of water, and then connected with A, the joint being greased with vaseline. The absorption tube C is connected with A in a similar way. The whole apparatus is then weighed with taps closed, and the weight recorded. The ends of the apparatus, *a* and *b*, are next connected by means of rubber tubing with calcium chloride tubes. First, the tap *b* is opened, then *a*, and lastly *c*, very gradually, so that the acid only drops slowly into A, and thus prevents a too rapid evolution of carbon dioxide. When the acid has all been added and evolution of gas ceases, the taps *a* and *c* are closed, the apparatus held in the fingers at *f*, and heated over a very small flame almost to boiling. The tap *b* is then closed, so that by cooling the lessened pressure will cause any carbon dioxide remaining in the solution to be liberated. As the vessel cools, the taps *c* and *a* are opened at intervals, to prevent accident, and, after 1–1½ hours' cooling, dry air

is passed through for about 20 minutes. The whole apparatus is now weighed with closed taps, and the loss in weight gives the amount of carbon dioxide evolved.

The author recommends this apparatus also for estimating manganese dioxide in manganese ores, pyrolusite, &c. The powdered mineral, together with water and potassium oxalate, is inserted into the flask A, and concentrated sulphuric acid is run slowly from the vessel B into the mixture, as in the Will-Fresenius method.—H. M.

*Ratio of Saccharimeter Degrees on the Ventzke Scale to Angular Degrees for Sodium Light.* E. Rimbaech. Ber. 1894, 27, 2282—2285.

ACCORDING to Schmitz (Ber. 10, 1420), 1° Ventzke (for saccharose) is equal to 0·3455 degree of arc (sodium light); whilst the observation of Tollens (*ibid.* 10, 1411; 17, 1757) indicates the ratio 1:0·3465. With the exception of some measurements by Landolt and Rathgen (Ber. 21, 194), no direct experiments have been made to ascertain this ratio; these chemists give the ratio 1:0·3465 for saccharose. The last-named experiments were made, however, by comparing the indications obtained with two polaristrometers by Laurent and Lippich respectively, with those obtained by a half-shadow saccharimeter. It is therefore not possible to judge the extent to which the results are vitiated by the unavoidable errors in construction peculiar to each instrument. To eliminate as far as possible this uncertainty, the author has repeated the observations, using a polarimeter recently constructed by Schmidt-Haensch. The instrument was at once a polaristrometer and a saccharimeter; as polariser, Lippich's combination was employed, whilst a Glan-Thompson prism, the rotation of which could be read to a minute, served as analyser. Besides this, the instrument was furnished with a quartz compensating arrangement and a Ventzke sugar scale.

The mean ratio S:K (S = Ventzke degrees; K = degrees of arc for sodium light) for the undermentioned compounds as observed by the author, are as follows:—

Saccharose,  $\frac{K}{S} = 0\cdot34394$ , which increases slightly with the concentration.

Glucose,  $\frac{K}{S} = 0\cdot3444$ , which decreases slightly with the concentration; the value is also affected according as an ordinary gas or petroleum lamp, or an Auer's lamp, is employed for the saccharimeter readings.

Santonin was examined in a chloroform solution, and camphor in an alcoholic solution. The ratio  $\frac{K}{S}$  is practically the same for these substances when either an Auer's lamp or sodium light is employed for the saccharimeter, but is somewhat higher when an ordinary gas or petroleum lamp is used.

For ordinary purposes it is sufficiently accurate to take the ratio  $\frac{K}{S} = 0\cdot344$  in all cases.—A. R. L.

#### PATENT.

*An Improved Machine or Apparatus for Testing Paper and the like.* G. O. Woolley, Gloucester. Eng. Pat. 13,633, July 16, 1894.

THE machine described is for the purpose of testing the breaking strain of paper or similar material. Referring to the drawing, the paper to be tested is placed between the rings A and B, the surface of the upper one being covered by india-rubber; the lower ring is then raised by the screw F so as to firmly clamp the paper sheet. By use of the hand-wheel at the top of the apparatus the sliding cylinder L is forced down, carrying with it the piston G. By means of the spiral spring N the ram U is thus brought to bear upon the paper until the latter breaks. The index J, which slides in a groove in the cylinder L, carries a scale indicating

the pressure exerted. The amount of depression of the paper is ascertained by the distance of the index below a

zero mark on the standard, and indicates the amount of stretching before rupture.—J. C. C.

#### INORGANIC CHEMISTRY.— QUANTITATIVE.

*The Analysis of American Refined Copper.* H. F. Keller. J. Franklin Inst., July 1894, 54—57.

THE author has found Hampe's original method (Zeits. f. Berg. Hütt. u. Salinenwesen, 21, 218, and 22, 93), which consists in precipitating by electrolysis the greater part of the copper, separating the metallic impurities in the usual manner from the remaining solution, and determining the non-metallic elements, such as oxygen and sulphur, in separate portions of the sample, well adapted for "Lake copper."

For other kinds, and especially for electrolytically refined copper, he prefers Hampe's second method, already abstracted in this Journal, 1894, 421.—J. H. C.

*Attempts to Estimate Sulphur Compounds in the Atmosphere.* H. Oates. Proc. Chem. Soc. 1894 [143], 218.

THE paper contains an account of attempts made to estimate the total amount of sulphur compounds present in the atmosphere of Sheffield.

Various forms of apparatus and different oxidising agents, such as hydrogen peroxide, sodium peroxide, iodine, and potassium permanganate, were tried, but in none of the experiments was it conclusively proved that all the sulphur compounds present in the air were oxidised and retained by the apparatus used.

The results of the determinations tend to show that the amounts of sulphur compounds present in the air, which have been previously published, are considerably too low, and that none of the forms of apparatus used in the experiments described, are capable of yielding correct results.

*Quantitative Electrolytic Analysis.* A. Classen. Ber. 1894, 27, 2060—2081.

STRONG emphasis is laid upon the necessity for including the current-measuring instrument, be it ammeter or voltmeter, in the electrolytic circuit, and upon the worthlessness of many published results, in obtaining which, a voltmeter of unknown resistance has been substituted for the electrolytic cell at the moment of measuring. The method of measurement adopted by the author is to couple in the main circuit, the battery, the electrolytic cell, an ammeter, a variable resistance, and a switch, by which the current may be stopped during the measurement of resistance; this latter is effected by means of a Wheatstone's bridge, rheostat, and separate battery, which can be uncoupled when not in use; the voltage at the electrodes is determined by a voltmeter, which may be switched on or off at will, and is placed in a shunt circuit between the anode and cathode connections of the cell. Using always the same electrode-dimensions and interpolar space, he has made a number of observations, which are detailed in the paper, showing the

temperature, current intensity, interpolar voltage, polarisation, added resistance, and electrolyte resistance at different periods of the work; and from these it is seen that the cyanide solutions have resistances higher than those of double oxalates, and far higher than those of acid-baths. In practice, one ammeter may be made to serve any number of electrolytic cells, and a special switch-board is described, which is so arranged that the current in any given cell may be passed either through a separate ammeter circuit, or through a resistance equal to it, at pleasure; in this way a reading may be taken without any break of current or change of resistance. All the electrolysis cells are arranged parallel, but each has its own rheostat, capable of interposing a resistance of 60 ohms. Four secondary cells, with an aggregate interpolar E.M.F. of about 8.5 volts, are recommended for general use; they are more constant than primary batteries, and are preferable even in small laboratories. A separate circuit with special switch-boards is arranged so that the voltage at the poles of any electrolysis cell may be at once determined, one voltmeter being used for all. Illustrations of the author's laboratory and of the various connections with the battery and instruments are given. A long series of experiments is then described, from which the numbers in the following table have been collated, to show the wide range of experimental conditions under which good quantitative results are obtainable. Italicised figures are those which the author especially recommends:—

Metal.	Bath.	Free Acid, of any.	Good results obtained with				Remarks.
			Ampères per 100 Sq. Cm.	Volts.	Temperature.	Time.

Mn	Sulphate.....	Acetic ...	0.3	4.3—4.9	50—68	3	" " limited to Mn <sub>2</sub> O <sub>4</sub> .

In nearly all these tabulated experiments, material was taken for analysis sufficient to give from 0.2 to 0.1 gm. of deposit, and the lowest current intensity in any one series corresponded with the highest time requirement. The zinc is deposited in a platinum dish previously covered with a thin film of copper; the antimony in a platinum dish, the surface of which has been rendered matt by means of a sand blast, as it is found that the deposit on such a surface is more adherent, so that the current intensity may be increased and the duration of the analysis lessened. The methods used for preparing the solutions are sketched in the original paper; and further numbers are given to show that the known separations of metals may be satisfactorily made. In the electrolytic separation of antimony from tin it is now found that by raising the temperature of the solution from normal to 60° C., a stronger current (1.5 ampères) may be safely employed, and the usual period for the deposition of the antimony may thus be reduced from 15 to 2 hours. In separating copper from nickel by the acid oxalate process, the voltage must be maintained within the limits 1.1 and 1.3. In the iron-aluminium separation unduly high current intensity is to be avoided, as the solution thus tends to become heated, and the troublesome

deposit of alumina upon the iron is more likely to be formed.—W. G. M.

*Quantitative Analysis by Electrolysis.* F. Rüdorff. Zeits. angew. Chem. 1894, 388—389.

For the separation of mercury from other elements by electrolysis, the smallest possible current must be used, and more free acid than usual, as the tendency of mercury to dissolve co-precipitated metals, removes them in part from the influence of the liquid. Not more than 0.2 gm. should be used, or the deposited mercury may unite into globules, which will be mechanically carried away by the wash-water.

For the mercury-cadmium separation add from 2 to 5 cc. of nitric acid (sp. gr. = 1.2), and use two cells for eight hours.

For mercury and zinc use the chloride or nitrate solution with 1 cc. of nitric acid, or ten drops of strong sulphuric acid, and two or at most three cells for eight hours; with four cells, zinc also should be separated.

For mercury and iron add four to five drops of strong sulphuric acid, and employ two or three cells.

For mercury and nickel add six drops of sulphuric acid, and use two to three cells over-night; the same process

may be employed for cobalt, substituting 1 to 2 cc. of nitric for the sulphuric acid.

In the case of manganese and mercury, both may be precipitated simultaneously, but the manganese must not exceed 0.03 grm.; three drops of dilute sulphuric acid are used, and two cells, the manganese being collected as hydrated oxide on the platinum spiral anode (this Journal, 1892, 459). In all these cases the solution is diluted to 120 cc., and the battery used is that of Meidinger. In depositing nickel from the sulphate, no trace of nitric acid must be present, or precipitation by even six cells will be incomplete, and the operation must be finished with the aid of a stronger current, as, for example, that from a Gulcher thermopile.—W. G. M.

*The Separation of Metals by Hydrogen Peroxide in Alkaline Solutions.* P. Jannasch and E. Rose. Ber. 1894, 27, 2227—2231. (See this Journal, 1891, 659 and 1037; 1892, 270; and 1894, 67.)

*Separation of Bismuth and Zinc.*—The metals are dissolved in nitric acid (0.3—0.45 grm. in 5 cc. of strong acid), evaporated to dryness, redissolved in 50 cc. of water, and poured with constant stirring into a mixture of 25 cc. of a 3 or 4 per cent. hydrogen peroxide solution with 15 cc. of strong ammonia. The yellowish flocculent precipitate of hydrated bismuth peroxide settles readily and is poured upon a filter, where it is washed, first with dilute ammonia, and then with water; redissolved in dilute nitric acid (1:4), and reprecipitated as described; the dilute acid used for dissolving and washing the precipitate should not exceed 40 cc. and should be measured first. The precipitation must be effected by pouring the metallic salt solution into the alkaline peroxide, as the contrary order would involve the local acidification of the first drops of ammonia, with a consequent loss of oxygen, and it would cause a co-precipitation of a part of the zinc before the ammonia was added in excess, and a portion of this zinc would be permanently retained in the bismuth precipitate, even though the greater proportion ultimately passed into solution. For ordinary analyses a single precipitation will suffice. The bismuth precipitate is detached from the filter paper, and the latter is cut up and heated in a platinum crucible placed within a nickel air-bath covered with asbestos card, until charred; the cover is then removed, and the residue burned to ash; it is next moistened with strong nitric acid and dried. The bulk of the precipitate is now added, and the whole is first completely oxidised in the air-bath, and then ignited until constant in weight. The authors prefer this method to the oxygen ignition previously described by one of them (this Journal, 1894, 67). Since both the hydrogen peroxide and the ammonia generally contain traces of silica, it is safer to examine the bismuth precipitate, or to make a blank test with volumes of these substances equal to those that are used in the process. The filtrate from the bismuth is evaporated to dryness with constant stirring in a deep porcelain (not platinum) dish; the residue, after removal of the stirrer, is heated on an air-bath, and then on asbestos card, until all ammonia salts are expelled; it is then moistened with two drops of nitric acid, dissolved in water, filtered, and precipitated with sodium carbonate. The zinc carbonate is ignited in a porcelain crucible, and the oxide is examined for silica and foreign bases. The results are good.

*Separation of Bismuth and Nickel.*—This separation is conducted like the last; but the nickel may, if wished, be precipitated directly with soda, without previous heating.

*On metal separations by means of ammonium persulphate.*—The substitution of ammonium persulphate for the hydrogen peroxide in these separations, generally involves longer heating, and produces a less agreeable precipitate to work with, and moreover, owing to the formation of sulphuric acid by its decomposition, it is impossible to estimate sulphates in the same solution, whilst it produces interfering reactions in the presence of metals which form difficultly soluble sulphates. The authors are continuing their experiments in this direction.

—W. G. M.

*Separation and Estimation of Tin and of Antimony in Alloys.* Mengin. Comptes rend. 1894, 119, 224.

The author treats the alloy (for example, anti-friction metal) with nitric acid, collects the insoluble oxides of tin and antimony, washes, calcines and weighs them (M). The mixed oxides are next suspended in hydrochloric acid and water, and a ball or plate of pure tin added, whereupon the antimony is reduced to metal, and the tin converted into chloride; the reaction is best accelerated by heat; about 3 hours being then necessary, for 1.5 to 2 grms. of oxides. The precipitated antimony is washed by decantation with water which has been boiled and cooled out of contact with air; then collected and washed, first with water and then with alcohol; dried and weighed (A). There is no appreciable oxidation of the antimony and the method is very exact. The tin is estimated by difference.

$M - A \times 1.262 =$  weight of tin oxide: the latter multiplied by 0.78667, gives the weight of tin in the alloy.

An alternative method for the estimation of the tin is to precipitate the latter by zinc.

The following figures (indicating grms.) of an analysis show the accuracy of the method:—

Samples taken.	Oxides found.	Metals found.
Tin..... 1.162	3.131	Tin..... 1.154
Antimony..... 1.312		Antimony..... 1.309

The plate of tin, introduced to effect the reduction of the oxides, lost 6.918 grms.—E. R. B.

*The Valuation of Artificial Manures.* E. Henfeldt. Zeits. angew. Chem. 1894, 383—386.

This is a review of the principal phosphatic, nitrogenous and potassic manures, and of the methods of analysing them. Thomas slag from different works varies; for whilst the value of the tetra-basic phosphoric acid may be usually taken as half that of "soluble" phosphoric acid, it may in practice range from two-thirds to one-third, Bohemian slags being the less, and those from Rhenish, Westphalia the more valuable. The cause of this variation is not yet known, but high manurial value appears to be correlated with high silica percentage. The citrate solution method gives the most trustworthy indication of the value of Thomas slag, but is somewhat too lengthy for general use when many samples are being treated concurrently. In applying it, the basicity of the slag is first ascertained by shaking 5 grms. of the meal with a 1 per cent. citric acid solution, and determining the degree of neutralisation by acidimetry. 5 grms. of fresh slag are then weighed into a litre flask, and to this are added consecutively, sufficient 5 per cent. citric acid solution to satisfy the basicity, 200 cc. of an acid citrate solution, and enough water to bring the total volume to 500 cc. The whole is shaken for half an hour in a Stutzer apparatus, and is then ready for the molybdate determination. The acid citrate is prepared by dissolving 150 grm. of citric acid in water, neutralising with ammonia, adding 10 grms. of citric acid, and making the whole up to a litre. Among nitrogenous manures, nitrates are best, because the whole of their nitrogen is directly assimilable by the plant, whilst ammoniac nitrogen loses 10 per cent. during its conversion into nitric nitrogen, and organic nitrogen proportionately more during its successive conversion into ammonia and nitrate. In applying Kühn's modification of the zinc-iron method, the iron must be free from oxide, so that metal reduced by hydrogen should be avoided. As a means of applying potash and phosphoric acid conjointly to the soil, especially when mixed with ammonium nitrate, potassium phosphate should command a large market if it could be produced at a reasonable price.—W. G. M.

*Estimation of Phosphoric Acid by the Citrate Method.*  
F. Glaser. *Zeits. angew. Chem.* 1894, 543—545.

It is well known that when solutions of phosphates containing neither lime, iron, alumina, nor manganese are analysed by the citrate method variable results are obtained according to the quantity of magnesia mixture employed. Grupe and Tollens (*J. f. Landw.*, 30, 23) have already observed that a portion of the phosphoric acid remains in solution; on addition of a large excess of magnesia mixture, however, more magnesia is precipitated than corresponds with the phosphoric acid contained in the precipitate, and a compensation of errors is the result. But in the case of solutions of phosphates containing lime it is found that the analytical results are not affected to so great an extent by increasing the amount of magnesia mixture, consequently differences must in these cases be ascribed to the retention of phosphoric acid in solution. Neubauer has shown (*Zeits. anorg. Chem.* 2, 45; 4, 251) that when phosphoric acid is precipitated from an ammonium solution (such as a solution of the molybdic precipitate) by magnesia mixture and the precipitate is ignited, a loss of phosphoric acid by volatilisation occurs. This he believes to be explained by the formation of the salt  $\text{Mg}(\text{NH}_4)(\text{PO}_3)_2$ , which is first converted into  $\text{Mg}(\text{PO}_3)_2$ , and subsequently into  $\text{P}_2\text{O}_5$  and  $\text{Mg}_2\text{P}_2\text{O}_7$ .

The present author's experiments show that also with the citrate method a portion of the phosphoric acid is volatilised under certain circumstances. This was actually proved by igniting the precipitate in a crucible, the lid of which was covered with magnesia to absorb the  $\text{P}_2\text{O}_5$ ; the volatile phosphoric acid was then estimated by the molybdenum method. When a solution of alkali phosphate is mixed with 100 cc. of ammonium citrate solution and precipitated with only a slight excess of magnesia mixture, a portion of the phosphoric acid is volatilised on igniting the precipitate; this loss, is, however, quite annulled if a certain excess of magnesia mixture is made use of and the amount of magnesium pyrophosphate then obtained corresponds with that obtained by the molybdenum method. The author gives the following theoretical explanation:—Ammonium citrate enters into double decomposition with magnesium chloride, so that when but a slight excess of magnesia mixture is used there will be present, at a given period of the operation, relatively little magnesium chloride and much ammonium salt, so that the salt,  $\text{Mg}(\text{NH}_4)(\text{PO}_3)_2$ , will be formed as stated by Neubauer. The author worked with quantities of disodium and dipotassium phosphate corresponding with about 0.3—0.4 gram. of magnesium pyrophosphate. To ensure accuracy, it appears to be essential to employ about 40 cc. of magnesia mixture, and to stir well during the precipitation; the test should then be placed aside for several hours and stirred at intervals.

The results have no practical bearing on the estimation of phosphoric acid in manures, for the presence of lime and iron salts in these (using 25 cc. of magnesia mixture) reduces the volatility of phosphoric acid (even when large quantities are present) to such an extent that it need not be taken into account.—A. R. L.

*The Testing of Zinc Ores and Products of Manufacture.*  
F. Meyer. *Zeits. angew. Chem.* 1894, 391—395.

THE methods used in zinc-works are described with the hope of eliciting discussion, which may lead to the selection of an uniform standard process.

**Determination of Zinc.**—0.5 gram. of the finely-powdered ore (raw or roasted), zinc-dust or zinc-white, or 1 gram. of retort residue, is treated with 10 cc. of cold aqua regia (1  $\text{HNO}_3$ :2  $\text{HCl}$ ) in a small flask, which is then warmed. After evaporating off excess of acid, the residue is dissolved in 10 cc. of sulphuric acid (1 of 66° B + 211.0), which is next evaporated until fumes of sulphuric anhydride are given off. On cooling, 60 to 80 cc. of water and 10 cc. of sodium thio-sulphate solution (1:8) are added, and the mixture is boiled until the liquid portion has become clear, when it is filtered from the precipitated copper and cadmium sulphides

lead sulphate, and sulphur. It is now mixed with 6 cc. of nitric acid, and boiled until precipitated sulphur (from the thio-sulphate) has collected into globules, leaving the solution clear. The addition of 30 cc. of ammonia (22° B) precipitates iron and alumina, and a further addition of 20 cc. of bromine water when almost cool, brings down the manganese also. After standing, the liquid is boiled, to remove excess of bromine, and filtered; the mixed precipitate is redissolved, without thorough washing, in 5 cc. of aqua regia, and reprecipitated. The two filtrates, being united, are made up to 500 cc., and allowed to stand overnight. On the following day this liquid is titrated with sodium sulphide solution (1 cc. circa 0.01 gram. Zn), which must be re-standardised each time, using a quantity of zinc approximately equal to that in the test, dissolving it in 10 cc. of aqua regia, adding 20 cc. of ammonia, diluting to 500 cc., and allowing it to stand overnight. In titrating, the sulphide is run in with constant stirring, the thin glass tube used as a stirrer serving to withdraw a drop from time to time, for test with a strip of lead-paper. The formation of a just perceptible dark ring on the paper at the edge of the drop marks the end of the reaction. Tests are made in duplicate, and give closely-approximate results in different hands; out of 167 determinations worked simultaneously by two chemists, only five showed a variation exceeding 1 per cent.

**Sulphur Determination.**—0.5 gram. of the finely powdered raw blende, or 2 grams. of roasted ore or retort residue, are treated with 10 cc. of fuming nitric acid in a small flask; with rich blendes, the addition of a few potassium chlorate crystals prevents separation of sulphur. When all action in the cold has ceased, the liquid is evaporated to dryness twice with hydrochloric acid, to expel all nitric acid, and is then diluted to 80 or 100 cc. The iron is then precipitated by ammonia, and filtered off. After boiling to expel ammonia, 5 cc. of hydrochloric acid is added, and the sulphuric acid is precipitated boiling by barium chloride. The roasting-furnace manager judges of the completion of his work by the degree of discolouration produced by the reaction of 10 cc. hydrochloric acid with a measured quantity of the ore upon a neutral or weakly alkaline lead acetate paper, suspended in the neck of a flask tightly closed by the thumb. A long table is given for the conversion of grms.  $\text{PbSO}_4$  into percentages of sulphur.

In dealing with metallic zinc, 5 grams. of borings are dissolved in dilute sulphuric acid (1:4), filtered from the lead residue into a 500 cc. flask, from which, after filling to the mark, 50 cc. are withdrawn for each determination. The separation by means of thio-sulphate and the zinc titration are carried out as above described.—W. G. M.

*Quantitative Estimation of Nickel by Means of Ammoniacal Mercuric Cyanide.* F. W. Schmidt. *Ber.* 1894, 27, 1624—1627.

BEARING in mind the known fact that nickel may be precipitated as sulphide by means of normal (colourless) ammonium sulphide, and that the precipitation is assisted by the presence of ammonium salts, the author has devised the following method:—The nickel solution (10 cc. containing about 1 per cent. of metal) is mixed with an excess of ammonium nitrate and sufficient ammonia added until the liquid has a faint bluish colour; too great excess of ammonia must, however, be avoided as it leads to the formation of poly- (yellow) sulphide of ammonium during the treatment which follows. An excess of sulphuretted hydrogen water is now added to the boiling solution whereby, after continuing the boiling for a short period the whole of the nickel is thrown down as sulphide, and in a form which can easily be filtered from the colourless supernatant liquid; it is then washed with a hot solution containing sulphuretted hydrogen, and ammonium nitrate. The nickel sulphide so obtained resists the oxidising influence of the air to about the same extent as freshly-precipitated cupric sulphide. After washing the nickel sulphide it is converted into nickelous oxide by evaporating with mercuric cyanide and subsequent ignition

in the manner previously described (this Journal, 1894, 548) and weighed as such. The test analyses show that the method yields perfectly satisfactory results.

In considering the action of ammonium nitrate in promoting the precipitation of metallic sulphides, the author mentions that from a solution of zinc sulphide in ammonium chloride, the sulphide may be precipitated completely by adding calcium chloride, magnesium sulphate, and certain other neutral salts. In the same manner from the solution of oxythioarsenious acid, obtained by mixing solutions of sulphuretted hydrogen and arsenic trioxide, the whole of the arsenic may be precipitated as trisulphide on addition of sodium chloride, potassium iodide, ammonium carbonate, magnesium sulphate, &c., whilst such a solution undergoes decomposition on addition of hydrochloric acid. Also the hitherto unknown orange-red solution of thio- or oxythioantimonious acid, which the author obtained by mixing a very dilute solution of tartar emetic with sulphuretted hydrogen, is precipitated by addition of certain neutral salts thereto. All these exhibit, therefore, the behaviour of colloidal solutions, from which the fact that certain neutral salts favour the precipitation of the corresponding sulphides derives a simple explanation.

The author's previously expressed opinion that ammoniacal mercuric cyanide would effect the decomposition of many sulphides is therefore confirmed. Not only is powdered copper pyrites rendered black when evaporated with ammoniacal mercuric cyanide, but the residue, after ignition, is completely soluble in hot hydrochloric acid. This operation may be carried out in a short time, whereas the oxidation of copper pyrites with fuming nitric acid or potassium chlorate and hydrochloric acid takes several days.

The author mentions in a footnote that a good method of decomposing copper pyrites is to carefully roast the finely-pulverised mineral in a porcelain crucible; the residual copper and ferric oxides are then readily soluble in warm concentrated hydrochloric acid, and both metals may be estimated in the solution.—A. R. L.

#### ORGANIC CHEMISTRY.—QUALITATIVE.

*The Influence of the Acid Molybdates of Soda and Ammonia on the Rotatory Power of Rhamnose (Isodulcitol).* D. Gernez. Comptes rend. 119, 1894, 63—65.

The following conclusions are drawn:—

1. A small addition of a molybdate to a solution of Rhamnose, determines a relatively large increase in the rotatory power; but further equal increments in the proportion of molybdate produce a less and less marked effect, until at length the rotatory power ceases to grow.

2. The maximum increase is obtained when the amount of added molybdate equals  $\frac{6.75}{24}$  of the molecular weight.

The rotatory power then becomes,  $(\alpha)_D^{18} = +22^\circ.95$  and  $+19^\circ.91$  in the case of acid sodium and acid ammonium molybdate respectively. (Rhamnose dissolved in water alone,  $(\alpha)_D = +9^\circ.7$ .)

3. The relative weight of molybdate required to produce the maximum effect, is identical with that which exerts a similar influence in the case of mannitol, sorbitol, and persistol.—H. T. P.

#### ORGANIC CHEMISTRY.—QUANTITATIVE.

*The Determination of the Nitrogen in Nitrates, Nitro- and Nitroso-Compounds in the Wet Way.* M. Krüger. Ber. 1894, 27, 1633.

KJELDAHL's original method cannot be applied to the determination of nitrogen in substances containing the nitrogen linked to oxygen. The author reduces such substances by means of a solution of stannous chloride in hydrochloric acid (containing 150 grms. of tin to the litre) and metallic tin. The latter should be made by precipitating a solution of stannous chloride with zinc. After reduction, the substance is treated with strong sulphuric acid and potassium bichromate, in the way previously described by the author (this Journal, 1894, 425).

The numbers obtained in this way are said to be very satisfactory.—T. E.

*Examination of Beeswax.* E. J. Parry. Chem. and Druggist, 1894, 692.

A CAREFUL application of Hüll's test of titrating with standard alkali, and then saponifying with alkali, will yield excellent results. If this test, combined with those of specific gravity and melting point (which should closely approximate  $63^\circ \text{C.}$ ) be applied, the deduction drawn will be such as to exclude adulteration with nearly all other substances. The figures for specific gravity of pure white wax are, with Parry and Estcourt, 0.962 and 0.963 respectively, whilst Schmidt obtained the number 0.961.

*Remarks on the Alcohol Extraction of Beetroot.* Wiskirchen. Zeits. Zuckerind. 1894, 44, 700.

TOLLENS and Hermann recommend that basic lead acetate shall be added to the beetroot sludge, instead of to the filtered extract. The author remarks that this is advantageous to the extraction as to the digestion; it not only hastens the operation considerably, but also lessens the dilation of the cell membrane.—A. R. L.

*The Gravimetric Method of Estimating Cupric Reducing Sugar with Fehling's Solution.* C. Killing. Zeits. angew. Chem. 1894, 431—433.

Of the numerous methods that have been devised for the gravimetric estimation of sugars the Märcker-Alilhn is the most generally adopted; it consists in collecting the cuprous oxide in a Soxhlet's asbestos filter, reducing it in a current of hydrogen, and weighing as metallic copper. The method leaves nothing to be desired in point of accuracy when the tubes are packed with asbestos, which will withstand the action of hot potash and nitric acid. At the present time, however, long-fibered asbestos is no longer obtainable on the market, and since this is so, the method cannot give such good results. Märcker (*Handbuch Spiritusfabrikation* 4 Aufl., 85) has already observed that certain kinds of asbestos are not adapted for this use. The author describes the following experiments made with the object of verifying this observation:—

A tube was packed with glass-wool and asbestos, which had been treated with soda and acid, and had already been used six times for the estimation of sugar; it was dried and weighed. Through it was filtered 60 cc. of boiling Fehling's solution diluted with an equal volume of boiling water, as in Alilhn's method. It was then successively washed with water, alcohol, and ether, dried and re-weighed, when it was found to have lost 0.0053 grm.; on treatment with nitric acid it sustained a further loss of 0.0032 grm.; when again treated with Fehling's solution it lost 0.0029 grm.; and under the influence of 2 cc. of nitric acid it lost 0.0076 grm. A tube was packed with new specially-selected long-fibre asbestos; it was treated successively with 20 per cent. soda, water, and nitric acid; on being subsequently washed with water, alcohol, and ether it was found to have lost 0.0086 grm. It was now

treated with 60 cc. of hot Fehling's solution and 60 cc. of water, when the loss amounted to 0.0020 gram. Treated with nitric acid it lost 0.0032 gram, and treated subsequently with Fehling's solution it lost 0.0011 gram; a further loss of 0.0031 gram. was sustained when it was again treated with nitric acid. Glass-wool, which is employed for packing the lower part of the filtering tubes (beneath the asbestos), also frequently sustains loss under similar treatment to that above described; thus:—0.8 gram. of glass-wool lost 0.0045 gram. after being used for the filtration of Fehling's solution; 0.0030 gram. on subsequent treatment with 2 cc. of nitric acid; and a further loss of 0.0062 gram. occurred when it was again used for filtering Fehling's solution.

The author then quotes the recent experiments of Nihoul (Chem. Zeit. 1893, 500; this Journal, 1894, 845) and of Grünhut (this Journal, 1894, 815); he then describes the following method, which is, he states, easily carried out and gives good results:—

The cuprous oxide is collected and washed on a paper filter, and the whole dried at 100°; the dry oxide is then detached as completely as possible from the filter, transferred to a tared crucible, weighed, and calculated to metallic copper by means of the factor 0.888. The filter-paper is then incinerated in a separate crucible; the residue, after deducting the ash of the paper and the copper retained by it (which is arrived at by a special experiment), is weighed as cupric oxide, and the weight, after being calculated to metallic copper by the factor 0.7986, added to that of the main quantity. The author ignores the presence of the organic substance, which is said to be retained by the cuprous oxide (see Nihoul, *loc. cit.*), as the quantity is too small to be taken into account; in one experiment, however, 0.4641 gram.  $\text{Cu}_2\text{O}$  gave, on reduction with hydrogen in a Rose's crucible, 0.4117 gram. Cu instead of 0.4120 gram.—A. R. L.

**Gravimetric Estimation of Cupric Reducing Sugars by Means of Fehling's Solution.** A. Prager. Zeits. angew. Chem. 1894, 520—521.

KILLING (Zeits. angew. Chem. 1894, 431; this Journal, 1894, 1226) has drawn attention to the inaccuracy of the Märcker-Allihn method of estimating cupric reducing sugars; Nihoul (Chem. Zeit. 17, 500, 18, 881; also this Journal, 1894, 845) and Grünhut (Chem. Zeit. 18, 447; this Journal, 1894, 815), in the course of a controversy on the respective merits and demerits of the asbestos filtration method and the paper filtration method, have pointed out several sources of error in both. The author states that the reason that low results are obtained, even after repeatedly evaporating the precipitated cuprous oxide with nitric acid previously to igniting it, is to be traced to the formation of small lumps, which occlude reduced copper and protect it from oxidation. The formation of these lumps is avoided by the modifications to be described, and the method then gives exact results:—The precipitated cuprous oxide is collected on a double filter. The filter and precipitate are then dried, which can be accomplished in 15 minutes; the precipitate is then detached and placed on a piece of glazed paper, the filter being meanwhile incinerated in a platinum crucible, and the ash reduced to powder by means of a piece of platinum wire. When cool, the cuprous oxide is transferred to the crucible, which is then ignited over a minute flame and the cuprous oxide stirred until it is converted into a fine powder. The crucible and its contents are now ignited for some minutes in a larger flame and then weighed. No increase in weight is obtained by treatment with nitric acid and subsequent ignition. If ash-free filter papers of equal size are employed, it is only necessary to make one blank experiment with pure Fehling's solution in order to arrive at the amount of copper which is retained by the filter. The results are generally in agreement with those obtained by the asbestos filtration method.—A. R. L.

**A New Gravimetric Method of Estimating Glucose.** F. Gaud. Comptes rend 119, 1894, 478—479.

The author states that Soxhlet's method yields too high results because small quantities of cuprous oxide escape reduction with hydrogen.

The method proposed by the author is as follows:—

Measure 50 cc. of freshly prepared Fehling's solution and 50 cc. of water into a porcelain dish; boil for two or three minutes, place the dish on a boiling water-bath, and add 25 cc. of the saccharine liquid to be estimated, which should be previously diluted to a strength of about 1 in 100. At the end of 10 minutes, reduction being complete, the supernatant liquid is decanted and the precipitate washed with boiled distilled water, care being taken to retain the precipitate. When the washings are no longer alkaline to phenolphthalein the precipitate is washed into a flask of 20 to 25 cc. capacity, of which the volume at 0 °C. is known. The volume is made up with boiled distilled water. Then, if  $P$  be the weight of the liquid, plus the precipitate contained in the flask at temperature  $t$ , the volume—

$$V_t = V_0[1 + 3\beta(t - t_0)]$$

Also, the density  $\Delta$  of dry cuprous oxide being 5.881, and  $d$  the density of water at  $t$  (deduced from tables), the weight of the precipitate  $p$  is obtained by the formula—

$$p = \frac{P - V_t d}{1 - \Delta}$$

The weight of cuprous oxide obtained does not vary proportionally with the weight of the sugar, and the author gives the following tables:—

$\text{Cu}_2\text{O}$ .	Glucose.	$\text{Cu}_2\text{O}$ .	Glucose.
Mgrms.	Mgrms.	Mgrms.	Mgrms.
10	5.413	100	46.221
20	9.761	200	91.047
30	14.197	300	135.842
50	23.036	400	180.928

The error of experiment is claimed to be only 1 in 1,000 when  $P$  is carefully corrected for temperature and pressure.

—T. A. G.

**The Estimation of the Sugar-Content of Tanning Materials, Tanning Extracts, Tanning Liquors, and Weighted Leather.** V. Schroeder, A. Bartel, and W. Schmitz-Dumont. Dingl. Polyt. J. 1894, 293, 234—237.

SEE this Journal, 1894, 1101, where it was stated that the authors have shown that for the estimation of sugar in tanning materials a longer heating than that recommended by Allihn is necessary, on account of the presence of unknown and slowly reducing sugars, 30 minutes having been found to give the best results.

The following table has been constructed showing the mgrms. of glucose corresponding to mgrms. of copper weighed, when the Fehling's solution is heated with the sugar solution for 30 minutes:—

*Determination of Glucose by Means of Alkaline Copper Solutions.* F. Gaud. *Comptes rend.* 1894, **119**, 650—652.

It is well known that when certain sugars are boiled with Fehling's solution various compounds are produced. The author has already shown (*Comptes rend.* **119**, 604) that in the case of glucose, tartaric acid, formic acid, and oxalic acid are formed by partial oxidation; whilst glucinic acid, catechol, gluconic acid, lactic acid and glyceric acid are among the products of the action of the alkali on this sugar. Thus a portion of the sugar escapes the oxidising action of the alkaline copper solution and an error is thereby introduced. In order that this error may have a constant value it is necessary to standardise the copper solution and perform the titrations under as nearly as possible the same conditions. To this end a preliminary titration is made and from its indications the sugar solution is adjusted to a concentration of 0.5–1 per cent. The author also finds that undiluted solutions, *i.e.*, those having a concentration up to 10 per cent., may be titrated direct if the following correction be applied which has been deduced from 400 experiments:— $y = -0.00004801x + 0.02876359x^2$  in which  $y$  denotes the error as a function of the exact titre  $x$ . To calculate analyses the experimented titre  $\theta$  must be introduced and the formula becomes  $0.02876x^2 - 1.00004801x + \theta = 0$  whence the value of  $x$  may be calculated. As an alternative it is suggested to employ ammonia instead of potash and soda in preparing alkaline copper solutions for sugar titration (compare, however, Allen and Gaud, next abstract).—A. R. L.

*New Method of Estimating Cupric Reducing Power.* Allen and Gaud. *J. Pharm. Chim.* 1894, [5], **30**, 305—307.

When glucose is heated at 100° with ammonia in a sealed tube for 50–40 hours only a small quantity is decomposed, corresponding with the production of 5–6 per cent. of formic acid; whereas when it is heated in the same manner with the fixed alkalis—soda and potash—the amount of decomposition corresponds with as much as 60 per cent. of lactic acid. These observations led the author to substitute ammonia for the fixed alkalis in preparing a solution for the volumetric estimation of sugars by the cupric reduction method.

The solution employed by the author is prepared as follows:—Pure electrolytic copper (8.7916 grms.) is dissolved in concentrated sulphuric acid (93 grms.) diluted with an equal volume of water; the solution is then made up to 1 litre with concentrated ammonia. 10 cc. of this solution is equivalent to 0.05 grms. of glucose, and since it contains no organic matter it keeps well.

In carrying out the titration, 10 cc. of the copper solution are measured into a flask, and 10 cc. of ammonia solution added thereto. The flask is closed by a cork having three

borings, the end of the burette being inserted into one whilst the two others permit of arrangements for passing a current of hydrogen through the liquid during the reaction. The flask is placed on a water bath heated at 90–95°, the temperature of the solution contained therein being maintained at 80–85°, during the addition of the sugar solution, which is run in drop by drop until the blue colour is destroyed; the cuprous oxide formed by the reducing action of the sugar is of course dissolved by the ammonia. It is important that the temperature of the solution should not rise above 80–85° or loss of ammonia will occur, which has the disadvantage of considerably slackening the reaction.

—A. R. L.

*Behaviour of Normal and Basic Lead Acetate towards Sodium Carbonate, Sulphate, and Phosphate in presence of Invert Sugar.* A. Borntraeger. Zeits. angew. Chem. 1894, 521–528.

THE author's results show that the presence of large quantities of disodium phosphate exert but a trifling effect on the titration of invert sugar. For the estimation of reducing sugar in sweet and non-sweet wine this influence can be completely ignored. Sodium phosphate is, however, the only convenient compound whereby the excess of lead can be precipitated from sweet wines after clarification with basic lead acetate (sodium carbonate, and sodium sulphate were also tried). Before using the phosphate (and the same applies to carbonate) the basic lead acetate precipitate must be filtered off. The removal of the lead from a wine containing more than 1 per cent. of sugar is unnecessary. In the analysis of non-sweet wines sodium phosphate has no advantage over sodium carbonate as a reagent for the removal of lead; the same may be said also of sodium sulphate, and the latter has the special advantage that the precipitate produced by basic lead acetate need not be removed before using it. The wine, after neutralisation and removal of the alcohol, is treated with one-tenth its volume of basic lead acetate solution, and subsequently with a similar volume of a cold saturated solution sodium sulphate; after remaining for an hour it is filtered and titrated.—A. R. L.

*Removal of the Lead from Musts and Wines which have been Clarified with Lead Acetate.* A. Borntraeger. Zeits. angew. Chem. 1894, 554–559.

THE author's results show that sodium sulphate is a better reagent than sodium carbonate for precipitating lead from wines which have been clarified for analytical purposes with lead acetate.—A. R. L.

*Influence of Normal and of Basic Lead Acetate on the Cupric Reducing Power of Invert Sugar.* A. Borntraeger. Zeits. angew. Chem. 1894, 579–582.

REFERRING to his observations on the influence of lead on the titration of sugar in wine analysis (see preceding two abstracts) the author shows that normal lead acetate exerts but little influence on the cupric reducing power of invert sugar even when solutions of the two have remained together for a day; if, however, a solution of invert sugar is evaporated with lead acetate a diminution in the reducing power is observed, this being the more pronounced the larger the relative proportion of lead acetate present. The author also finds that 2.5 cc. of basic lead acetate solution, prepared according to the German pharmacopœia, per 100 cc. of invert sugar solution has practically no influence on the cupric reducing power of the latter even when the mixture has been kept for two days. A far less relative amount of basic lead acetate diminishes the cupric reducing power of invert sugar on being evaporated with it.

—A. R. L.

*Influence of the Volume occupied by the Basic Lead Acetate Precipitate on the Titration of Sugar in Wine Analysis.* A. Borntraeger. Zeits. angew. Chem. 1894, 583–591.

THE author's experiments show that the volume occupied by the lead precipitate, together with that obtained on eliminating the excess of lead by addition of sodium sulphate, has for practical purposes no influence on the titration of sugar in wine analysis; hence he considers it quite superfluous to wash this precipitate; its volume may be ignored.—A. R. L.

## ANALYTICAL AND SCIENTIFIC NOTES.

*Contributions to the Chemistry of Cellulose. 1. Cellulose Sulphuric Acid and the Products of its Hydrolysis.* A. L. Stern. Proc. Chem. Soc. 1894 [142], 186–187.

WHEN cotton cellulose is added to strong sulphuric acid, it dissolves; if the solution be diluted, neutralised with baryta, and filtered, a solution of barium cellulose disulphate is obtained. The free acid,  $C_{12}H_{19}O_9(SO_3H)_2$ , may be obtained by removing the barium by sulphuric acid; it is very unstable, and almost impossible to isolate. The barium salt is a white or slightly-coloured glassy powder, very hygroscopic, soluble in all proportions in water, and precipitated from strong solutions by alcohol.

When an aqueous solution of cellulose disulphuric acid is boiled with dilute sulphuric acid, it is hydrolysed. This reaction takes place in two stages, which are, however, not sharply marked off from one another. In the first stage, sulphuric acid is eliminated, and the disulphuric acid is gradually converted into cellulose monosulphuric acid,  $C_{12}H_{19}O_9 \cdot SO_3H$ , no other product being formed. In the second stage, cellulose acids containing less sulphuric acid are formed, and also dextrose. The analytical results indicate the presence of only two of these acids, i.e.,  $C_{12}H_{19}O_9 \cdot SO_3H$  and  $H \cdot C_{12}H_{11}O_9 \cdot SO_3H$ .

*On the Composition of the Waters of Coal Mines.* J. König. Zeits. angew. Chem. 1894, 389–391.

THE occurrence of heavy spar in or with coal has long been known, and believed to be due to the action of sulphates upon waters containing soluble barium salts. The frequent presence of barium and strontium in the strata immediately above and below the coal-bearing strata of the Devonian, Permian, and Triassic formations, would account for the reaction; it is therefore desirable to look for these elements in waters which are free from sulphates, although the small proportion of barium chloride as compared with the total chlorides, negatives the possibility of poisoning by any water that is at all drinkable. The following analyses of mine-waters were made, using R. Fresenius' method for the separation of the alkaline earth metals (this Journal 1893, 627); the results are given in grms. per litre:—

	1.	2.	3.
Cl .....	43.6128	19.8240	61.5960

—W. G. M.

*A White Form of Tin Sulphide soluble in Ammonium Carbonate.* F. W. Schmidt. Ber. 1891, 27, 2739—2743.

In course of preparing pure tin, the author treated the sulphide with a 10 per cent. ammonium carbonate solution to dissolve traces of arsenic, and found that the subsequent addition of dilute sulphuric acid to the filtered solution brought down an exceedingly voluminous white precipitate, easily soluble in ammonia and ammonium sulphide, from which it could be re-precipitated in like form on acidification. Heated to 105° C., it became dark brown, and on roasting yielded  $\text{SnO}_2$ . In large quantities this white sulphide may be prepared by precipitating the pure yellow sulphide from a solution of stannous chloride previously peroxidised with nitric acid, boiling the precipitate with strong hydrochloric acid, to separate arsenic, filtering, and re-precipitating the filtrate by hydrogen sulphide, and digesting the well washed purified sulphide with ammonia solution, in which it dissolves in the course of a few days, leaving only traces of lead and bismuth sulphides; the addition of dilute sulphuric acid throws down an almost white precipitate, which dissolves readily in ammonium carbonate solution when freshly precipitated, but is only soluble to the extent of two-thirds after washing upon the filter, or of half after drying; the addition finally of dilute sulphuric acid to this solution gives the precipitate required. The intermediate, nearly white, precipitate from the ammonia solution evolves an odour of freshly-precipitated sulphur on drying, and becomes greenish-yellow in colour. It is partly soluble in ammonium and sodium carbonate solutions, leaving a brown residue, dissolves readily in ammonia, and is apparently represented by the formula  $\text{Sn}_2\text{S}_3\text{O} \cdot 11 \cdot 5 \text{H}_2\text{O}$ . On air-drying, the final white sulphide (from the ammonium carbonate solution) gives an amber-coloured mass easily crushed to a yellowish powder. At first it may be completely dissolved in ammonium carbonate, but the longer it is dried the less soluble it becomes, although even after a year it dissolves readily in ammonium, from which the completely-soluble modification is again precipitated by acid. This change in solubility appears to be due to an increasing compactness in form accompanying a loss of water, which is indicated by the formula obtained for the substance after one, three, and six months standing viz.:  $\text{Sn}_2\text{S}_3\text{O}$  with  $11 \text{H}_2\text{O}$ ,  $10 \cdot 5 \text{H}_2\text{O}$  and  $5 \text{H}_2\text{O}$  respectively. In each case the sulphur percentage is slightly too high, owing apparently to the presence of a small proportion of that element uncombined. The tin obtained from the white precipitate had an atomic weight of 118.5, which indicates the purity of the precipitate. The fact that the ordinary yellow precipitate of tin sulphide dissolves to the extent of 10 per cent. in ammonium carbonate solution must not be lost sight of in separations of tin from arsenic by means of that reagent.—W. G. M.

## New Books.

**HANDBUCH DER ANORGANISCHEN CHEMIE**, unter Mitwirkung von Drs. Benedict, Gadebusch, Haitinger, Lorenz, Philipp, Stavenhagen, und Profs. Dr. Ernst, Schellbach, von Sommaruga und Zeisel. Herausgegeben von Dr. O. DAMMER. Drei Bände. 1894. Stuttgart: Verlag von Ferdinand Enke. London: H. Grevel and Co., 33, King Street, Covent Garden. Price 4l. 8s.

THIS great work on Inorganic Chemistry is just completed, and is comprised in four large 8vo volumes, Vol. II. actually appearing in two books, the First and Second Parts, so that, whilst nominally a work of three volumes, it is actually one of four volumes. Vol. I., issued in 1892,

contains a Preface, a Table of Contents, and subject-matter covering 745 pages, the volume ending with an alphabetical index. It treats of the following branches of the subject:—

THE GENERAL PART, Introduction, Principles of Modern Research. I. *The General Properties of Matter.* 1. Gaseous; 2. Liquid; and 3. Solid States; 4. Physical Mixtures (Theory of Solutions). II. *The Properties of the Molecules.* 1. Determining Atomic Weights; 2. Determination of Molecular Weights; 3. Further Construction of the Molecular Hypothesis; Chemical Composition and Physical Properties. III. *The Changes of Matter.* 1. Law of the Chemical Action of Mass; 2. Chemical Statics, Homogeneous System; 3. Chemical Statics, Non-homogeneous, Complete Equilibrium; 4. Chemical Statics, Non-homogeneous, Incomplete Equilibrium; 5. Chemical Kinetics. IV. *The Changes of Energy.* 1. Heat and Chemical Energy (Thermo Chemistry); 2. Electrical and Chemical Energy (Electro-Chemistry); 3. Radiant and Chemical Energy (Photo-Chemistry).

SPECIAL PART.—Hydrogen, Oxygen, Chlorine, Bromine, Iodine, Fluorine. The Halogens generally. Sulphur, Selenium, Tellurium. Vol. II, Part 1, issued in 1891, contains a Table of Contents, 702 pages of subject-matter, and an alphabetical index, the text treating of the following items:—Nitrogen, Phosphorus, Arsenic, Antimony, Bismuth, Carbon, Silicon, Titanium, Germanium, Zirconium, Tin, and Thorium. Vol. II, Part 2, also issued in 1891, with Table of Contents, 943 pages of subject-matter, and alphabetical index, is devoted to a detailed treatment of the following metals, &c., and their compounds:—Potassium, Sodium, Lithium, Rubidium, Cesium, Ammonium, Calcium, Strontium, Barium, Beryllium, Magnesium, Zinc, Cadmium, Lead, Thallium, Copper, Silver, and Mercury. Vol. III., issued in 1893, contains Table of Contents, 928 pages of subject-matter, and the alphabetical index, and treats in the text of the following metals, their compounds, and other matters:—Yttrium, Cerium, Lanthanum, Didymium (Neodymium and Praseodymium), Erbium (Holmium, Thulium, Dysprosium), Terbium, Gadolinium, Samarium, Decipium, Ytterbium, Boron, Aluminium, Glass, Mortar, Earthenware, Ultramarine, Scandium, Gallium, Indium, Manganese, Iron, Cobalt, Nickel, Chromium, Molybdenum, Tungsten, Uranium, Vanadium, Tantalum, Niobium, Gold, Platinum, Ruthenium, Rhodium, Palladium, Iridium, and Osmium.

**TABELLÄRISCHE UEBERSICHT ÜBER DIE KÜNSTLICHEN ORGANISCHEN FÄRBSTOFFE UND IHRE ANWENDUNG IN FÄRBEREI UND ZEUGDRUCK.** VON DR. ADOLF LEHNE, Herausgeber der Färber-Zeitung. Sechste (Schluss) Lieferung. Berlin: Verlag von Julius Springer. 1894. London: H. Grevel and Co., 33, King Street, Covent Garden.

IN this, the sixth number, the Tabular Review of the Artificial Organic Colouring Matters has reached its conclusion. All the requisite tests are given for the dyestuffs described, the methods of application, solubilities, powers of resistance, and one column devoted to patterns and samples of materials dyed, printed, or represented in lakes, &c. This part, No. 6, commences with Rose Bengal and after reaching Cœrulein S, and SW, gives examples of the Indophenols, and then passes on to the Oxazines and Thiazines. On page 86 the Azines are represented and illustrated with (a) Eurlhodines and (b) Safranines. Examples and descriptions are then given of Artificial Indigo and Indigo Carmine in paste, and then follow the Quinoline and Acridine Colours, with the Thiobenzoyl dyes. The work concludes with Group XVI., devoted to Dyestuffs of unknown constitution, and a Table of Contents, List of Errata, and a comprehensive Alphabetical Index.

This work is closely connected with the well-known Tables of Schultz and Julius, by corresponding numbers placed against the several dyestuffs in a corresponding column running through both works. Each work thus serves as an index to the other, and the chemistry and technology of the dyestuffs represented, are therefore complete in the two sets of Tables of Schultz and Julius, and of Lehne.

CHEMISCH TECHNISCHES REPERTORIUM. Uebersichtlich geordnete Mittheilungen der neuesten Erfindungen, Fortschritte und Verbesserungen auf dem Gebiete der technischen und industriellen Chemie, mit Hinweis auf Maschinen, Apparate und Literatur. Herausgegeben von Dr. EMIL JACOBSEN. 1893. Zweites Halbjahr, Zweite Hälfte. Mit in der Text gedruckten Illustrationen. 1894. Berlin, S.W.: R. Gaertner's Verlagsbuchhandlung. Herman Heyfelder, Schönebergerstr. 26. London: H. Grevel and Co., 33, King Street, Covent Garden.

THE second issue for the second half-year of Dr. Jacobsen's Repertory of Chemical Technology.

It contains Reports of the progress of the following branches of Chemical Industry:—Foodstuffs; Paper; Photography; Refuse Matters, Manures; Disinfectants and Sanitation; Soaps; Explosives and Matches; Preparation and Purification of Chemicals; Chemical Analysis; Apparatus, Plant, and Machinery; Electro-technology and Thermo-technology; Adulteration of Trade Products; New Books; and lastly the Alphabetical Index of the four quarterly issues of the Repertorium for 1893.

## Prizes.

CITY AND GUILDS OF LONDON INSTITUTE FOR THE  
ADVANCEMENT OF TECHNICAL EDUCATION.

### Foundation of Research Fellowships.

The Court of the Salter's Company have placed at the disposal of this Institute a grant of 150*l.* a year for founding one or more fellowships for the encouragement of higher research in chemistry in its relation to manufactures, applications for which are invited.

The grant will be applied to founding one or more fellowships entitled "Salters' Company's Research Fellowships," for the encouragement of higher research in chemistry in its relation to manufactures.

The Research Fellowships will be awarded by the executive committee of the Institute, with the consent and during the pleasure of the Court of the Salter's Company, in accordance with the present scheme, or with such modifications as the Court of the Company may from time to time approve.

The amount of the grant attached to each Research Fellowship will be determined by the executive committee, with the approval of the Court of the Salter's Company, with reference to the nature of the research, the time required to complete it, and the merits of the candidate.

The executive committee will appoint a special committee to report on the selection of candidates and the progress of researches, and such committee will include the representative or representatives for the time being of the Salter's Company on the executive committee.

The executive committee will each year apply the sum provided by the Salter's Company to the award of fellowships to British-born subjects, of a value not exceeding 150*l.* (a) to students of the Institute who have completed a full three-years' course of instruction in the chemical department of the Central Technical College, or (b) to candidates duly qualified in the methods of chemical research in its relation to manufactures, without restriction as to age or place of previous study.

The executive committee will report to the Salter's Company the award of each Research Fellowship, and at the close of each session the results or progress of the research or researches undertaken during the session.

A Research Fellowship may be renewed for a second and third year, but shall not be held by anyone for more than three years.

The holders of Research Fellowships must devote their whole time to the prosecution of research, unless otherwise sanctioned by the executive committee; and must report as required on their work.

The researches are to be carried out at the Institute's Central Technical College, and the holders of Research Fellowships will be subject to the regulations of the college and the supervision of the board of studies.

Applications for Salter's Company's Research Fellowships must be made in writing addressed to the Honorary Secretary of the Institute, at Gresham College, Basinghall Street, E.C., and must state the nature of the research proposed to be undertaken, and the qualifications of the candidate.

The first award will be made early in the new year.

## Trade Report.

### TARIFF CHANGES AND CUSTOMS REGULATIONS.

(From the Board of Trade Journal.)

#### RUSSIA.

##### Customs Decision.

Pound = 36 lb. airdupois; Rouble (gold) = 3*s.* 2*d.*

The following decisions affecting the classification of articles in the Russian Customs tariff have recently been given by the Russian Customs authorities:—

As articles liable to duty with toilet soap are to be considered all receptacles, wrappers, cardboard boxes, &c., which are intended for sale together with such soap.

Enamel paints, prepared with oil with an admixture of drying substances, such as turpentine, &c., to be cleared under section 137. Duty, 3 roubles gold per pound.

#### JAMAICA.

##### Tariff Changes.

The following changes in the rates of duty leviable in Jamaica on the importation of the undermentioned articles have been made by the Governor and Legislative Council of that colony, as set forth in Ordinance No. 13 of 1894:—

Ale, beer, and porter, 9*d.* per gallon.

Spirits:—brandy, 12*s.* 6*d.* per gall.; gin, 12*s.* 6*d.* per gall.; rum, the produce of and imported from British Possessions, 12*s.* 6*d.* per gall.; whiskey, 12*s.* 6*d.* per gall.

Spirits of wine, alcohol, and all other spirits, cordials, or spirituous compounds, except methylated spirits, 12*s.* 6*d.* per gall.

Spirits, methylated, 12½ per cent. *ad val.*

#### UNITED STATES.

##### Customs Decisions.

The following decisions respecting the construction to be given to Acts of Congress relating to the classification of articles in the Customs tariff, and the application of the Customs laws of the United States, have recently been given by the Customs authorities in that country:—

Collodion, a fine spun yarn or thread, used as a substitute for silk, to which it bears a striking resemblance, is dutiable at 60 cents a pound and 25 per cent. under paragraph 21, Act of October 1st, 1890.

Saké, a liquor made from rice by a process of fermentation and pressing, and not distilled liquor or spirits, containing from 11 to 14 per cent. of alcohol developed by fermentation, is dutiable at 50 cents per gallon under paragraph 336 as still wine.

Symphorol, or sodium caffeine sulphonate, a chemical salt and a chemical compound, and a medicinal proprietary preparation of which alcohol is not a component part, and in the preparation of which alcohol is not used, is dutiable at 25 per cent. *ad val.* under paragraph 76.

The residuum obtained in the distillation of petroleum, and partaking of the nature of pitch or bitumen, is dutiable under section 4 at 20 per cent. *ad val.*

Orthotoluidine, a coal-tar preparation, a chemical compound, and commercially known as aniline oil, is free of duty under paragraph 661 as aniline oil.

## NEW LAWS AFFECTING CHEMICAL INDUSTRIES.

### THE MARGARINE TRADE IN FRANCE.

In its sitting of the 20th July last, a bill was presented to the French Chamber of Representatives for the repression of fraud in the butter trade and in the manufacture of margarine. The French *Journal Officiel* for the first of November, publishes the text of the bill together with the *exposé des motifs* to the same. In the *exposé* it is pointed out that it is 25 years since Mège-Mouriez discovered a way to utilise tallow so that it could be used as a substitute for butter in cooking. This discovery was favourably received, and the Academy of Science granted a prize to the discoverer.

At first the invention of Mège-Mouriez was put to unscrupulous uses. Real butter was very dear, and some makers were addicted to palming off the margarine as such. As a result commercial credit suffered and demands for legislation to put a stop to the abuses came in from all sides. But, as the *Journal Officiel* observes, the evil from which agriculture is suffering is not confined to France, and France was not the country in which the adulteration originated.

In 1893 the exports of Mouriez margarine from France amounted to 7,456,647 kilos.; it has varied very little since 1887.

In Scandinavia the exports in 1893 exceeded 2,000,000 kilos.; in Belgium they were 3,437,325 kilos.; in the Netherlands they were not less than 74,000,000 kilos. England received from foreign countries in the same year 65,000,000 kilos. of margarine. The Netherlands was accountable for 60,000,000 kilos., and France for scarcely 2,000,000 kilos.

The complaints as to the unfair competition of margarine with butter are heard on every side. This has a detrimental effect on production, and brings about a reduction in the price of the butter.

The following is a précis of the French bill:—

Art. 1 prohibits the sale, import, and export of margarine as butter.

Art. 2 is to the effect that all food substances resembling butter are to be designated as "margarine."

Art. 3 proposes to prohibit the manufacture and sale of butter and margarine in the same building.

Art. 4 provides that the manufacturer of margarine should make a declaration to the communal authorities in the district where he intends to establish his factory; and Art. 5 requires the places where it is made or sold to bear the inscription "fabrique, dépôt ou débit de margarine ou d'oleo-margarine."

Art. 6 provides for the factories being subject to the supervision of government inspectors, and by Arts. 7 and 8 the duties and pay of these inspectors are fixed.

Art. 9 stipulates that all the necessary tubs, boxes, and papers used in the sale of margarine or oleo-margarine must bear distinct inscriptions of the names "margarine" and "oleo-margarine."

Art. 10 provides for the same process to be carried out as regards imports, exports, or consignments.

Art. 11 prohibits any other course from being followed than that indicated in the two preceding articles.

According to Art. 12, all invoices, way-bills, &c., must mention only margarine or oleo-margarine. The absence of such reference will be taken to indicate that the merchandise is butter.

Art. 13 provides that the inspectors mentioned in Art. 6, and, if necessary, special experts, may visit margarine factories, warehouses, Customs houses, &c., and take samples for analysis; and if fraud be discovered may take steps for criminal prosecution. By Art. 14 it is the duty of the Minister of Agriculture to supervise the proceedings to be taken as to analysis under the preceding section.

Art. 15 provides for the disposal of fees for analysis and fines for fraud.—*Board of Trade Journal.*

### NEW UNITED STATES LEGISLATION AS TO DISCHARGE OF REFUSE INTO STREAMS AND HARBOURS.

The River and Harbour Act of August 17th, 1894, contains the following section:—

Section 6. That it shall not be lawful to place, discharge, or deposit, by any process or in any manner, ballast, refuse, dirt, ashes, cinders, mud, sand, dredgings, sludge, acid, or any other matter of any kind other than that flowing from streets, sewers, and passing therefrom in a liquid state, in the waters of any harbour or river of the United States, for the improvement of which money has been appropriated by Congress, elsewhere than within the limits defined and permitted by the Secretary of War; neither shall it be lawful for any person or persons to move, destroy, or injure in any manner whatever any sea-wall, bulkhead, jetty, dike-levée, wharf, pier, or other work built by the United States, in whole or in part, for the preservation and improvement of any of its navigable rivers, or to prevent floods, or as boundary-marks, tide-gauges, surveying-stations, buoys, or other established marks; any and every such act is made a misdemeanour, and every person knowingly engaged in, or who shall knowingly aid, abet, authorise, or instigate a violation of this section shall, upon conviction, be punishable by fine or imprisonment, or both, such fine to be not less than two hundred and fifty dollars nor more than twenty-five hundred dollars, and the imprisonment to be not less than thirty days nor more than one year, either or both united, as the judge before whom conviction is obtained shall decide, one-half of said fine to be paid to the person or persons giving information which shall lead to conviction of this misdemeanour.

Sections 7 and 8 refer exclusively to boats or vessels dumping prohibited materials in any harbour contemplated in section 6. That section, however, as will be observed, has a much wider range. It is reported to have been introduced by Mr. Alderson, a representative from West Virginia, and to have been specially intended to apply to New River, in that State. But it may operate against many operations in coal-washing, ore-washing, stamp-milling, &c. elsewhere. Apparently, every such operation, if it discharges mud or other injurious refuse into the streams or harbours contemplated, is absolutely prohibited until the Secretary of War shall have granted specific and defined permission for it. And the waters thus protected are those of "any harbour or river of the United States for the improvement of which money has been appropriated by Congress." This clearly includes all past appropriations, as well as those contained in the act of which this section is a part. Congressmen who have heretofore secured public money for the improvement of insignificant streams, with the idea that they were making themselves popular among their constituents, may turn out to have subjected local industries to considerable vexation, through the jurisdiction thus conferred upon the general government. There is, however, no reason to anticipate more than a temporary inconvenience to such industries as are not in fact injuring navigable waters. The Secretary of War may be relied upon to use his discretionary power with common-sense. But it is evident that the practice of producing shoals for the government to dredge out, if it has anywhere obtained, will have to cease; and that the waters into which solid matter shall be hereafter permitted to be discharged, for the benefit of private enterprises, will not figure in the

river and harbour bills of the future. If they are really "navigable," individuals must let them alone; if they are not "navigable," the United States ought to spend no money on them.—*Engineering and Mining Journal*.

#### THE BRASS TRADE.

The Home Secretary (Mr. Asquith) has appointed a special committee to make inquiries into the condition of the brass trade, with the view, if necessary, to the construction of special rules for its conduct as an unhealthy occupation. The committee consists of Mr. W. Dawkins Cramp, one of the Superintending Inspectors of Factories and Workshops; Dr. R. M. Simon, of Birmingham; Mr. W. R. Lane, manager to Messrs. Winfield, Birmingham; Mr. W. J. Davis, secretary to the Brassworkers' Association; and Mr. Seymour Henry Knivett, one of H.M. Inspectors of Workshops in Birmingham. Dr. Simon, I understand, is appointed as a medical expert, who has given special attention to the conditions of the brass trades, and the health of those engaged in them. The committee is instructed to make "inquiry into and report on the conditions of work as they affect the health of the operatives in the processes of brass casting and mixing; brass dipping, polishing, and finishing, and in all other processes in brass manufacture; and also in the casting and mixing of gun-metal, bell-metal, and other kindred amalgams, and in particular to report what, if any, special rules should be made under section 8 of the Factory and Workshops Act, 1891, for the protection of the persons employed in such processes—whether the special rules so made should be applicable to all works in which such processes are carried on, or whether any exception should be made in cases where brass-casting, &c., is only a subsidiary operation." The committee will sit principally in Birmingham, but will visit other places where the brass trade is carried on. Mr. Knivett will be glad to receive communications from individual manufacturers and individual workmen, or associated bodies of either, who may wish to give evidence before the committee.—*Ironmonger*.

#### CHEMICAL WORKS AND THE SUNDAY-REST ACT.

A conference of chemical manufacturers met in Berlin last month to discuss the question of Sunday labour in chemical works (a stringent Sunday-rest Act being now in operation in Germany), and to frame representations to Government on the subject. It was decided to urge upon the authorities the absolute necessity of exempting from the Sunday Act all processes of reaction in the manufacture of organic dyes requiring more than 24 hours, as well as drying-room operations in the same industry. The permission to work on Sunday was further declared to be necessary in the sublimation of sal ammoniac, the feeding of the drying room ovens in mineral-paint works, in English-umber works, saltpetre works, camphor refineries, ceresin, cyanide of potassium, and sulphate of ammonia works. Many of the manufacturers present also demanded the exemption of the Easter, Whitsun, and Christmas holidays from the Act.—*Chemist and Druggist*.

#### PROCEEDINGS OF CHAMBERS OF COMMERCE.

##### MANCHESTER.

A meeting of the Board of Directors of the Manchester Chamber of Commerce was held on the 14th November, Sir F. Forbes Adam, C.I.E., in the chair.

In the minutes of the Chemical Sectional Committee a resolution appeared, suggesting that the preparation of evidence to be laid before the Parliamentary Committee on the Food and Drugs Act should be undertaken by a joint sub-committee selected from the members of the Produce and the Chemical Sectional Committees. The suggestion was made on the ground that in some cases the knowledge of chemical experts would be of essential service. With

this view the chairman of the former committee entirely concurred, and the Board accordingly agreed to the appointment of the joint committee.

On the proposition of the Chemical Sectional Committee the Board sanctioned the appointment of a deputation of chemical manufacturers to seek an interview with the Health Committee of the Manchester City Council, for the purpose of showing what steps have been taken by chemical manufacturers for the abatement of smoke, and to request that a distinction may be made, as already partly promised, between intermittent fires and ordinary steam-boiler fires. The resolution was approved by the Board.—*Board of Trade Journal*.

#### EXTRACTS FROM DIPLOMATIC AND CONSULAR REPORTS.

##### THE PRODUCTION OF TARTARIC MATERIALS IN ITALY.

In a report to the Foreign Office, dated the 7th November, Mr. E. H. B. Hartwell, Her Majesty's Consul at Naples, submits a statement of the production of tartaric materials in Italy for the 12 months, 1st October 1893 to 30th September 1894. From this statement it appears that of half-refined tartar there were produced 1,266½ tons, valued at 70,955*l.*; of Vinaccia argols, 2,396 tons, valued at 109,070*l.*; of crude argols, 2,255½ tons, valued at 81,220*l.*; and of winelees, 2,676 tons, valued at 37,470*l.*; showing a total production of 8,594 tons, valued at 298,715*l.* The exports to the United States reached 3,949 tons, to Great Britain 994½ tons, to Germany 1,580½ tons, to France 419½ tons, and to other countries 1,650½ tons.—*Board of Trade Journal*.

#### GENERAL TRADE NOTES.

##### THE PETROLEUM SUPPLY OF THE CAUCASUS.

According to the *Moniteur Officiel du Commerce*, the petroleum springs existing around Baku do not appear to have lost their prolific character, at all events in the districts of Balakhani-Salrundschi, Bibi Kibat, and Romany, where the petroleum industry is concentrated. In 1893 the production of mineral oil was 337,051,834 pounds; of this quantity, 324,763,197 pounds (13·6 per cent. more than in 1892) underwent treatment in the local refineries, the remainder having been used for purposes fuel or lost. The increase arises chiefly from the fact that the springs, without the aid of pumps, supplied about one third of the aforesaid total. The price of the unrefined petroleum has been affected by this abundant supply; it has varied from 2·75 copecks per pound in winter to about 0·75 copeck in summer.

In 1893 there were 38 springs and 458 wells with pumps. A set of pipes, from 75 to 150 mm. in diameter and of a total length of 260 kilom., connecting the wells and the works, has permitted of the refining of about 1,440,000 pounds daily. There are only 85 refineries in work, and several have had but little to do, because in Russia, as everywhere else, the larger establishments are crushing out the smaller.

The refineries have produced and exported the following quantities:—Refined petroleum, 85,633,791 pounds; lubricating oils, 6,232,740 pounds; benzine, 252,493 pounds; tar and gasoline, 437,620 pounds; and petroleum residues, 145,538,399 pounds. To these figures there should be added those for local consumption.

According to the *Chemiker Zeitung*, the tools and processes employed by the refineries are often incomplete and defective; there is no longer pure water in sufficient quantity.

Sulphuric acid and caustic soda used for the treatment of petroleum are now made on the spot; four establishments supply about 9,000 tons of sulphuric acid, and three firms produce 2,700 tons of black acids, which are used for refining purposes. Two factories prepare soda, the one by means of Glauber salts (sulphate of soda), and the other according to the Leblanc method. As the residues have

increased in price and are generally sold at a higher price than the oil, 30 per cent. of the raw product only is distilled, instead of 36·5 per cent. as formerly.—*Ibid.*

#### THE RUSSIAN PETROLEUM (NAPHTHA) INDUSTRY, AND THE PETROLEUM OUTPUT IN 1893.

*F. Thiess. Journ. f. Gasbeleuchtung u. Wasserversorgung. 1894. 37, 704—706.*

In the petroleum industry of the Baku district the demand for the heavy residuals (masut, astatki, &c.), which

were formerly by-products of little value, has so increased during the last few years that these residuals have now become the most important products, and the kerosene really the by-product. The residuals are now very largely used (especially in Russia) for fuel on railways, steamers, and in factories; and quite recently an Astrakhan engineer is said to have successfully introduced their use for domestic fuel. For steamers this liquid fuel has the great advantage that it occupies little more than half as much storage space as the equivalent amount of coal.

The following table gives an idea of the growth of the liquid fuel (petroleum residuals) industry—

	1881.	1884.	1885.	1886.	1890.
Number of steamers using liquid fuel.....	..	126	..	1,507	1,824
Horse-power represented thereby.....	..	79,105	..	86,404	103,177
Tons of petroleum residuals consumed on these steamers.....	..	217,502	..	279,549	575,169
" " " " on Russian railways .....	1,900	..	82,607	..	280,138

The author calculates that in the last 13 years about 8,200,000 tons of residuals have been used on railways and steamers, &c. This would correspond to about 105,000,000 cub. yds. of wood (the former principal fuel), and would represent the saving from destruction of about 1,136,000 acres of forest.

The quantity of crude petroleum obtained in 1891 was 4,500,000 tons, in 1892 4,690,000 tons, and in 1893 5,320,000 tons. Of the latter quantity 1,790,000 tons were obtained from 38 fountain-springs, the remainder being pumped from wells. The present storage tanks in the Baku district number 250 and have a storage capacity of 452,920 tons, but it is proposed to erect further storage for about 820,000 tons. Of the petroleum collected in 1893 4,775,440 tons were worked up, with the production of 1,402,728 tons kerosene, 102,095 tons lubricating oil, 4,136 tons benzine, 7,758 tons asphalt, gasoline, &c., and 2,351,241 tons residuals. Thus 3·41 tons of crude petroleum were used for the production of one ton of kerosene, or burning oil. The sale of residuals increased from 1,013,068 tons in 1888 to 1,699,509 tons in 1891 and to 2,351,241 in 1893. The large increase of residuals is in part due to the fact that with the increasing demand for the latter and the falling demand for illuminating oils the distillation of the latter is not now carried so far as formerly. Thus formerly an average of 30—35 per cent. of the crude oil was distilled off for illuminating oil, whilst now only about 20—25 per cent. is so distilled off. In fact, the distillation is sometimes so reduced that the dangerously light and inflammable oils are left in the so-called heavy residuals and becomes virtually a process of adulteration. The annual increase in residuals exported (mainly by the Caspian) averaged in recent years 196,566 tons, whilst it was 425,893 tons in the first ten months of 1893.

Until recently the Russian petroleum industry was almost exclusively confined to the rich petroleum fields south of the Caucasus, but lately petroleum wells have been successfully sunk and worked in the Terek (or Tersk) district north of the Caucasus. In one boring of about 400 ft. deep a petroleum fountain was produced throwing out about 4,900 tons in 24 hours, with such force as to destroy much of the boring apparatus. New pipe lines and railways bring this district in connection with the Caspian. Very extensive new pipe lines are also planned both in this and the Baku districts for facilitating the petroleum transport.

—L. T. T.

#### THE HUNGARIAN COMMERCIAL MUSEUM AT BUDAPEST.

The primary aim of this State-supported institution is to encourage the sale of native manufactures. It consists at present of an enquiry office, library, museum, and a sale department, and it runs a trade newspaper and occasional special exhibitions. It is under the control of a society with a membership of about 800, strictly limited to Hungarian manufacturers, no traders being admitted.

The income of the society consists of:—(1) annual subscriptions of members at 10 florins; (2) rent of space in the exhibitions, at 2 florins per square metre in the open, and 5 florins per square metre for glass cases; and (3) a commission of 2½ per cent. on all sales. Any deficit is met by the State.

The staff consists of 5 officers and 1 servant (enquiry office), 1 officer and 1 servant (library), 12 officers and 15 servants (museum), and 42 officers and 12 servants in the sales department. The enquiry office (Academic Strasse 12), open from 9 a.m. to midday and again from 3 to 6 p.m., affords general information as to customs and freights. Members also may obtain information as to foreign credits. The library contains works on law, political economy, and trade, together with directories and newspapers. The trade newspaper of the museum (*Kereskedelmi Közlemények*), issued once a week to members only, contains:—consular, trade, market and exhibition reports, statistics, and home and foreign commercial and technical notices. The museum is devoted to foreign samples and models for native imitation, and native goods and samples. It offers special facilities to the small craftsman, who possesses no showroom, to exhibit and sell his work. The large producer also finds it to his advantage, for the museum sells his products from the exhibited samples and models. Six inspectors or store-keepers are entrusted with the safe custody of the exhibits, each one of whom is under guarantee to the small extent of 300 florins, and sells the exhibits in person.

The museum is situated in the central pavilion or "Industrial Hall" built for the Exhibition of 1885. The ground space occupies 10,000 square metres, while the vertical show space can be increased at will by means of movable screens (écrans). The museum supplies glass cases, but private cases are also admitted. Only members may exhibit; each one is entitled to free ground space to the extent of one square metre.

The visitors in 1893 numbered 80,000. No charge for admission is made, except on Sunday afternoons. The exhibits consist of Agricultural and Horticultural implements; Farm products, such as milk, cheese, and butter; silk, honey, wool, feathers, and bristles; Products of woods, forests, and mines; Chemicals; Foods and Beverages; Ceramics; Metals; Clothes; Furniture; Gold and Silver work; Millinery; Printing; Musical and Scientific Instruments, Carriages; Machines; Road, Canal, and Railway Constructions; Posts and Telegraphs; Naval and Fishery appliances; Equipments; Hospital and other Sanitary appliances; Home Industries, and Educational appliances.

The annual special exhibitions are not exclusively Hungarian. Up to the present the following have been held—Railways and Railway appliances; Leather; Pottery and Earthenware; and Electrical appliances.

*Sale Department.*—The permanent museum at Budapest does the largest business. Twelve branches are also now open, viz.: Serajevo, Banialuka, Mostar, Bukarest, Saloniki, Bricksa, Fiume, Belgrade, Sofia, Philippolis, Rust.

chuk, and Constantinople. This number will shortly be increased.

Prior to the opening of the first foreign branch at Sarajevo in 1891, Hungarian goods to the value of four million florins had been sold by the museum. Each member can correspond direct with the foreign sale branches and receive therefrom any required information free of cost.

The central museum has only at present a temporary home pending the completion of the great Millennial Exhibition of 1896 to commemorate the foundation of the Hungarian State by Arpad. During this Exhibition the museum officers will be transferred to the Stephanie Weg, Stadtwaldchen.

The President of the museum is the Hungarian Minister of Trade, and the Vice-President is the Secretary of State for the same department. The Committee consists of seven and the Council of 28 members, all nominated by the Minister of Trade.—*J. Lazarus.*

#### THE INDIAN SHELLAC INDUSTRY.

Dr. George Watt, Economic Reporter to the Government of India, observes, in a report recently drawn up by him, that within recent years the demands for shell and button lac have far exceeded the supply, so that it may be said that a considerable revival of interest in this peculiarly Indian article of trade has taken place. During the past five years the exports have increased 95 per cent. in value, and only 21 per cent. in quantity, and the returns would appear to manifest a steady improvement. But it would be unwise to advance too emphatic assurances, since the history of the trade has often manifested the wildest eccentricities. During the past 18 years the lowest exports were in 1879-80, viz., 57,335 cwt., valued at 33,490,600 rs., but, as showing the erratic nature of the trade, it may be mentioned the figures for the immediately preceding year were 83,722 cwt., valued at only 2,895,430 rs. Still more puzzling are the returns for 1875-76, viz., 92,915 cwt., valued at 7,291,760 rs.; and of 1876-77, 109,665 cwt., at 4,991,230 rs. It will thus be seen that few articles of Indian export trade manifest more sudden changes than that of lac. To the people of India it might almost be said the interest in lac lies in the fact that it is collected from wild sources, and that the industry is a positive boon to people in tracts of country that stand greatly in need of such aid. Its encouragement is, therefore, of considerable consequence, though, as compared with other specially Indian products, it is not of much value. There are 21 native lac factories, and one European at Mirzapore, in the North-West Provinces. In Bengal there are 35 factories, but, excepting the Cossipore Factory near Calcutta, they are all small native works. There are, for example, 25 native shellac factories in Manbhoom, one in Beerbhoom, one in Palamow, and seven in Lohardugga. These various factories give employment to 2,614 permanent hands, and 1,665 additional ones during the working season.—*Chemist and Druggist.*

#### NITRATES IN EGYPT.

##### *Report of the Commission.*

This report to the Egyptian Council of Ministers deals with the nitrate-bearing clay in Upper Egypt, which commonly contains nitrates equivalent to 15 per cent. of sodium nitrate. The supply is stated to be practically inexhaustible. At a distance of 760 kilometres south of Cairo, on the east bank of the Nile, are low ranges of hills at the foot of the principal range of limestone cliffs. These "foothills," which were examined for a length of 15 miles, are formed of nitrate-bearing clays with a thin cap or covering of limestone. The clay is termed "Marog," and is a blue or grey foliated marl. Large numbers of cultivators are engaged at the appropriate season in removing the clay for use in the neighbourhood as a fertiliser. Rains appear to remove the

nitrate rapidly, but it was the opinion of the workers on the spot that under favourable conditions nitrification goes on equally rapidly. They rely upon the taste in judging whether the clay is in a good, or nitrated, condition, when it is said to be "hami" or bitter. With regard to the mode of nitrification the authors point out that "in these hot valleys there is no trace of organic life nor of vegetable matter . . . and . . . microscopical organisms cannot here be the active agent, for the sun's heat is too intense."

The nitrate-bearing clay is supposed to occur over an area stretching from 24° to 27° N. lat., and from 28° to 34° E. long. Without the use of this "marog," agriculture, it is said, would be impossible between Assuan and Armut. Subjoined are analyses of "marog" made by Dr. Mackenzie at the Tewfikia College of Agriculture.

—Cairo National Printing Office.

#### ADULTERATION OR IMPROVEMENT OF CEMENT?

We are indebted to our contemporaries the *Ironmonger, Journal of the London Chamber of Commerce*, and the *Chemical Trade Journal* for the following particulars:—

A meeting of English Portland cement manufacturers was held recently in London, called on the initiative of Knight, Bevan, and Sturge, "for the purpose of establishing an association of English cement manufacturers," and "of dealing with, and, if possible, of putting a stop to, the unprincipled and disreputable practice" of "adulterating cement by the mixture of Kentish rag-stone, other stone, furnace, or oven ashes, disused or exhausted firebricks, and other inert material." It was attended by representatives of 29 manufacturers of Portland cement, Mr. Bevan occupying the chair. There were considerable differences of opinion on various points. Some of those present approved of the proposed association; others decidedly objected to it; and others preferred leaving the question of adulteration in the hands of the London Chamber of Commerce. One gentleman, Mr. Holt (of Macevoy, Holt, and Co.), boldly denied that the addition of Kentish rag-stone was an adulteration. He frankly admitted having used it, and after two years' experience declared it improved the cement in point of colour and in its tensile strain: the sand tests were higher, and in every respect it was a better article. It did not follow, he said, that because Portland cement had been made for 30 or 40 years by the admixture of chalk and clay that there was no other article by which it could be improved. Mr. Holt quoted figures in support of his views, and indignantly repudiated the charge of "adulteration." Mr. Leedham White (J. Bazley White and Brothers) said English cement manufacturers were making a better article than they did some years ago, but he admitted they had been distanced by

German skill. He thought they ought not to be debarred from imitating that German skill, from taking advantage of scientific research, and from making all the progress they could. He held, therefore, that the matter should be sifted by a qualified body in a scientific manner, and then fully reported upon. Ultimately the meeting broke up, and several firms signed a statutory declaration, joining the association, and avowing that they never had "adulterated" their cement the manner indicated.

In this connection it is instructive to note what the Germans have done in the same direction. According to the *Chamber of Commerce Journal*, early in the year 1880, when adulteration threatened to become very prevalent, the Union of German Cement Manufacturers found itself compelled to set its face in the strongest manner possible against the admixture of foreign materials with cement, both in order to protect the good name of German Portland cement, and at the same time to protect the building trade from disadvantage and danger. There have not been wanting, on the other hand, attempts to defend the admixture of foreign materials with the cement. It has been asserted that the strength of Portland cement was more than sufficient for many purposes, and that it was in the interest of the building trade to produce for them a cement which should be cheaper, and yet sufficiently strong for their requirements. It was even argued that the admixtures employed were an improvement to the cement, and in support of this assertion the defenders of the system pointed to the investigations of Professor Tetmeyer and Dr. Michaelis, who by certain admixtures obtained an increase in the strength of the cement.

With regard to the first point (cheapness), the Union insisted that it must be left to the consumer, if he wished to cheapen cement, to make the desired admixtures himself. If either the manufacturer or the dealer were permitted to do this, the door would be opened wide to fraud, and the confidence of the public in Portland cement would be shattered, for the consumer would not be in a position to know or to test either the degree of the adulteration or the characteristics of the added material.

With regard to the second point (*i.e.*, the alleged improvement), it was certainly known that by the addition of ultramarine, precipitated silicic acid, preparations of potters' clay, and such like, the strength of Portland cement could be increased, but it is still doubtful whether the other valuable qualities of Portland cement do not suffer, and, moreover, these admixtures are excluded from us, if only by reason of their high price. If the defenders of the system point to the admixtures of "compositions" made by Michaelis and Tetmeyer in their laboratory experiments, and the constitution of which was not made public, there is no evidence that the materials used in the works where this adulteration is practised are identical with the materials used by these gentlemen.

It is quite certain that the quality of cement is not in the least improved by the granulated blast furnace slag, which is used for the production of Puzzuolan cement, and which hardens well when mixed with lime. On the other hand, the ordinary ground or disintegrated slag (and it goes without saying that the same remark applies to ground limestone) deteriorates the quality of the cement, and is to be regarded simply as "ballast" in cement.

It has been found that adulteration is chiefly practised with these two materials, and it is agreed that the mixed cements hitherto put upon the market were all of little value, and they have been so considered to this day.

For all these reasons, the Union of German Cement Makers, which since 1888 has borne the title of the "Union of German Portland Cement Manufacturers," has continuously exerted itself to root out, as far as possible, this system of adulteration.

With this view the Union has drawn up certain information as to what may legitimately be added to cement and what may not. The following were the conclusions arrived at:—

**Admixture of Gypsum.**—The addition of unburnt gypsum, made at the time of grinding, has for its advantageous object

the retarding of the setting of such Portland cements as are by their nature quick setting, and thereby rendering them more fit for use. The action of the gypsum is probably owing to the fact that when the cement is mixed with water into mortar, the gypsum is first dissolved, and then precipitated in extremely fine particles on the grains of the cement, in exactly the same way as it is recommended for lime by F. Schott. (*See Dingler's Journal*, 207, 52, and 209, 30.) If the particles of cement are enveloped in the thinnest possible film of gypsum, the chemical incorporation of the water is notably delayed. In consequence of this the cement becomes slower setting, and by this means (possibly also by the simultaneous occurrence of some chemical action) cement, mixed with a little gypsum, gives a higher degree of strength than the unmixed quick-setting cement. Inasmuch as the addition of from one-half to two per cent. of gypsum is sufficient for the attainment of this object; and as, moreover, the addition of a larger percentage would cause the cement to "blow," there can be no possible ground for asserting that the admixture of gypsum is made with a fraudulent intention; nay, more, such an addition, within the prescribed limits, must be regarded as an improvement. In consequence of this the united declaration of the German Portland cement manufacturers specially permits additions, not exceeding 2 per cent., if made with the object of regulating the time of setting.

**Fraudulent Admixtures.**—Of materials which may from time to time be mixed with Portland cement with the intention of adding to the profits, and without open acknowledgment of such admixture, it is evident that only those can be employed which are cheap, and which resemble Portland cement both in weight and colour. Chief amongst such materials are slag, principally blast furnace slag, grey limestone, slate, hydraulic lime, black or grey limestone, and trass. The most popular adulterant is slag, because, when pulverised, it is very similar in appearance to Portland cement, and is therefore less easily detected, even when added in large proportions.

All the foregoing admixtures make the cement inferior, not only in respect of strength, but also in respect of those other valuable qualities (or characteristics) of Portland cement, such as resistance to frost, durability, cohesiveness, &c., as has been proved by the most exhaustive researches.

The subsequent proceedings of the English movement have been as follows:—

At a meeting of the cement trade, held at the London Chamber of Commerce, it was resolved—"That a committee be appointed, with power to engage experts to investigate into the question of the admixture of Kentish rag-stone, other stone or other material with Portland cement, so far as carried on at home and on the Continent, and to report and advise thereon." Representatives of 11 firms were appointed upon the committee. The formation of a Cement Manufacturers' Association, with the object of stopping adulteration, is also well on the way towards completion.

The above-mentioned committee appears now to have decided that Kentish rag-stone is not a desirable constituent in Portland cement, for at another meeting it is reported by *Industries and Iron* to have resolved with only one dissentient "that it is advisable that all manufacturers of Portland cement who have used any outside material in their manufacture should at once discontinue the practice." The use, however, of not more than 2 per cent. of gypsum, as practised by the German manufacturers for the purpose of regulating the setting of the cement, is considered optional.

#### THE GERMAN CEMENT TRADE.

There are upwards of 63 cement works in Germany. The year's output is about 10,600,000 barrels, and in the production of this quantity of cement 18,000 workmen were employed in 1893, occupying 5,500,000 working days, and earning 14,250,000 marks in wages.

Near Hamburg there are three or four factories for the production of this article, but the centre of the production is on the Rhine. The largest customers for cement are the United States, Brazil, Chile, and Venezuela, and in Europe,

Norway, and Russia, as follows, quantity in cwt., and value in pounds :—

Country.	Quantity.	Value.
United States.....	1,386,872	168,023
Brazil.....	446,338	40,280
Chile.....	131,067	13,102
Venezuela.....	102,904	9,736
Norway.....	58,356	6,709
Russia.....	34,353	2,941

The importation to Great Britain was insignificant, but British possessions, such as Australia, the Cape, and British East India, took 123,666 cwt., valued at 12,247*l.*--*Chemical Trade Journal.*

#### THE COMPARATIVE WORKING OF COKE OVENS.

According to the report of Mr. Farrell, an American furnace engineer, who spent three months in Europe last year investigating the different coking systems, and who had access to the records of all leading oven builders, the following is a comparison of results in by-products, as accomplished by ovens of the different models working on similar grades of Westphalian coal :—

Names.	Period.	Tar.	Sulphate of Ammonia.
		Per Cent.	Per Cent.
Semet-Solvay.....	Oct. 1892 to Mar. 1893	1·6	0·61
Carvès-Hussener..	Oct. 1892 to Feb. 1893	1·81	1·0
Otto Hoffman....	Oct. 1892 to Mar. 1893	3·53	1·18

—*Ibid.*

#### GERMAN ELECTRO-CHEMICAL SOCIETY.

This new society held its first meeting at Berlin recently. The object of the society is the development of electro-chemistry in its scientific, technical, and economic aspects. Amongst the first communications to the society is one by Professor Ostwald on the work done by J. W. Ritter, a contemporary of Galvani and Volta, who was the first to perceive that Volta's electro-chemical arrangement of the metals corresponded to the order of their affinity for oxygen. Dr. O. Frölich has communicated a paper on "The Practical Application of Ozone," which has been introduced into many different branches of manufacture, the most important of these being bleaching, the ageing of spirits, tobacco, and coffee, and also of wood for the sounding-boards of pianos, for which latter purpose it has been applied by a piano manufacturer, Mr. René, of Stettin, since 1881. In this case the chemical change due to action of ozone on the resins contained in the wood is probably an important factor. The thickening of linseed oil, which is effected in linoleum manufactories by allowing it to trickle over strips of gauze for several months, can in like manner be done with ozonised air in a few days. The conversion of crude potato starch into the soluble variety, as well as into dextrin and other gummy substances by ozone, has been effected by Dr. Frölich, and the method is to be introduced practically into a manufactory now in process of construction. Dr. Frölich also hopes to accomplish the production of nitric acid from the air by means of ozone.—*Chemist and Druggist.*

#### BOARD OF TRADE RETURNS.

##### SUMMARY OF IMPORTS.

Articles.	Month ending 30th November	
	1893.	1894.
	£	£
Metals.....	1,670,249	1,481,266
Chemicals and dyestuffs.....	474,816	421,196
Oils.....	552,965	642,351
Raw materials for non-textile industries.	3,299,044	3,683,795
Total value of all imports....	35,801,961	35,236,790

##### SUMMARY OF EXPORTS.

Articles.	Month ending 30th November	
	1893.	1894.
	£	£
Metals (other than machinery) ....	2,162,042	2,428,450
Chemicals and medicines .....	674,972	708,077
Miscellaneous articles.....	2,357,699	2,444,388
Total value of all exports.....	17,653,759	18,083,087

##### IMPORTS OF METALS FOR MONTH ENDING 30TH NOVEMBER.

Articles.	Quantities.		Values.	
	1893.	1894.	1893.	1894.
Copper :—			£	£
Ore..... Tons	9,892	6,764	62,373	35,024
Regulus .....	8,106	5,915	188,192	112,584

## Monthly Patent List.

\* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

#### APPLICATIONS.

22,524. J. H. Bowden. Improvements in apparatus for drying china-clay, stoneware, or other suitable materials. November 21.

23,031. H. J. Haddan.—From the Ferry Manufacturing Co., United States. Improvements in apparatus for carbonating liquids. Complete Specification. November 27.

23,032. H. J. Haddan.—From the Ferry Manufacturing Co., United States. Improvements in the method of and means for carbonating liquids. November 27.

23,220. J. A. Yeadon and W. Adgie. Improvements in apparatus for producing or revivifying animal charcoal and other analogous materials. November 30.

23,235. J. Foster. Improvements in and relating to evaporating apparatus. November 30.

23,956. S. J. Robinson and S. Pope. Improvements in open hearth steel-melting furnaces and regenerative furnaces generally. December 10.

23,961. J. Weir. Improvements in and connected with steam-heated evaporators. December 10.

24,199. J. A. Fisher. Improvements in non-conducting compositions for coating boilers and for like uses. December 12.

24,447. M. Otto. Improvements in apparatus for distillation. December 15.

24,457. E. G. Scott. Improvements in evaporating brine and other liquors, and apparatus therefor. December 15.

#### COMPLETE SPECIFICATIONS ACCEPTED.\*

##### 1893.

22,736. A. F. Beyer and A. G. Beyer. Improvements in and connected with apparatus for cooling, solidifying, and drying substances in a liquid or viscous state. November 28.

23,069. R. Cunliffe. See Class XVII.

##### 1894.

1790. D. Stewart. See Class XVI.

1866. O. Hamilton. A new or improved drying apparatus. December 5.

3665. H. Evers-Swindell. Improved manufacture of gas retorts, also applicable to other tubular objects of fire-clay or earthenware, and apparatus therefor. December 19.

3702. W. Chorley. Improvements in machinery for the compression of air or other elastic fluids. December 19.

18,992. H. L. Doulton and A. W. Manger. Improvements in the process of and apparatus for softening waters and purifying waste liquors. November 28.

19,085. A. Müller. Improvements in apparatus for effecting the absorption of gases by liquids and for cooling gases. November 28.

20,202. E. Entwistle.—From W. L. Wallis. Improvements in means and apparatus for treating smoke and fumes. November 28.

21,326. W. P. Thompson. — From J. Fathrieger. Improvements in muffle furnaces. December 12.

21,778. I. S. McDougall. Improvements in evaporating pans for the concentration of sulphuric acid and other liquids. December 19.

## II.—FUEL, GAS, AND LIGHT.

### APPLICATIONS.

17,71A. W. Felton. Improvements in apparatus for producing and burning gas to heat furnaces. Filed November 1, date claimed September 18, 1894.

22,452. H. A. Allport and A. Crossley. Improvements in coke ovens and in the method of removing and utilising the products of combustion from such coke ovens. November 20.

22,504. S. Banner. Improvements in deodorising and bleaching hydrocarbons and volatile oils or spirits. November 21.

22,615. L. Denayrouze. Method of and apparatus for illumination by means of combustible gas with forced supply produced by electrical energy. November 22.

23,230. R. V. Horsfall. Improvements in retorts for distilling, cracking, or gasifying oils, tars, or any liquid hydrocarbons. November 30.

23,278. J. M. Bosselaar and J. F. M. van den Elshout. Improvements relating to the manufacture of gas and to apparatus therefor. November 30.

23,297. N. van der Sleen and A. Schnellen. Improvements in and relating to an apparatus and a method for causing chemical changes of gases and mixtures of gases by dark electric discharges. December 1.

23,559. F. J. Koopmann. Improvements relating to the manufacture of artificial fuel. December 4.

23,631. A. Greg. The purification of and utilisation of wood-gas for illuminating purposes. December 5.

23,662. J. Henderson. Improvements in or relating to gas retorts and such like apparatus. December 5.

23,839. W. S. Tailleur. Improvements in the utilisation of natural and artificial mineral or hydrocarbon oils and their various products and by-products in the production of heat and making and enriching gas. December 7.

23,996. C. Weygang and The Petroleum Products Syndicate, Ltd. Manufacture of artificial fuel from petroleum. Complete Specification. December 10.

24,005. A. G. Glasgow. Improvements in the method and apparatus for carburetting water-gas. Complete Specification. December 10.

### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

22,638. E. de Pass. — From L. J. Baptiste. Improvements in machines for the manufacture of hollow candles. November 28.

23,433. W. R. Herring. Improvements in and in apparatus for manufacturing oil-gas. December 5.

23,950. J. H. R. Dinsmore. Improvements in or connected with apparatus for making gas from coal or analogous material. December 12.

1894.

1231. F. B. Hill and R. D. Brett. Improvements relating to the burning of hydrocarbons for heating and lighting purposes, and to apparatus therefor. November 28.

1238. D. Hancock, J. B. Craig, and A. H. Hancock. Improvements in or relating to the employment of air for lighting and heating purposes. December 19.

1485. T. H. Jones. Improvements relating to the carbonising of wool for the production of charcoal, and in the utilisation of the products given off in the process of carbonisation. November 28.

1490. J. Galletly and H. Armour. Improvements in the manufacture of gas from mineral oils and in the apparatus employed therefor. November 28.

1650. C. C. Walker. Improvements in apparatus to be used in the purification of coal gas or for analogous operations. December 5.

2488. C. J. Yarnold. Improvements in the method and apparatus employed in the production of ozon. December 12.

2702. T. de Zebrowski. A new or improved manufacture of briquettes or artificial fuel blocks. December 12.

1189. C. W. Pinkney. Improvements in and apparatus for the manufacture of gas suitable for use in gas engines or for heating purposes. December 12.

## III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, ETC.

### APPLICATION.

23,373. A. Weil and A. Goutierre. New or improved system of and apparatus for the simultaneous carbonisation and distillation of animal and vegetable matters, and the recovery therefrom of useful products. December 1.

## IV.—COLOURING MATTERS AND DYES.

### APPLICATIONS.

22,154. H. E. Newton. — From The Farbenfabriken vormals F. Bayer and Co., Germany. The manufacture or production of dyestuffs and materials therefor. November 20.

22,533. O. Imray. — From W. J. Matheson and Co., Ltd., United States. Manufacture of colouring matter from logwood. November 21.

22,603. J. Y. Johnson. — From The Badische Anilin and Soda Fabrik, Germany. The manufacture and production of new black colouring matter, and the production of black colour on vegetable fibre. November 22.

22,743. L. G. Williams and A. Turner. Improvements in dyes. November 23.

22,904. J. Imray. — From La Société Anonyme des Matières Colorantes et Produits Chimiques de St. Denis, France. Manufacture of new blue colouring matters which resist alkaline carbonates. November 26.

22,914. S. Pitt. — From L. Cassella and Co., Germany. The production of fast yellow dyestuffs from the sulpho acids of dehydrothiotoluidine or analogous bases. November 26.

23,435. C. D. Abel. — From The Actien Gesellschaft für Anilin Fabrikation, Germany. Manufacture of dichlorotolidine and of colouring matters therefrom. December 3.

23,584. H. E. Newton. — From The Farbenfabriken vormals F. Bayer and Co., Germany. The manufacture or production of colouring matters and materials therefor. December 4.

23,927. H. E. Newton. — From The Farbenfabriken vormals F. Bayer and Co., Germany. The manufacture or production of derivatives of hydroxyanthraquinone. December 8.

24,005. E. B. Aspinall. Improvements in obtaining colouring matters from cotton-seed oil and other like oils. December 11.

## COMPLETE SPECIFICATIONS ACCEPTED.

1894.

1227. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. Improvements in the manufacture of  $\alpha_1$ - $\alpha_2$ -dihydroxynaphthalene- $\alpha$ -monosulpho acid. November 28.

1229. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of dyestuffs by means of trihydroxynaphthalenemonosulpho acid. November 28.

1555. H. Loesner. Manufacture of azoxy compounds of the aromatic series. November 28.

1641. G. W. Johnson. From Kalle and Co. Improvements in the manufacture of new azo-dyestuffs. November 28.

1920. S. Pitt.—From L. Cassella and Co. The production of perichloronaphtholdisulpho acid and disazo dyestuffs therefrom. November 5.

2206. H. Loesner. Improvements in the manufacture of ortho-nitro-toluene, meta- and para-azoxytoluene, meta- and para-toluidin. December 5.

2325. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture of hydroxyanthraquinone quinolines. December 12.

2503. Read, Holliday, and Sons, Lim., and K. B. Elbel. The manufacture of a bluish-red dye belonging to the rosinduline series. December 12.

2591. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture of dyestuffs. December 12.

2592. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The production of azo colouring matters upon fibres. December 12.

2758. J. Altschul. Manufacture of a new diazo compound for use in dyeing and printing. December 12.

3026. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation. Manufacture of new bases containing sulphur of their sulpho acids and of colouring matters derived therefrom. December 12.

3032. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture of azo dyestuffs. December 19.

3036. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik. The manufacture of new mordant-dyeing colouring matters and intermediate products relating thereto. December 19.

3113. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture of colouring matters. December 19.

3301. S. Pitt.—From L. Cassella and Co. Trisazo dyestuffs. December 19.

3397. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik. The manufacture of new nitrosamine compounds suited for use in the preparation of diazo compounds. December 12.

3474. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik. The manufacture of new mordant-dyeing colouring matters. December 5.

3843. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation. Manufacture of colouring matters. December 19.

6198. B. Willcox.—From F. von Heyden, Nachfolger. Improvements in the treatment or purification of commercial toluol-sulpho-amide. December 5.

## V.—TEXTILES, COTTON, WOOL, SILK, Etc.

## APPLICATIONS.

22,366. E. Esser and P. Scheider. Machine for treating textile fabrics. Complete Specification. November 19.

22,416. R. J. Maclean. An improved method or process for producing mixed coloured silk yarn. November 20.

22,595. W. P. Thompson.—From J. F. Kerr, United States. A new or improved method of softening vegetable fibres. Complete Specification. November 22.

22,785. J. B. Fearnley and J. S. Fearnley. Improvements in the waterproofing of textile fabrics and in apparatus therefor. November 24.

22,969. R. J. Rastrick. Improvements in the treatment of rhea and other fibrous plants. November 27.

23,118. P. P. Faure. Improvements in the method of and machinery for decorticating ramie and other textile plants and leaves. November 28.

23,872. W. Warburton. Improved method of and apparatus for rendering textile fabrics or paper waterproof and porous. December 8.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

24,769. J. H. Openshaw. Improvements in the manufacture of cloths known as cotton cords. December 19.

24,904. P. P. Craven. Improved process and machinery for glazing, polishing, and finishing textile fabrics. December 5.

1894.

943. E. B. Manby. See Class XIV.

3554. J. V. Eves. Improvements in the treatment of wet spun flax yarn. December 19.

20,341. G. C. Franklin. Improvements in broad silk pieces, and in the manufacture of the same. December 12.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

## APPLICATIONS.

22,603. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik, Germany. See Class IV.

23,119. J. Arnold. Improvements in or relating to dyeing. November 28.

26,741. S. H. Sharp. Improved method and machinery or apparatus for producing designs on textile and felted fabrics and the like. Complete Specification. December 6.

## COMPLETE SPECIFICATIONS ACCEPTED.

1894.

1656. J. C. Mewburn.—From La Société Leblais Piceni et Co. Improvements in preparing for bleaching and dyeing, and in bleaching, dyeing, and washing vegetable textile material, and in apparatus therefor. November 28.

18,218. J. Bolet. An improved machine for printing on textile fabrics and the like. November 28.

## VII.—ACIDS, ALKALIS, AND SALTS.

## APPLICATIONS.

22,316. R. Pearson. Improvements in the method of evaporation of brine. November 19.

22,511. G. T. Boilby. The conversion of sulpho-cyanides into ferrocyanides. November 21.

22,569. B. Peitzsch. Improvements in the manufacture of sulphides of the alkalis. November 22.

22,826. J. Brock, A. E. Wareing, and F. Hurter. Improvements in the treatment of solutions of zinc chloride for the purification thereof for electrolytic purposes. November 24.

22,827. J. Brock, A. E. Wareing, and F. Hurter. Improvements in and relating to the treatment of solutions of chloride of zinc for the purification thereof for electrolytic purposes. November 24.

22,828. J. Brock, A. E. Wareing, and F. Hurter. Improvements in the utilisation of zinc blende for obtaining metallic zinc and sulphur, and in effecting the decomposition of common salt for the production of soda and chlorine. November 24.

22,844. I. Levinstein. Improvements in the method of and apparatus for concentrating sulphuric acid. November 26.

22,853. J. W. Walker. Improvements in obtaining a continuous supply of hydrochloric acid or nitric acid gas, and in utilising acid sulphates. November 26.

22,862. W. Garroway. Improvements in the manufacture of chromates and of nitric acid. November 26.

22,917. J. Brock, A. E. Wareing, and F. Hurter. Improvements in the treatment of the residual solutions of the ammonia soda process, and in the recovery therefrom of ammonia and chlorine. November 26.

23,262. C. F. Claus. Improvements in the roasting of sulphide ores. November 30.

23,274. L. P. Hulín. Process and apparatus for the conjoint manufacture of metallic peroxides and caustic alkalis. Filed November 30. Date applied for May 8, 1894, being date of application in France.

23,370. L. P. Hulín. Process and apparatus for the manufacture of caustic alkalis from alloys of the alkali-metals. Filed December 1. Date applied for May 9, 1894, being date of application in France.

24,113. J. Holt and J. G. Lorrain. See Class XVIII. A

24,313. A. G. von Gratz. Improvements in the manufacture or production of aluminates of alkalis. December 14.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

24,563. M. N. D'Audria. Improvements in and connected with the manufacture of magnesium hydrate. December 19.

1894.

2618. A. Crossley. Improvements in apparatus for producing ferro-ferric and ferric oxides. December 12.

2696. A. R. Davis. Improvements in the production of sulphate of manganese and oxide of iron. December 12.

3037. J. Brock, and others. Improvements in and apparatus for the treatment of "caustic salts" obtained as a by-product in the manufacture of caustic soda. December 19.

6621. J. B. Readman. Improvements in obtaining cyanides and ferrocyanides. December 5.

21,778. I. S. McDougall. See Class I.

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

## APPLICATIONS.

22,440. H. Gurnard. Improved process of making hollow glass ware. Complete Specification. November 20.

22,834. La Société Anonyme des Matières Manufacturées des Glaces et Produits Chimiques de St. Gobain, Chauxy et C<sup>ie</sup>. The manufacture of a new vitrified material. Complete Specification. Filed November 24. Date applied for June 14, 1894, being date of application in France.

23,708. D. Moore. Improved beer or light for annealing glass. December 6.

24,974. T. Arrow-smith, H. T. Arrow-smith, and J. Arrow-smith. Improved construction of thimble pins for use in supporting pottery-ware whilst being fired. Complete Specification. December 10.

## COMPLETE SPECIFICATIONS ACCEPTED.

1894.

20,964. F. von Hardtmuth. Improvements in presses for the production of tiles and other ceramic ware. December 5.

21,091. F. H. Stubbs. Improved method or methods of decorating tiles or the like. December 12.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

## APPLICATIONS.

22,308. C. G. Picking. Improvements in bricks or blocks to be employed in the construction of the floors of fireproof and other buildings. Complete Specification. November 19.

22,449. M. Thury. Improvements in presses for manufacturing compressed bricks, such as briquettes from granular or pulverulent materials. November 20.

22,633. J. Leuba. An improved paving stone. November 22.

22,793. W. Orr. Improvements in concrete and composite buildings or structures. November 24.

23,123. W. P. Campbell-Everden. An improved method of and means for mixing clays and other materials of a similar nature, more especially suitable for use in the manufacture of cement. November 28.

23,905. J. E. Stephenson. Improvements in the manufacture of bricks or building blocks and the like. December 8.

23,918. T. Potter. Improvements in the construction of fireproof floors and ceilings. December 8.

24,139. J. Bromilow. Utilising slag and coal ashes to produce substitutes for bricks, stone, and concrete. December 12.

## COMPLETE SPECIFICATIONS ACCEPTED.

1894.

1157. H. H. Lake.—From B. Gran. Improvements relating to the manufacture of artificial marble. December 18.

1427. A. McAr. Improvements in the manufacture of Portland cement. November 28.

15,753. J. Elliott. A stone composition for repairing any natural stone and refacing cement floors, &c., also for making imitation stone and bricks of any colour. December 12.

19,437. E. Tortora. Improvements relating to the treatment of terra-cotta, wood, clay, gypsum, limestone, and other materials for preserving and other purposes. December 5.

20,650. L. Küpper. Improvements in walls and wall plates or slabs. December 5.

## X.—METALLURGY, MINING, Etc.

### APPLICATIONS.

19,510A. H. G. Partin. Solder for aluminium. Filed December 6. Date claimed October 13, 1894.

22,415. P. Inch. An improved composition of metals. Complete Specification. November 20.

22,514. A. J. Hobson. An improved metallic alloy for use in the manufacture of pocket cutlery. Complete Specification. November 21.

22,657. G. Hookham. A new metallic alloy for cartridge cases and articles subjected to high temperatures. November 23.

22,740. L. Oliven. Improvements in or relating to the soldering of aluminium and its alloys. November 23.

22,797. W. J. Langham. An improved method of utilising bosh dirt in the manufacture of iron and steel. November 24.

22,903. J. J. Atkinson. An improvement in the manufacture of composite sheet metal. November 26.

23,006. L. C. Daumas. An improved process for the extraction of gold from its ores and apparatus employed therefor. November 27.

23,065. A. J. Maskrey. An improvement relating to the manufacture of tin andterne plates. November 28.

23,385. A. Carter and E. Purser. Improvements in the manufacture of iron from iron sand. December 3.

23,518. W. Fairweather. From G. W. Webber, United States. Improvements in the cyanide process of recovering gold from its ores. December 4.

23,557. J. Pflieger. Improvements in or relating to processes for the extraction of gold and silver from ores. December 4.

23,739. J. Pflieger. Improvements relating to the extraction of gold or silver from their ores. December 6.

23,855. P. H. Bertrand. An improved method of producing magnetic oxide on wrought or cast iron. December 7.

24,092. E. Meyer. Improved process for disintegrating Thomas slag. Complete Specification. December 11.

24,278. C. D. Abel. From Electricitäts-Gesellschaft Geinhausen mit beschränkter Haftung, Germany. Method and apparatus for the production of metals and other fusible materials in pulverulent form. December 13.

24,360. The Cowper-Coles Galvanising Syndicate, Lim., and S. O. Cowper-Coles. Improvements in or connected with the coating of iron or steel articles with nickel, cobalt, silver, platinum, and like metals. December 14.

### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

23,492. E. T. Zohrab. An improved method of hardening or converting into steel the surfaces of iron plates and other objects made from iron. December 12.

24,704. D. W. Sagg. Improvements in the manufacture of alloys. November 28.

24,767. W. Jenks. Improvements in furnaces for annealing iron and steel sheets, and in other furnaces employed in the manufacture or treatment of iron and steel. December 5.

24,939. H. L. Sulman. Improvements in the treatment of gold ores. December 12.

20,247. D. W. Sagg. An improved metallic alloy. November 28.

20,422. W. P. Thompson.—From E. Bertrand and O. Thiel. Improvements in the manufacture of steel, steely iron, or homogeneous metal. December 5.

20,615. J. C. Fell.—From F. A. Gooch and L. Waldo. Improvements in processes for reducing aluminium. December 5.

20,616. J. C. Fell.—From F. A. Gooch and L. Waldo. Improvements in processes for reducing aluminium. December 5.

20,872. P. de Wilde. A method for the extraction of gold. December 5.

## XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

### APPLICATIONS.

22,613. J. C. Richardson. Improvements in or relating to the electro-chemical decomposition of solutions of salts. Complete Specification. November 22.

22,965. W. P. Thompson.—From C. L. Coffin, United States. Improvements in or relating to electrically heating metal or other conducting bodies, or welding metals electrically. Complete Specification. November 27.

22,973. C. S. W. Brown. Improvements in and relating to storage batteries. November 27.

23,117. L. P. Hulin. An improved electrolytic process and apparatus for obtaining rich alloys of the metals of the alkalis or alkali earths and the production of halogen elements. Filed November 28. Date applied for May 5, 1894, being date of application in France.

23,160. E. L. Levetus. Improvements in and relating to primary batteries and such like. November 29.

23,198. L. P. Hulin. Process for the treatment of certain metallic alloys for the manufacture of elements for voltaic batteries and caustic alkalis or their derivatives. Filed November 29. Date applied for May 7, 1894, being date of application in France.

23,441. J. C. Fuller and G. Fuller. Improvements in and connected with galvanic batteries. Complete Specification. December 3.

23,486. F. L. Berners and F. Griffin. Improvements in or relating to secondary batteries or accumulators. December 4.

23,553. L. Wagner and J. Marr. Improvements in apparatus for the electrical treatment of beer or other liquid or material. Complete Specification. December 4.

23,590. H. T. Barnett. Improvements in gas batteries. December 5.

23,669. The Cowper-Coles Galvanising Syndicate, Lim., and S. O. Cowper-Coles. Improvements in or connected with the electro-deposition of zinc upon iron. December 5.

23,679. La Société des Cuivres de France. Process for the manufacture of metallic articles by electro-deposition. Filed December 5. Date applied for May 22, 1894, being date of application in France.

23,680. A. M. Clark.—From La Société des Chèvres de France, France. A process of and apparatus for making compressed electrolytic copper, applicable also to other metals capable of being deposited by electrolysis. December 5.

23,688. G. Platner. An improved charging material for galvanic elements. Complete Specification. December 5.

24,297. W. McChleary. An improved porous cell for an electric generator or battery. December 14.

24,364. P. de Wilde. Improved method of treating battery slimes from gold mines. December 14.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

22,674. R. Haddan.—From H. Rignelle. Improvements in or relating to electric regenerative batteries or accumulators and in porous cells therefor. November 28.

23,669. P. Schoop. Improvements in electrolytic vessels for primary and secondary batteries or accumulators, and other processes of electrolytic decomposition and electrolytic action, such as for the extraction of metals from their ores, electro-depositions, and the like. December 12.

1894.

494. W. P. Thompson.—From C. L. Coffin. Improvements in apparatus for heating or working metals electrically. December 5.

835. J. Hargreaves and T. Bird. Improvements in the construction of electrolytic apparatus, and in the application thereof in oxidising, chlorinating, and analogous processes. December 19.

2487. C. J. Hall. Improvements in or relating to secondary batteries. November 28.

13,358. H. H. Lake.—From I. L. Roberts. Improvements relating to electrolysis and to apparatus therefor. November 28.

#### XII.—FATS, OILS, AND SOAP MANUFACTURE.

##### APPLICATIONS.

22,504. S. Banner. See Class II.

23,054. H. Heaton. Improvements in dry soap. Complete Specification. November 28.

23,228. S. Crowder. Improvements in the methods of recovery of oils or fatty substances from clays, sands, ores, mine slimes, or finely-divided substances. November 30.

23,995. C. Weygang and The Petroleum Products Syndicate, Ltd. Manufacture of saponaceous products from petroleum. Complete Specification. December 10.

24,080. D. H. McClelland and R. D. Jackson. Improvements in and connected with oil purifiers. Complete Specification. December 11.

24,095. F. B. Aspinall. See Class IV.

24,103. S. Banner. Improvements in the treatment or oxidation of fixed oils, fats, and the like, and the application thereof as a menstruum for paint, varnish, oil-cloth, and the like. December 11.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1894.

264. F. Burton. A process for the purification of oils, fats, and the like. November 25.

2132. F. Petit. Improvements in the acid saponification of fatty bodies and in apparatus employed therein. December 5.

3497. H. Lambert. Improvements in the method of and apparatus for extracting oil from seeds and the like, and for forming cakes from such or any suitable substances. December 5.

#### XIII.—PAINTS, PIGMENTS, VARNISHES, RESINS, INDIA-RUBBER, ETC.

##### APPLICATIONS.

22,363. A. Gutensohn. An improved process, and means used therein, for the manufacture of oxidised lead. November 19.

22,905. C. E. Bergeon. Improved method of and apparatus for effecting the vulcanisation of caoutchouc articles. November 26.

22,966. W. P. Thompson.—From W. Grisco, jun., United States. Improvements in or relating to the production of compounds applicable for such uses as for paints for electric insulating and waterproofing, as substitutes for vulcanisable rubber and gum compounds, and for other purposes. Complete Specification. November 27.

23,849. J. Holliday and A. Cameron. An improved anti-fouling paint. Complete Specification. December 7.

24,049. J. Moore, J. Sampson, and E. T. Whitelow. Improved substitute for india-rubber, and improvements in the process of producing the same. December 11.

24,103. S. Banner. See Class XII.

24,199. J. A. Fisher. See Class I.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1894.

2428. D. J. Harris. A composition or solution for making waterproof, hardening, and preserving the soles of boots and shoes. December 12.

19,878. A. J. Boulton. From G. Philippe. Impermeable paint for mirrors. December 19.

#### XIV.—TANNING, LEATHER, GLUE, AND SIZE.

##### APPLICATIONS.

22,968. W. R. Earp. Improvements in or relating to the treatment of hides for the manufacture of leather. November 27.

23,585. A. Zimmermann.—From The Chemische Fabrik auf Actien vormals E. Schering, Germany. A process for rendering insoluble albumen and albumen-like matters, casein, albumos, and the products of conversion of glue and gelatine. December 4.

24,404. J. Marshall. Improvements in the method of separating hair, wool, and fur from skin or hide. December 15.

24,442. F. Blenkins and F. G. Bate. Improvements in coloured gelatine sheets, and in apparatus for the production of the same. December 15.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

24,098. H. Neil. Improvements in the treatment of leather. December 12.

1894.

943. E. B. Manby. An improvement in the sizing, dressing, and finishing of textile products, and material for that purpose. December 12.

## XV.—AGRICULTURE AND MANURES, Etc.

## APPLICATIONS.

22,756. T. Twynam and F. T. Barnett. Improvements in the manufacture of fertilisers. November 24.

24,013. A. J. Thoroye. A new composition for improving the soil. December 10.

24,063. W. P. Thompson.—From Wirth and Co., Germany. An improved process for obtaining dry manure and ammonia from faeces or faecal matter, and apparatus therefor. December 11.

24,092. E. Meyer. See Class X.

24,365. A. L. Radford and M. F. Hutton. Improved binding composition for use with fertilising and other substances. December 14.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

24,465. A. R. O. Pieper. Improvements relating to the manufacture of artificial manure. December 19.

1894.

792. M. C. Ginster. Improvements in the manufacture of manure and fertiliser. December 5.

20,971. C. H. Thompson. The manufacture of improved fertilised and fertilising materials for promoting the growth of plants. December 5.

## XVI.—SUGARS, STARCHES, GUMS, Etc.

## APPLICATIONS.

22,568. G. Gin. Improvements in the method of and apparatus for purification of saccharine syrups or liquids. November 21.

22,726. J. Y. Jobuson.—From T. von Heyden, Nachfolger, Germany. A new crystallised sweet compound called erystallöse, and process for manufacturing the same. November 23.

## COMPLETE SPECIFICATION ACCEPTED.

1894.

1790. D. Stewart. Improvements in centrifugal apparatus for drying and purifying sugar or other crystalline or granular matters. December 5.

## XVII.—BREWING, WINES, SPIRITS, Etc.

## APPLICATIONS.

22,504. S. Banner. See Class H.

23,330. W. H. Walker. Improvements in or relating to the treatment or manufacture of extracts of malted grain or the like. December 1.

23,553. L. Wagner and J. Marr. Improvements in apparatus for the electrical treatment of beer or other liquid or material. Complete Specification. December 4.

23,069. R. Cunliffe. Improvements in machines for drying brewers' refuse and other substances or materials. December 5.

23,224. A. Collette. See Class XVIII. A.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

23,069. R. Cunliffe. Improvements in machines for drying brewer's refuse and other substances or materials. December 5.

25,052. S. H. Sheldrake. An improved process for the preparation of ale and stout. December 12.

1894.

2966. W. R. Reffell. An external mashing apparatus for the use of brewers and others in mashing malt with water or raw grain liquor, in brewing or distilling. December 19.

3076. D. A. Blair. Improvements in and relating to continuous working spirit stills. December 19.

14,919. L. Prochazka. An improved process and appliances for mashing and brewing in breweries. December 5.

19,662. T. R. Timby. Mechanism for ageing liquors. November 28.

20,796. P. Kropf and A. Gruell. Improvements in and connected with the fermentation of beer. December 19.

## XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

## APPLICATIONS.

## A.—Chemistry of Foods.

22,437. J. H. Payne. A preparation of herbal solutions, sauces, and similar dietetic materials, in tablet or block form. November 20.

23,194. J. Imray.—From La Société Anonyme des Matières Colorantes et Produits Chimiques de St. Denis, France. Improvements in the preservation of alimentary substances. November 29.

23,270. G. A. Clowes. A new or improved medicinal and nutritive compound or preparation. November 30.

23,853. G. Gaertner. Process and appliance for sterilising or pasteurising liquids without any contact with the atmosphere, and for preserving these liquids in sterilised condition and preventing their motion within the vessels in which they are kept. December 7.

24,113. J. Holt and J. G. Lorrain. Improvements in the manufacture of vinegar. December 11.

**B.—Sanitary Chemistry.**

23,415. J. S. Pickering. Improvements in or relating to precipitation tanks for the clarification of sewage. December 3.

23,847. Bacillite Sewage Purification Syndicate, Ltd., and A. P. Hope. Improvements in and apparatus for treating sewage, sewage effluent, sewage sludge, or other like waters or matters. December 7.

**C.—Disinfectants.**

22,491. F. M. Spence. Improvements in disinfecting powders. November 21.

22,725. G. F. Strawson. Improvements in copper fungicide. November 23.

23,101. A. A. Beeheraz. A new or improved composition or preparation for the destruction of insects. November 28.

23,135. C. T. Gardner. An improved sterilising, disinfecting, and deodorising fluid. Complete Specification. November 29.

23,580. C. Stern. Improvements in preservative compounds for fresh meat and other articles of food. December 4.

24,310. E. Andreoli. Producing disinfectants and antiseptics by ozone. Complete Specification. Filed December 14. Date applied for May 16, 1894, being date of application in Belgium.

**COMPLETE SPECIFICATIONS ACCEPTED.****A.—Chemistry of Foods.**

1893.

23,224. A. Collette. Improvements relating to the preservation of yeast and other vegetable and animal substances. December 12.

1894.

1405. F. T. Bond. Improvements in the preparation of cheese. November 28.

2445. C. Kidson. A new method of preserving eggs. December 5.

**B.—Sanitary Chemistry.**

1894.

5819. J. Schmerser and A. Billig. An improved process and apparatus for impregnating air with the essence of fir-wood. December 12.

**C.—Disinfectants.**

1893.

24,531. S. Pitt.—From The Chemische Fabrik auf Actien vormals E. Schering. An improved antiseptic, disinfectant, or deodorant. November 28.

1894.

21,815. A. B. F. Wegemund. Process for the manufacture of a solution for destroying vermin. December 19.

**XIX.—PAPER, PASTEBOARD, ETC.****APPLICATIONS.**

22,566. A. Grandjean. Improvements in or relating to the manufacture of paper or paper pulp. Filed November 21. Date applied for June 1, 1894, being date of application in Belgium.

22,929. F. Wehlers and R. Crosse. An improved manufacture of artificial ivory. November 26.

23,405. H. G. Forbes and E. M. Sommerville. An improved apparatus for producing water marks in paper. December 3.

23,872. W. Warburton. See Class V.

**COMPLETE SPECIFICATIONS ACCEPTED.**

1894.

2923. B. Cawthorn and J. P. Cornet. Improvements in the process of bleaching fibrous materials in the manufacture of paper. December 19.

20,051. W. P. Thompson. From M. C. Stone. Improvements in or relating to the treatment of paper or other tubes. November 28.

**XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.****APPLICATIONS.**

22,617. H. E. Newton. — From the Farbenfabriken vormals F. Bayer and Co., Germany. The manufacture or production of pharmaceutical compounds. November 22.

22,902. F. Ludy. Manufacture of bis-muthoxyiodide-gallate. Complete Specification. November 26.

23,438. R. Jurgensen and A. Kauschlicher. Improvements in the manufacture of acetone. December 3.

24,308. T. Chamings. Germ extract. December 14.

24,146. M. Otto and A. Verley. Improvements in the manufacture of perfumes. December 15.

24,147. M. Otto. Improvements in apparatus for distillation. December 15.

**COMPLETE SPECIFICATIONS ACCEPTED.**

1893.

24,459. S. Pitt.—From The Chemische Fabrik auf Actien vormals Schering. Improvements in the manufacture of levulose. November 28.

1894.

1287. F. W. Warwick. An improved pharmaceutical preparation of ferrous salts. December 5.

**XXI.—PHOTOGRAPHIC PROCESSES AND MATERIALS.****APPLICATION.**

22,952. A. G. Adamson. Improvements in and connected with the developing of photographs. Complete Specification. November 27.

## XXII.—EXPLOSIVES, MATCHES, Etc.

## APPLICATIONS.
